Pituitary adenectomy is incorrect. Cushing's disease occurs due to an ACTH-secreting pituitary adenoma resulting in high levels of cortisol and aldosterone. Although this remains within the differential diagnosis, there are no other clinical features (e.g. proximal myopathy, abdominal striae, weight gain) to support a diagnosis of Cushing's.

Question 95 of 114

A 54-year-old man attends with persistent hypertension. His blood pressure is 175/101mmHg.

His past medical history includes type 2 diabetes mellitus for which he takes metformin.

Tests are arranged and the results are detailed below:

Na +	136 mmol/L	(135 - 145)
K +	3.3 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Urea	4.5 mmol/L	(2.0 - 7.0)
Creatinine	65 µmol/L	(55 - 120)
Aldosterone	680 pmol/L	(100-450)
Renin	0.3 mU/L	(5.4-30)

A saline infusion test is completed and the results post-infusion are as follows:

Aldosterone	550 pmol/L	(100-450)

The patient is keen to undergo surgical management of his condition if possible.

What investigation would be the most reliable in confirming the location of the lesion in this case?

A. Adrenal venous sampling
B. Delayed contrast-enhanced CT adrenals
C. Fine-needle aspiration adrenal biopsy
D. MRI adrenals
E. MRI brain

A. Adrenal venous sampling

Adrenal venous sampling (AVS) can be used to distinguish between unilateral adenoma and bilateral hyperplasia in primary hyperaldosteronism

The most likely diagnosis here is hyperaldosteronism. Adrenal adenomas and adrenal hyperplasia are the most common causes. Secondary hyperaldosteronism can occur due to renin-angiotensin-aldosterone system overactivity as seen in cardiac failure, ascites, and fibromuscular dysplasia. In this case, renin is suppressed, so primary hyperaldosteronism is the most likely answer.

Adrenal venous sampling is the correct answer. This involves sampling blood from the adrenal veins and assessing the levels of aldosterone. This is the gold-standard test to distinguish between unilateral adrenal adenoma and bilateral hyperplasia and should be completed to confirm the location of the abnormality if surgery is to be considered. CT scanning can help identify lesions, however, many adrenal adenomas are non-functioning and not clinically relevant. Hormonal studies via AVS are therefore advised to confirm the location to avoid the removal of an adrenal gland unnecessarily.

Delayed contrast-enhanced CT adrenals is incorrect. Although CT scanning is a good modality to look for adrenal pathology many adrenal adenomas can be too small to pick up on CT. CT can also pick up incidental adenomas that are non-functioning and of no clinical consequence. CT is therefore not the most reliable modality to use to confirm the location of the lesion.

Fine-needle aspiration adrenal biopsy is incorrect. Adrenal adenomas are usually extremely small and not amenable to biopsy.

MRI adrenals is incorrect. Although MRI can be used, there are similar pitfalls to CT scanning as detailed above - MRI may pick up nonfunctioning adrenal adenomas or miss small adenomas.

MRI brain is incorrect. Pituitary lesions are not implicated in primary hyperaldosteronism.

Question 96 of 114

A 24-year-old nurse is admitted after collapsing at the end of a night shift. She is found to have a capillary blood glucose of 1.2mmol/L. Following administration of IV glucose, she recovers quickly.

She undergoes a CT scan of the abdomen and pelvis which shows a hypervascular lesion within the pancreas which enhances with contrast.

What further finding would be most supportive of the likely diagnosis?

A. Elevated C-peptide following administration of IV insulin
B. Low serum C-peptide level
C. Normal serum proinsulin level
D. Positive anti-GAD antibodies
E. Sulphonylurea detectable in urine

A. Elevated C-peptide following administration of IV insulin

An elevated C-peptide level following administration of IV insulin can confirm insulinoma

The correct answer is **elevated C-peptide following administration of IV insulin**. IV insulin administration should generally suppress endogenous insulin secretion and therefore C-peptide levels should fall. An inappropriate elevation in C-peptide levels should raise the suspicion of an endogenous source of insulin secretion. The CT findings are suggestive of an insulinoma.

Low serum C-peptide level is incorrect. This would be expected in cases of factitious hypoglycaemia related to insulin administration. While this patient's employment would give her access to insulin and may raise suspicion of this, the CT findings suggest an insulinoma is more likely.

Normal serum proinsulin level is incorrect. This would also be expected in a patient with factitious hypoglycaemia, whether related to insulin or sulphonylurea administration. In an insulinoma, we would expect elevated proinsulin levels, especially after a prolonged fast.

Positive anti-GAD antibodies is incorrect. These would be expected in a patient with type 1 diabetes mellitus. In the absence of treatment, this would present with hyper- rather than hypoglycaemia.

Sulphonylurea detectable in urine is incorrect. In this context, this would be suggestive of factitious hypoglycaemia related to sulphonylurea use. Again, this patient would have access through her employment but the CT findings suggest insulinoma is more likely.

Question 97 of 114

A 28-year-old woman is referred by her GP with refractory hypertension. Despite combination therapy with ramipril, amlodipine, bendroflumethiazide and atenolol, her blood pressure in clinic today is 181/105 mmHg. Some of her bloods are shown below. On direct questioning she also admits passing urine more than 10 times per day. What is the most likely diagnosis?

Na +	145 mmol/l
K +	3.0 mmol/l
Urea	6.0 mmol/l
Creatinine	71 µmol/l

What is the most likely diagnosis?

A. Phaeochromocytoma
B. Coarctation of the aorta
C. Renal artery stenosis
D. 21-hydroxylase deficiency
E. Conn's syndrome

E. Conn's syndrome

All of the answers above are causes of secondary hypertension, except for 21-hydroxylase deficiency which accounts for over 90% of congenital adrenal hyperplasia.

The high sodium and low potassium in the bloods reflects the increased levels of aldosterone produced in Conn's syndrome. Aldosterone stimulates the Na+/K+-ATPase membrane transporter in the distal convoluted tubule resulting in increased sodium reabsorption and potassium excretion. Polyuria and polydipsia can result from the kidneys inability to concentrate urine.

The diagnosis is usually confirmed using plasma aldosterone:renin ratio

Question 98 of 114

A 40-year-old woman found a neck lump that was palpable in the left lobe of her thyroid gland. She was clinically euthyroid.

TSH	3.6 (NR 0.4-5.0)
free T4	15.1 (NR 10-25)
corrected calcium	2.41 (NR 2.2-2.6)

USS: 1.7 x 1.6cm solid lesion in left lobe of thyroid with microcalcification.

What is the next step in management?

A. Fine needles aspiration cytology
B. Radio-iodine uptake scan
C. Left lobectomy
D. Calcitonin level
E. Thyroglobulin level

A. Fine needles aspiration cytology

This nodule Is suspicious for malignancy because: microcalcifications, solid lesion, and no evidence of a hot lesion (as euthyroid). The next step is therefore FNA of the nodule.

Work up for thyroid nodules is as follows:

1. Check TSH
2. TSH suppressed → Thyroid uptake scan → Cold/iso nodule → FNA cytology
3. TSH suppressed → Thyroid uptake scan →Hot nodule → No FNA required
4. 2. TSH normal/elevated → Thyroid USS → Suspicious features → FNA cytology
5. FNA cytology is then graded using the Royal College of Pathologist classification on a spectrum from benign → malignant.

Question 99 of 114

A 22-year-old Asian woman with a body mass index of 24 kg/m² presents with new onset acne, hirsutism, and weight gain. Upon further questioning, it is found that she has had irregular periods for the last two years. On examination, there is mild acne and thick hair growth on her chin and areola region. Abdominal exam is unremarkable.

What are the most likely biochemical results given the clinical findings?

A. Raised testosterone, low LH/FSH ratio, insulin resistance
B. Low testosterone, low LH/FSH ratio, insulin resistance
C. Low testosterone, raised LH/FSH ratio, insulin resistance
D. Raised testosterone, raised LH/FSH ratio, increased insulinsensitivity
E. Raised testosterone, raised LH/FSH ratio, insulin resistance

E. Raised testosterone, raised LH/FSH ratio, insulin resistance

The clinical description is consistent with polycystic ovary syndrome (PCOS). This presents with hirsutism, acne, oligo/amenorrhoea and subfertility. Biochemical findings in PCOS include insulin resistance, raised testosterone, raised LH/FSH ratio, raised prolactin and low HDL.

Question 100 of 114

A 45-year-old patient presents to the endocrinology clinic. She presented to her GP with a small palpable thyroid nodule and the GP referred her to the endocrinology clinic because of this. She has a roughly 6mm thyroid nodule which is not painful or tender which she noticed incidentally. She has had no problems with her throat or systemic features. Following the GP appointment, she has had an ultrasound which demonstrates no evidence of malignant features. She has a past medical history of post-partum depression and fibroids. She takes no regular medications.

What is the most appropriate plan?

A. Thyroid function tests
B. US guided FNAC
C. CT neck
D. MRI neck
E. Thyroid autoantibodies

A. Thyroid function tests

A new thyroid nodule does not need FNAC if the ultrasound features are benign

This patient has a small thyroid nodule. If the US features are benign in nature and there are no worrying features then a biopsy is not needed. A CT or MRI of the neck can be useful in the case of a large goitre of which the extent cannot be seen on ultrasound. Thyroid function tests would be useful to determine any level of thyroid dysfunction to exclude a toxic thyroid nodule. Autoantibodies can be useful in determining Grave's disease.

Question 101 of 114

A 69-year-old lady presents for a follow-up appointment. She had presented 3 months previously under the acute medical take with headaches, sweating, abdominal pain and wild fluctuations in blood pressure. She is currently being followed up by the appropriate surgical team and her symptoms are currently well controlled with medical treatments. On examination today, you note a lump in her anterior neck and you are given the following blood tests:

Calcium (corrected)	3.68 mmol/l
Phosphate	0.38 mmol/l
Vitamin D3	115 nmol/l (75-200 nmol/l)
Parathyroid hormone	19 pmol/l (0.8 - 8.5 pmol/l)

You have referred the patient to endocrine surgeons for neck biopsies and urgent review. Her daughter, who came with her to the consultation) is concerned she may have the same symptoms later in life.

What should you offer the daughter?

A. Reassurance
B. Genetic testing for patient and daughter
C. Offer annual follow up for surveillance
D. CT abdomen/pelvis with contrast
E. Serum bone and calcium homeostasis profile

B. Genetic testing for patient and daughter

The patient describes features consistent with phaeochromocytoma, the appropriate surgical team would be endocrine surgery, who would arrange for a resection. The new blood tests are suggestive of primary hyperparathyroidism, the neck lumps possible medullary thyroid tumour, resulting in a unifying diagnosis of MEN 2a. The daughter can undergo genetic testing for RET-mutation.

Question 102 of 114

A 25 year old woman presents to the endocrinology clinic. She is concerned because her father had a 'brain tumour' removed 2 years ago and has now been told he has another tumour in his abdomen after going to his doctor with reflux and indigestion. He has been told it might be a genetic problem and is awaiting testing. She is concerned she might also have the condition and so her GP has referred her to the clinic.

She is currently asymptomatic.

On examination there is no abnormality on the cardiovascular, respiratory, abdominal or neurological examinations.

The doctor explain that the most appropriate person to see would be the geneticist to whom her father has been referred. He asks her to obtain the details if her father is willing to provide them and says that he will refer her. In the meaning time he offers to carry out some screening blood tests.

Given the likely underlying diagnosis, which of the following is most likely to be abnormal?

A. Cortisol
B. Fasting glucose
C. Parathyroid hormone
D. Prolactin
E. Thyroid stimulating hormone

C. Parathyroid hormone

This lady's father is likely to have multiple endocrine neoplasia type 1 (MEN1) as evidenced by 2 MEN1 associated tumours, a pituitary adenoma and a gastrinoma.

Although this lady is asymptomatic, it is important she is offered genetic screening, as the condition is autosomal dominant.

Fasting glucose, parathyroid hormone and prolactin are all biochemical screening tests used for MEN1 associated tumours (insulinoma, parathyroid adenoma and pituitary adenoma respectively). However, hyperparathyroidism is by far the most common initial manifestation and will eventually develop in 90% of MEN1 patients.

Question 103 of 114

A 34-year-old woman is referred to endocrinology clinic for assessment after reporting symptoms of heat intolerance, tremors and diarrhoea to her General Practitioner. Blood tests in primary care showed evidence of thyrotoxicosis. Further assessment at clinic revealed the symptoms had been present for approximately 4 weeks. The patient had initially attributed the symptoms to the stress of caring for her new baby, who had been born 6 weeks previously. She denied any symptoms of pain on eye movements, diplopia or skin rashes.

Past medical history included only her recent pregnancy with delivery by vaginal delivery. The patient took no regular medications. There was no family history of thyroid disorders. Prior to taking maternity leave, the patient worked as a lawyer. She did not drink or smoke.

Examination revealed a small, diffuse and mildly tender goitre with no evidence of thyroid bruit. There was fine tremor of outstretched hands but no exophthalmos or proptosis. Investigations requested following clinic review are listed below.

Thyroid stimulating hormone	0.1 microU / L (reference 0.4-5.0)
T4 free serum	19.5 pmol / L (reference 8.5-15.2)
T3 free serum	8.1 pmol / L (reference 3.5-6.5)
Thyroid peroxidase antibodies	250 mU / L (reference < 150)
Erythrocyte sedimentation rate	21 ml / h

Thyroid scintiscanning (Technitium-99): no significant thyroid uptake

What is the most likely diagnosis?

A. Graves' disease
B. Toxic thyroid nodule
C. Viral thyroiditis
D. Toxic multinodular goitre
E. Post-partum thyroiditis

E. Post-partum thyroiditis

Post-partum thyroiditis is associated with elevated thyroid peroxidase antibodies but no significant uptake on thyroid scintiscanning and is, therefore, the correct answer in this case given that symptoms began approximately two weeks postpartum.

Viral thyroiditis is usually associated with an elevated ESR and negative anti-thyroid antibodies. Graves' disease, toxic multinodular goitre and a toxic thyroid nodule would be associated with different patterns of uptake on thyroid scintiscanning.

Question 104 of 114

A 43-year-old woman attends with a 1-year history of recurrent lethargy, shakiness, slurred speech, and diplopia. Symptoms most commonly develop in the mornings and then resolve after breakfast.

She has a past medical history of type 2 diabetes mellitus, alcohol excess and a functional neurological disorder.

Observations: SpO2 97% on room air, respiratory rate 22 breaths/minute, blood pressure 92/64, heart rate 116 beats per minute, apyrexial

Capillary blood glucose: 5.2

During your review, she becomes shaky and feels unwell. A repeat blood glucose is 2.4.

You send a set of blood tests and then administer 40% dextrose gel. The blood tests are reported as follows:

Insulin	43 pmol/L	(<25)
C-peptide	114 pmol/L	(<75)
Pro-insulin	23 pmol/L	(3.6-22)

What is the most likely diagnosis?

A. Alcohol-related hypoglycaemia
B. Exogenous insulin administration
C. Glimepiride use
D. Insulinoma
E. Non-insulinoma pancreatogenous hypoglycaemia syndrome

D. Insulinoma

An elevated C-peptide level following administration of IV insulin can confirm insulinoma

The most likely diagnosis here is insulinoma. This should be suspected in patients with symptoms of hypoglycaemia that improve after eating. Symptoms of hypoglycaemia can be varied and diagnosis of insulinoma can take months to years due to difficult diagnosis.

Insulinoma is correct. An insulinoma is a rare neuroendocrine tumour that secretes insulin, as a result insulin, pro-insulin, and C-peptide levels are raised.

Exogenous insulin administration is incorrect. Pro-insulin cleavage results in C-peptide and insulin which are then released from pancreatic beta cells. It is a marker of insulin secretion. C-peptide does not form part of exogenous insulin injections and so would not be raised if insulin was being administered erroneously.

Glimepiride use is incorrect. Glimepiride is a sulfonylurea and so can be associated with episodes of hypoglycaemia. It can cause a rise in insulin, C-peptide, and pro-insulin levels as seen here, however insulin levels would generally not be increased to this degree. To confirm or refute the diagnosis a supervised fast may be appropriate.

Alcohol-related hypoglycaemia is incorrect. Alcohol causes hypoglycaemia by inhibiting gluconeogenesis. In these cases, you would expect to see low levels of insulin and C-peptide in response to low blood glucose levels.

Non-insulinoma pancreatogenous hypoglycaemia syndrome is incorrect. This is a rare syndrome characterised by post-prandial hypoglycaemia episodes and a normal 72-hour fast. This is usually due to a genetic mutation and pancreatic hyperplasia. You may expect to see elevated insulin, pro-insulin, and C-peptide, but the differentiating factor here is that the hypoglycaemic episodes commonly occur after meals which would be unusual in insulinoma.

Question 105 of 114

A 32-year-old man attends as a day case for minor surgery. You are asked to see him on arrival as his blood pressure is 197/135mmHg. You organise ambulatory blood pressure monitoring which confirms an average BP of 184/111mmHg. Blood tests are sent and the results are below.

Na +	144 mmol/L	(135 - 145)
K +	2.4 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	71 µmol/L	(55 - 120)

What is the most appropriate initial treatment?

A. Amlodipine
B. Fludrocortisone
C. Oral potassium supplementation

D. Ramipril
E. Spironolactone

E. Spironolactone

Primary hyperaldosteronism: manage with spironolactone

The correct answer is **spironolactone**. Such marked hypertension in a young patient should prompt consideration of an underlying cause and the hypokalaemia would be very suggestive of primary hyperaldosteronism. This is managed initially with mineralocorticoid receptor antagonists such as spironolactone. These are associated with improvements in both his hypokalaemia and hypertension.

Amlodipine is incorrect. This is a dihydropyridine calcium channel antagonist usually used in the management of essential hypertension. It is unlikely to be effective in primary hyperaldosteronism. Other calcium channel antagonists such as verapamil may help control hypertension while awaiting the results of confirmatory tests, but amlodipine is not recommended.

Fludrocortisone is incorrect. This is a mineralocorticoid with more of a use in adrenal insufficiency. It is likely to worsen hypertension here. It can occasionally be used in a suppression test to confirm a diagnosis of primary hyperaldosteronism but has no place in treatment.

Oral potassium supplementation is incorrect. While this may lead to a temporary improvement in the patient's hypokalaemia, this is unlikely to be sustained. It will also not treat his hypertension. Such treatments may be used in other causes of hypokalaemia such as Bartter's or Gitelman's syndrome. However, these are generally associated with normotension or even hypotension.

Ramipril is incorrect. This would be an appropriate treatment for essential hypertension. However, this patient's young age should raise suspicion of a secondary cause and the hypokalaemia points to primary hyperaldosteronism as the most likely. Ramipril is unlikely to improve this patient's blood pressure significantly and can also interfere with the diagnostics in this condition.

Question 106 of 114

A 39-year-old woman has undergone a total thyroidectomy for a papillary thyroid tumour which was 3.2cm in size without lymph node or metastatic involvement and negative margins. She is reviewed in the endocrinology clinic following her treatment and would like to know how best she should be monitored for recurrence of malignancy.

What is the most appropriate monitoring?

A. Annual CT neck
B. Annual US neck
C. Annual MRI neck
D. Annual thyroglobulin
E. Annual TSH and free T4

D. Annual thyroglobulin

Following surgery and radioiodine therapy, patients with papillary thyroid cancer should be monitored with thyroglobulin annually

This patient has a very good prognosis as she has had papillary thyroid cancer which is less than 4cm in size without lymph node or other organ involvement. The most appropriate way to monitor for cancer recurrence is annual thyroglobulin. Imaging is unlikely to detect a recurrence early and is therefore inappropriate. TSH and free T4 levels should be measured frequently as this patient will need thyroxine replacement, but this is not to detect recurrence of malignancy.

Question 107 of 114

A 66-year-old man is referred to the endocrinology outpatient department with resistant hypertension and hypokalaemia. He is asymptomatic. He is on regular ramipril, amlodipine, indapamide and doxazosin. He has a further past medical history of hypercholesterolaemia. He has smoked five cigarettes daily for thirty years and drinks 2-3 bottles of wine per week. He is a non-executive director of a large multinational company.

His observations are heart rate 76 beats per minute, blood pressure 181/88 mmHg, respiratory rate 12/minute, oxygen saturations 97% on room air. He is apyrexial and appears clinically well. An examination is unremarkable other than a raised body mass index of 35.2 kg/m².

Blood tests:

Hb	141 g/L	Male: (135-180)Female: (115 - 160)
Platelets	222 * 10 /L $_9$	(150 - 400)
WBC	6.2 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	138 mmol/L	(135 - 145)
K $_+$	2.9 mmol/L	(3.5 - 5.0)
Urea	4.6 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
Cortisol	589 nmol/L	(119 - 618)
Aldosterone: renin ratio	increased	

A CT of the abdomen demonstrates bilateral adrenal enlargement and adrenal vein sampling demonstrates the production of excess aldosterone bilaterally.

What is the most appropriate treatment?

A. Chemotherapy
B. IV hydrocortisone
C. Radiotherapy
D. Spironolactone
E. Surgery

D. Spironolactone

Primary hyperaldosteronism: manage with spironolactone

Spironolactone is the correct answer. Primary hyperaldosteronism caused by bilateral adrenal hyperplasia is treated by a mineralocorticoid receptor antagonist such as spironolactone.

Chemotherapy is the wrong answer. The first-line treatment for bilateral adrenal hyperplasia causing primary hyperaldosteronism is

a mineralocorticoid receptor antagonist such as spironolactone. If a patient had disseminated malignancy caused by an adrenal carcinoma, then this may be an option.

IV hydrocortisone is incorrect. This is the treatment for acute hypoadrenalism i.e. an Addisonian crisis. The patient's cortisol is within normal limits and he has no clinical features of hypoadrenalism.

Radiotherapy is incorrect. This type of treatment may be indicated for adrenal carcinoma. However, cancer is more likely to be a unilateral mass-like lesion, rather than bilateral diffuse enlargement.

Surgery is incorrect. This would be the correct option if the patient had a unilateral adrenal adenoma secreting excess aldosterone. This is not the case here.

Question 108 of 114

A 36-year-old woman is referred to the hypertension clinic with difficult to control hypertension. She describes having occasional aches and pains which mainly affect their arms and legs. They have also noticed an increase in their urinary frequency and urgency. Her blood pressure reading is taken at the clinic and reads as 175/95 mmHg.

They are currently being treated with amlodipine and lisinopril for hypertension.

Bloods tests taken prior to attending the clinic are shown below.

Na +	136 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)

An aldosterone and renin test is performed and demonstrates an increased ratio of aldosterone to renin. Based on this, a CT abdomen is arranged. This is reported as showing bilateral adrenal hyperplasia.

What is the most appropriate management of this?

A. Bilateral adrenalectomy
B. Unilateral adrenalectomy
C. Watch and wait
D. Low sodium diet
E. Spironolactone

E. Spironolactone

The correct answer is spironolactone. Bilateral adrenal hyperplasia can be safely and successfully managed with an aldosterone antagonist (either spironolactone or eplerenone) as this will reduce the effects of aldosterone.

There is no indication for surgical management in the treatment of bilateral adrenal hyperplasia so there is no rationale for an adrenalectomy. A low sodium diet is a reasonable lifestyle modification for hypertensive patients, but there is an underlying cause so medical management is more appropriate in this case.

Watch and wait would be inappropriate as there is a clear diagnosis and a treatment.

Question 109 of 114

A 45-year-old woman comes to the clinic some 6 months after thyroid resection for differentiated thyroid cancer. She is well, has recovered from her surgery and has a neatly healed scar across her anterior neck. Blood pressure is normal at 110/80 mmHg, and her pulse is 60 and regular. Her body mass index is unchanged at 25 kg/m². Only medication is thyroid hormone replacement.

Which of the following is the most appropriate way to monitor for a recurrence?

A. MRI neck
B. Technetium scanning
C. Thyroglobulin
D. Thyroid ultrasound scan
E. T3 levels

C. Thyroglobulin

Given this patient is prescribed thyroid hormone replacement, monitoring of T3 or T4 is not useful in monitoring for cancer recurrence. On the other hand the presence of thyroglobulin does indicate thyroid gland activity which isn't suppressed by thyroid hormone replacement and is therefore potentially cancerous in origin. Levels should be undetectable.

Radiological investigations such as MRI neck, technetium scanning or thyroid ultrasound scanning are potentially less sensitive than monitoring for thyroglobulin and are therefore not a preferred first line investigation. T3 levels are unsuitable as a marker of recurrence given that conversion of exogenously administered T4 to T3 confounds any measurement.

Question 110 of 114

A 34-year-old man is admitted after being found at home covered in his vomit and excrement. He is a known alcoholic and has not been seen for two weeks.

On examination, he is drowsy and complaining of generalised aches and pains.

An ECG shows prolonged PR interval and prolonged QTc of 620ms.

On examination JVP is not visible, his mucus membranes are dry, and his eyes are sunken. His chest is clear, his heart sounds normal, and his abdomen soft and non-tender. There is moisture damage to his buttocks.

CT head is unremarkable.

Blood tests are completed and results are detailed below:

Hb	114 g/L	Male: (135-180)Female: (115 - 160)
Platelets	98 * 10 /L 9	(150 - 400)
WBC	10 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	2.2 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	190 µmol/L	(55 - 120)
Calcium	1.9 mmol/L	(2.1-2.6)
Phosphate	0.6 mmol/L	(0.8-1.4)
Magnesium	0.4 mmol/L	(0.7-1.0)

What is the priority in the management of this man's electrolyte disturbances?

A. Replace magnesium intravenously
B. Replace potassium intravenously
C. Start insulin-dex infusion
D. Start oral magnesium, potassium, phosphate, and calcium
E. Start telemetry

A. Replace magnesium intravenously

Replace magnesium before correcting hypokalaemia. Hypomagnesemia prevents potassium absorption

In this question, the patient has multiple electrolyte abnormalities due to poor oral intake over the preceding 2 weeks.

Intravenous magnesium replacement would be recommended in this case due to the severity of magnesium deficiency. Severe hypomagnesaemia is defined as levels <0.4 mmol/L.

Although we do need to replace **potassium intravenously**, hypomagnesemia prevents potassium absorption, so we need to correct this before supplementing potassium.

Dex-saline can be used as part of the treatment of hyperkalaemia. It does not necessarily need to be used in hypokalaemia.

Start oral magnesium, potassium, phosphate, and calcium: this man has severe hypomagnesaemia (<0.4 mmol/L) and severe hypokalaemia (<2.5 mmol/L). He requires intravenous replacement and oral supplementation is not appropriate.

Telemetry would be required, but it is not the main priority here, electrolyte replacement should not be delayed in this case whilst awaiting telemetry.

Question 111 of 114

A 57-year-old female presents after noticing a lump in her neck. She reports it being non-tender and she is only concerned about it for cosmetic purposes. She reports no other symptoms. Her past medical history includes hypertension and constipation. Her current medications include ramipril, irbesartan, amlodipine and furosemide. No family history is unavailable. On examination, her neck lump is hard, non-tender and measures 2cm by 1 cm, moves with swallowing but not with tongue protrusion. Her heart rate is 84 beats/min and blood pressure 213/130 mmHg. Examination of her joints was unremarkable with no excessive laxity.

Her blood tests are as follows:

Hb	112 g/l
Platelets	349 * 10 /l9
WBC	7.2 * 10 /l9
Na +	138mmol/l
K +	4.2 mmol/l
Urea	6.9 mmol/l
Creatinine	72 µmol/l
Adjusted calcium	3.1 mmol/l
Phosphate	0.40 mmol/l

She undergoes an outpatient ultrasound and fine needle aspiration of her neck lump. After her procedure, the recovery nurses were concerned regarding her persistent hypertension and the patient is admitted for further investigation. She develops a mild headache with no visual disturbances, resolving on its own after her blood pressure falls to 182/101 mmHg two hours later. Urinary metanephrine collection was positive.

Which investigation is likely to produce the underlying diagnosis?

A. Genetic testing for RET mutation
B. Genetic testing for germline VHL mutation
C. Genetic testing for NF2 mutation on chromosome 22
D. CT chest/abdomen/pelvis with contrast
E. Urinary calcium collection

A. Genetic testing for RET mutation

The clinical collection of phaeochromocytoma and hyperparathyroidism should raise suspicion of multiple endocrine neoplasia type 2a, which is a genetic syndrome of near 100% penetrance caused by a mutation of the RET oncogene. The addition of a thyroid lump makes this scenario more suggestive of MEN 2, with medullary thyroid carcinoma completing the diagnosis. MEN2b is subtly differentiated from MEN2a by the lack of hyperparathyroidism and Marfanoid features. Unlikely MEN 1, genetic screening of family members for hyperparathyroidism and germline mutation is useful for long-term surveillance and monitoring. VHL and NF 2 mutations refer to von-Hippel Lindau syndrome and neurofibromatosis type 2 respectively: VHL presents classically as a combination of retinal haemangioblastomas, renal cell carcinomas and phaeochromocytomas while NF2 typically present with intracranial tumours, bilateral Schwannomas almost in all patients.

Question 112 of 114

A 43-year-old female presents with neck discomfort worsening over the past 2 months. She has no other past medical or family history. Examination reveals a firm neck lump moving with swallowing but not with tongue protrusion. Subsequent ultrasound of her neck with fine needle aspirate reveals a 2.5cm papillary thyroid carcinoma. A CT neck reveals one single lymph node in her left anterior cervical chain.

What is the optimum treatment?

A. Thyroidectomy and neck dissection with postoperative radioiodine ablation
B. Thyroidectomy and neck dissection without postoperativeradioiodine ablation
C. Lobectomy and neck dissection with postoperative radioiodineablation
D. Lobectomy and neck dissection without postoperativeradioiodine ablation
E. Monitor annually

A. Thyroidectomy and neck dissection with postoperative radioiodine ablation

Diagnosis of thyroid tumours are frequently made after the patient has self-palpated a neck lump or after an incidental finding following unrelated neck imaging. Most prevalent in young females, diagnosis is clinched on fine needle aspiration. The key considerations for treatment are the size of the thyroid mass and the presence of lymph node involvement: any lump greater than 1cm in

size or has any signs of metastatic spread should undergo thyroidectomy instead of a lobectomy. The postoperative use of concurrent radioiodine ablation enhances survival benefits in patients at high risk of disease recurrence and is recommended by both the American Thyroid association and a European consensus group. Patients with thyroid lumps greater than 4cm in diameter regardless of extrathyroid disease; those with lumps between 1 and 4cm in diameter and extra-thyroid disease; and all with high-risk histology such as aggressive histological subtypes benefit from radioiodine ablation. In the case of this patient with a 2.5cm mass and lymph node involvement, thyroidectomy, lymph node clearance with neck dissection and postoperative radioiodine ablation is appropriate. Annual monitoring is thus an unsafe option.

Question 113 of 114

A 47-year-old man attended his GP after checking his blood pressure at the local pharmacy. When he had it checked it was 179/102 mmHg. The GP confirmed it was high in the surgery at 186/103 mmHg. He started him on ramipril 2.5mg and titrated up to the dose to 10mg over the next few weeks. His repeat measurements showed consistently high readings so the GP added amlodipine, which had very little effect despite being tolerated at the maximum dose. After failing to get an adequate response with the addition of a third agent the GP referred the patient to the endocrine clinic.

Observations showed a blood pressure of 190/105 mmHg and a heart rate of 98 beats per minute. On examination, the man was thin with a body mass index of 23 kg/m². His apex was diffuse and displaced with normal heart sounds. The chest was clear and abdomen was soft and non-tender with no evidence of masses or renal bruits. He was noted to have a hard, painless nodule over the thyroid gland.

The 24 hour urinary catecholamines were raised and further investigations confirmed phaeochromocytoma. He was treated medically with an alpha blocker then beta blocker whilst awaiting surgery. In this period he had further investigation into the thyroid nodule, which was a cold nodule on radionucleotide scanning.

Which type of thyroid cancer would you expect this to be histologically?

A. Papillary
B. Follicular
C. Anaplastic
D. Lymphoma
E. Medullary

E. Medullary

This question tests your knowledge of multiple endocrine neoplasias (MEN). This patient could have MEN Type IIa or IIb, which both include phaeochromocytoma and medullary thyroid cancer.

Of all thyroid cancers, medullary thyroid cancer accounts for approximately 5% (and of these, 80% will be sporadic rather than associated with MEN).

Question 114 of 114

A 19 year-old man is referred by his GP to the outpatient department after having several episodes of collapse at college. He reports that during these episodes he feels tired and 'blacks out'. Afterwards, he feels shaky and weak. There is no tongue biting or incontinence during these episodes and the patient reports that he often feels dizzy after standing up too quickly from a chair. The only other symptoms he reports is a sore throat that has persisted for a few weeks and lethargy.

On examination of the patient's mouth and throat, there are some white plaques located at the back of the tongue and throat. His sitting blood pressure is 130/80 mmHg and his standing blood pressure is 95/70 mmHg. He is otherwise well.

Blood tests are performed and reveal:

Hb	13.9 g/dL
Platelets	200 * 10 /l9
WBC	6.2 * 10 /l9
Na +	132 mmol/l
K +	5.1 mmol/l
Urea	4.7 mmol/l
Creatinine	81 µmol/l
Calcium	1.9 mmol/l
Random glucose	3.9 mmol/l

What is the most likely diagnosis?

A. Type II polyglandular autoimmune syndrome
B. Thymoma
C. Type 1 polyglandular autoimmune syndrome
D. Type III polyglandular autoimmune syndrome
E. HIV

C. Type 1 polyglandular autoimmune syndrome

The most likely diagnosis is type 1 polyglandular autoimmune syndrome. This autosomal recessive syndrome is a subtype of autoimmune polyendocrine syndrome, whereby a number of endocrine glands dysfunction. The patient's oral candidiasis is caused by a mild immune deficiency and hyposplenism. Furthermore, the patient has hypocalcaemia, caused by autoimmune dysfunction of the parathyroid gland and hypoglycaemia with hypotension, caused by autoimmune dysfunction of the adrenal gland.

PASSMEDICINE PART 2

HEMATOLOGY

2024

Question 1 of 191

A 40-year-old woman attends the emergency department with sudden onset abdominal pain. She feels nauseated and has vomited 4 times in the past 2 hours. Her past medical history includes hypothyroidism and vitiligo.

On examination, she has a temperature of 38.2ºC. She has a heart rate of 135bpm with a blood pressure of 116/66mmHg. There is guarding and tenderness on palpation of her right iliac fossa. Rovsing's sign is positive. It is noted that she has mild bruising and petechiae over her back and extremities and on further questioning, she tells you she has been suffering from frequent nosebleeds over the past 2 weeks.

She is reviewed by the general surgical team who want to prepare her for theatre. Investigations:

Hb	127 g/L	Male: (135-180)Female: (115 - 160)
Platelets	28 * 10 /L 9	(150 - 400)
WBC	15.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	5.6 mmol/L	(2.0 - 7.0)
Creatinine	87 µmol/L	(55 - 120)
Prothrombin time (PT)	11 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	26 secs	(25-35 secs)
Fibrinogen	2.1 g/L	(2 - 4)
D-Dimer	275 ng/mL	(< 400)
CRP	60 mg/L	(< 5)

What is the next step in this patient's management?

A. Intravenous immunoglobulin
B. Plasma exchange
C. Platelet transfusion
D. Prednisolone
E. Romiplostim

A. Intravenous immunoglobulin

Human immunoglobulin (IVIG) is an alternative to steroids in treating ITP, particularly if the platelets need to be raised quickly

This patient has immune thrombocytopenic purpura (ITP) the immune-mediated destruction of platelets. It is more common in older females and those with a history of autoimmune disease. It may present as easy-bruising, petechiae or epistaxis or may be an incidental finding on routine blood tests as seen here. The first-line treatment of choice is oral prednisolone. However, in patients who do not respond to or have contraindications to prednisolone use or those who require a rapid rise of platelets (for example, prior to having surgery) then intravenous immunoglobulin (IVIG) can be given. This patient requires a rapid rise of platelets due to her urgent surgery for likely appendicitis making IVIG the more appropriate choice in this scenario.

Plasma exchange is not a treatment for ITP. However, it is the treatment of choice for thrombocytopenic thrombotic purpura (TTP) a rare acquired disorder of coagulation that is associated with fever, acute kidney injury, central nervous system dysfunction (including confusion, seizures or coma), thrombocytopenia and microangiopathic haemolytic anaemia.

Platelet transfusion is a treatment of choice in ITP. However, it is typically reserved for cases of an acute haemorrhagic event or cerebral haemorrhage. As this patient is otherwise well with only evidence of minor bleeding, it would not be the first-line treatment of choice.

Romiplostim is a thrombopoietin receptor agonist which is a 3rd-line agent to treat ITP. It is considered in patients who have not responded to 1st and 2nd line treatment or have symptoms of chronic ITP persisting for beyond 12 months.

Question 2 of 191

A 50-year-old gentleman presents with fatigue and bruising to the emergency department. On examination, hepatosplenomegaly is noted, but no peripheral lymphadenopathy is palpable. The following blood tests are obtained:

Hb	73 g/l
Platelets	43 * 10 /l9
WBC	2.3 * 10 /l9
Neutrophils	0.8 * 10 /l9
Lymphocytes	1.3 * 10 /l9
Monocytes	0.0 * 10 /l9
Basophils	0.02 * 10 /l9
Eosinophils	0.1 * 10 /l9

He is diagnosed with hairy cell leukaemia.

Which gene is mutated in this malignant condition?

A. BRCA1
B. BRAF
C. TP53
D. NOTCH1
E. HER2

B. BRAF

BRAF is mutated in hairy cell leukaemia

Hairy cell leukaemia is caused by a mutation in exon 15 of the gene for the protein kinase BRAF. Patients may be asymptomatic with the disease is identified incidentally or present with symptoms of cytopenia.

The most common laboratory finding is cytopenia, usually affecting two or three lineages. Leucocyte counts tend to be low, with a monocytopenia present in 90% of patients. Hairy cells are often seen in peripheral blood films but their proportion is variable. They have a characteristic appearance; lymphocytes with villous cytoplasmic projections, oval nuclei and finely mottled pale grey-blue cytoplasm.

A germline mutation in BRCA1 underlies an increased risk of malignancy (especially breast and ovarian) seen in some families. This gene is also mutated, as a somatic mutation, in other cases of breast and ovarian cancer.

A germline mutation in TP53, encoding tumour suppressor protein p53, underlies Li Fraumeni syndrome. However, p53 is mutated in over 50% of malignancies, the most commonly mutated protein. Activating mutations in NOTCH1 are implicated in T cell acute lymphoblastic leukaemia and the HER2 gene is amplified in some forms of breast cancer. These are somatic mutations.

Question 3 of 191

A 59-year-old woman presents to the haematology clinic for review. Despite treatment with cyclophosphamide, rituximab and fludarabine (FCR), she has experienced a steady rise in her lymphocyte count, accompanied by symptomatic anaemia. Examination reveals evidence of anaemia, her body mass index is 22 kg/m², and there is obvious splenomegaly.

Which of the following is the most appropriate intervention?

A. Ibrutinib
B. Lapatinib
C. Everolimus
D. Pazopanib
E. Sunitinib

A. Ibrutinib

Ibrutinib is effective and can be used for the treatment of CLL in patients who have failed a previous therapy

Ibrutinib is a small molecule kinase inhibitor which binds to Bruton's tyrosine kinase which is involved in B cell clonal replication. It therefore has an important role in the treatment of B cell malignancies including mantle cell lymphoma and chronic lymphocytic leukaemia (CLL). It is recommended for patients who have had at least one previous therapy for CLL or those with a 17p deletion or TP53 mutation.

Question 4 of 191

A 76-year-old gentleman with myelofibrosis is found to have a haemoglobin of 67 g/l on admission. He is transfused two units of red cells and discharged home three days later. Six days later, he is readmitted febrile and jaundiced. Blood tests show:

Hb	71 g/l	Na +	137 mmol/l	Bilirubin	39 µmol/l
Platelets	97 * 10 /l 9	K +	3.9 mmol/l	ALP	82 u/l
WBC	2.8 * 10 /l 9	Urea	4.9 mmol/l	ALT	15 u/l
Neuts	1.5 * 10 /l 9	Creatinine	79 µmol/l	Albumin	26 g/l

What is the most appropriate management for this condition?

A. Prednisolone
B. Intravenous immunoglobulin
C. Conservative management
D. Packed red cells
E. Tazocin

C. Conservative management

A delayed transfusion reaction occurs 7-10 days after the transfusion

This is a delayed transfusion reaction, which typically occurs 7-10 days post-transfusion. It occurs when patients are sensitised from previous transfusions or pregnancy and have alloantibodies against red cell antigens which are not picked up by cross-matching, if below detectable limits.

Management includes informing the laboratory and sending a repeat group and save sample for further testing. Usually, supportive management is sufficient, though if symptomatic from anaemia, they may require further transfusion after the further crossmatching testing is carried out. Prednisolone and intravenous immunoglobulin are not used in this situation typically. If this were bacterial contamination of the blood product, tazocin would be appropriate, though this presentation is too late and there are no other signs of sepsis.

Question 5 of 191

A 44-year-old woman is referred to ambulatory care with a 10-day history of lethargy and exertional dyspnoea. Prior to this episode, she reports having mild coryzal symptoms that have since settled. Her past medical history is only significant for hypothyroidism which is well controlled on levothyroxine.

A full screen of blood tests is sent:

Hb	71 g/L	(135 - 180)
Platelets	110 * 10 /L 9	(150 - 400)
WBC	7.0 * 10 /L 9	(4.0 - 11.0)
Urea	6.3 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
Prothrombin time (PT)	11 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	26 secs	(25-35 secs)
Fibrinogen	3.1 g/L	(2 - 4)
D-Dimer	345 ng/mL	(< 400)
Reticulocytes	2.5 %	(0.5 - 1.5)
Blood film	Schistocytes	
Coombs test	Negative	
Bilirubin	59 µmol/L	(3 - 17)
ALP	128 u/L	(30 - 100)
ALT	40 u/L	(0 - 40)
AST	50 u/L	(< 35)
Blood glucose	5.2 mmol/L	(4 - 7)
Total cholesterol	7.1 mmol/L	(< 5)

What is the most likely diagnosis?

A. Autoimmune haemolytic anaemia
B. Disseminated intravascular coagulation
C. Paroxysmal nocturnal haemoglobinuria
D. Thrombotic thrombocytopenia purpura
E. Zieve syndrome

A. Zieve syndrome

Zieve syndrome is a rare clinical syndrome of Coombs-negative haemolysis, cholestatic jaundice, and transient hyperlipidaemia

This patient has a likely diagnosis of **Zieve syndrome** given the triad of non-autoimmune haemolysis, jaundice and hyperlipidaemia. The negative Coombs test indicates non-autoimmune haemolytic anaemia. In Zieve syndrome, jaundice can be cholestatic in nature but also secondary to haemolysis. The raised ALP supports a cholestatic picture. Zieve syndrome is a rare syndrome and generally resolves following the cessation of alcohol use.

Autoimmune haemolytic anaemia is incorrect. Although there is evidence of haemolysis given the low Hb, reticulocytosis, raised bilirubin and presence of schistocytes, the Coombs test is negative. A negative Coombs test makes autoimmune haemolytic anaemia very unlikely.

Disseminated intravascular coagulation (DIC) is incorrect. DIC is a disease of abnormal coagulopathy characterised by a prolonged prothrombin time, prolonged APTT, low fibrinogen and a very high D-dimer. Triggers for DIC include malignancy, surgery and significant infection of which none are mentioned in this presentation. The resolved coryzal symptoms are unlikely to be significant.

Paroxysmal nocturnal haemoglobinuria (PNH) is incorrect. PNH is characterised by intravascular haemolysis, bone marrow hypoplasia and increased risk of thromboses. This does not completely fit the patient's presentation making this answer incorrect.

Thrombotic thrombocytopenia purpura (TTP) is incorrect. This condition presents as a pentad of fever, acute kidney injury, thrombocytopenia, microangiopathic haemolytic anaemia and cerebral dysfunction. The absence of the majority of these features makes TTP unlikely.

Question 6 of 191

A 54-year-old gentleman is admitted under the medical team with a diagnosis of urosepsis. Twenty four hours after admission he develops numerous bruises across his abdomen, arms and legs. It is also noted that he is bleeding from his cannula site

His blood results are as follows

Hb	110 x10 /L 12	130-168 x10 /L12
WCC	19 x10 /L 9	4.2-10.6 x10 /L9
Platelets	50 x10 /L 9	130-370 x10 /L9
CRP	300 mg/L	0-5 mg/L
Fibrinogen	3.8 g/L	1.8-4.0 g/L
PT	20s	9-12s
APTT	38s	23-31s
Creatinine	150µmol/L	60-125 µmol/L
eGFR	60 mL/min/1.73 m 2	>90 mL/min/1.73 m2

What is the most likely cause?

A. Idiopathic thrombocytopenia purpura (ITP)
B. Thrombotic thrombocytopenia purpura (TTP)
C. Disseminated intravascular coagulation (DIC)
D. Heparin induced thrombocytopenia (HIT)
E. Haemolytic uraemia syndrome (HUS)

C. Disseminated intravascular coagulation (DIC)

In DIC fibrinogen can be normal or elevated in over 50% of cases especially early on (as fibrinogen is an acute phase marker)

Fibrinogen is an acute phase marker. Therefore in DIC fibrinogen levels can be normal or elevated in over 50% of cases especially early on.

PT/APTT are usually normal in ITP, TTP, HUS and HIT

Renal function is markedly abnormal in HUS

In HIT the plasma prothrombin time (PT) is decreased but the activated partial thromboplastin time (aPTT), and the fibrinogen levels are normal.

Question 7 of 191

You are called to see a 68-year-old female on the oncology ward who has developed coffee ground vomiting. She has a diagnosis of colorectal cancer which she is currently undergoing curative chemotherapy for.

Blood results are as follows:

Hb	95 g/l
Platelets	34 * 10 /l9
WBC	14 * 10 /l9
PT ratio	2.4
aPPT ratio	2.1
D-dimer	1540 ng/ml (normal < 500)
Fibrinogen	0.8 g/l (normal 1.5-4.0)

You administer fresh frozen plasma. Repeat blood results are as follows:

Hb	91 g/l
Platelets	24 * 10 /l9
WBC	18.4 * 10 /l9
PT ratio	2.2
aPPT ratio	1.9
Fibrinogen	0.85 g/l (normal 1.5-4.0)

What treatment is indicated?

A. Cryoprecipitate
B. Vitamin K
C. Factor VIII
D. Factor IX
E. No further treatment

A. Cryoprecipitate

In bleeding patients with DIC with severe hypofibrinogenaemia (<1 g/l) that persists despite FFP replacement, then fibrinogen concentrate or cryoprecipitate is indicated

The patient has DIC likely secondary to malignancy. In bleeding patients with DIC and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT), administration of fresh frozen plasma (FFP) may be useful. Notably, this patient continues to have severe hypofibrinogenaemia despite administration of FFP. In bleeding patients with DIC with severe hypofibrinogenaemia (<1 g/l) that persists despite FFP replacement, then fibrinogen concentrate or cryoprecipitate is indicated.

Vitamin K would be indicated in Vitamin K deficiency. There is nothing in the history to suggest vitamin K deficiency.

Factor VIII and factor IX are indicated for Haemophilia A and B respectively.

Question 8 of 191

A 74-year-old woman is referred to the medical assessment unit with diffuse bone pain affecting her back and ribs that has persisted for two months. She has no significant past medical history and is not on any regular medications. She does not smoke and still workers as a potter.

Clinical examination is unremarkable and there are no focal areas of tenderness or swelling. There is no organomegaly or lymphadenopathy. Cardio-respiratory examination is unremarkable.

Blood tests:

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	389 * 10^9 /L	(150 - 400)
WBC	4.2 * 109 /L	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.8 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	10 mg/L	(< 5)
Calcium	2.68 mmol/L	(2.20-2.60)
Immunoglobulin G	24.1 g/L	(6.6 - 15.9)
Immunoglobulin A	4.4 g/L	(0.6-5)
Immunoglobulin M	2.2 g/L	(0.53 - 2.47)

Serum protein electrophoresis:

Paraprotein	present

Given the likely diagnosis, what is the first-line imaging investigation?

A. Isotope bone scan
B. Low dose whole body CT
C. Fluorodeoxyglucose positron emission tomography CT (FDG PET-CT)
D. Plain radiographic skeletal survey
E. Whole body MRI

A. Whole body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

Whole-body MRI is the correct answer. This patient presents with diffuse bone pain, anaemia, hypercalcemia, raised IgG and a paraprotein. She likely has multiple myeloma. Recent NICE guidelines state that imaging should be offered to all patients with suspected myeloma and that whole-body MRI is the first-line choice in the absence of contraindication.

Low dose whole-body CT is incorrect. This investigation can be offered if an MRI is contraindicated or not tolerated.

A plain radiographic skeletal survey is incorrect. This is only offered if CT or MRI are unsuitable or not tolerated.

Isotope bone scan is incorrect. This is not recommended in the investigation of suspected myeloma.

FDG PET-CT is incorrect. This imaging investigation is only an option for those patients with confirmed multiple myeloma who have not yet had any whole body imaging

Question 9 of 191

A 67-year-old man with a previous diagnosis of myelodysplasia presents to a haematology clinic with rapid weight loss, an increase in nosebleeds and a greater feeling of fatigue than previously. He has the single lineage dysplasia subtype and usually requires monthly transfusions; he has presented two weeks after his last red blood cell top-up.

His blood results are as follows:

Hb	66 g/L	Male: (135-180)Female: (115 - 160)
Platelets	9 * 109 /L	(150 - 400)
WBC	1.1 * 109 /L	(4.0 - 11.0)

A blood film is sent for and he is admitted for blood and platelet transfusions.

What is the blood film likely to show?

A. Burr cells
B. Fragmented red blood cells
C. Lymphoblasts
D. Myeloblasts
E. Smear cells

D. Myeloblasts

Myelodysplasia may progress to acute myeloid leukaemia

Myeloblasts is the correct answer as this is most likely a malignant transformation of myelodysplasia to acute myeloid leukaemia (AML). This is evidenced by the myeloblasts coupled with the significant drop in haemoglobin, platelets and white blood cells, with the B symptoms of weight loss and fatigue becoming more prominent. The clue in the blood tests is that he previously had single lineage dysplasia which causes refractory anaemia, but now he has platelet and white blood cell reduction indicating bone marrow failure. The white cells overproduced in AML are the immature myeloblasts, not normally found in the blood.

Burr cells are incorrect as these are spiculated red blood cells commonly found in chronic renal failure due to high levels of nitrogen in the blood destabilising the red cell membrane.

Lymphoblasts are incorrect as these cells are only found in the peripheral blood film in acute lymphoblastic leukaemia.

Smear cells are incorrect because they are the result of artefactual damage to mature lymphocytes during film production, often characteristic of chronic lymphoblastic leukaemia.

Fragmented red blood cells are seen in many conditions which result in intravascular haemolysis, such as renal failure, microangiopathic haemolytic anaemia, haemolytic uraemic syndrome or thrombotic thrombocytopenic purpura. The reason for the anaemia, in this case, is bone marrow failure as opposed to haemolysis.

Question 10 of 191

An 18-year-old woman presents to the haematology clinic with spontaneous bruising, heavy periods and recurrent epistaxis. This has been a continuous problem during her teenage years but she was recently found to have anaemia and received an iron transfusion which prompted further investigation into these symptoms.

On examination, she is well and alert. There are numerous purpura across both arms and she denies trauma or any itchiness.

Hb	98 g/l
Platelets	314 * 10 /l9
WBC	5.6 * 10 /l9
PT	13.8
APTT	34.3
PFA-100 assay	prolonged closure time
Flow cytometry	GPIIb/IIIa negative
Ristocetin-induced platelet aggregation	normal agglutination

What is the likely diagnosis?

A. Bernard-Soulier disease
B. Glanzmann thrombasthenia
C. Von Willebrand disease
D. Haemophilia A
E. Evan's syndrome

B. Glanzmann thrombasthenia

Innate defective glycoprotein IIb/IIIa -> Glanzmann's thombasthenia

This is a test of the coagulopathies. Von Willebrand disease and haemophilia tend to have raised APTT. Evan's syndrome is an autoimmune disease with low platelets and red blood cells. The PFA- 100 assay shows that platelets are not aggregating and this may be due to platelet glycoproteins or their interaction with von willebrand factor. The ristocetin effectively allows aggregation of von willebrand factor to GPIb and does not require GPIIb/IIIa. Therefore Glanzmann thrombasthenia will have normal platelet aggregation once ristocetin is added.

Question 11 of 191

A 48-year-old man was admitted to the acute medical unit with history of haematemesis and melaena. No previous history was available. He required fluid resuscitation and had eight-units of red cell transfusion. On review after his transfusion, his pulse was found to be 80 beats per minute and blood pressure 130/78mmHg. Chest and abdominal examination were essentially normal. Repeat bloods were taken and results are as shown below:

Hb	110g/l (130 - 180)
Platelets	80 * 10 /l (150 - 400)9
WBC	10 * 10 /l (4.0 - 11.0)9
Prothrombin time	14.2secs (11.5 - 15.5)
INR	1.3 (<1.4)
APTT	32secs (30 - 40)
Thrombin time	17secs (15 - 19)
Fibrinogen	2.1g/l (1.8 - 5.4)

Which blood product should he be given at this stage?

A. Cryoprecipitate and fresh frozen plasma
B. Fresh-frozen plasma
C. Fresh-frozen plasma and platelets
D. Platelets
E. No blood products are indicated

A. No blood products are indicated

Fresh frozen plasma is offered to bleeding patients who have either a prothrombin time or activated partial thromboplastin time greater than 1.5 times normal

Decisions on transfusion of blood products should recognize that over-transfusion may be as damaging as under-transfusion by exposing patients to the risk of fluid overload and other complications of transfusion. Do not offer platelet transfusion to patients who are not actively bleeding and are haemodynamically stable. Platelets may be given to those actively bleeding and have a platelet count of less than 50 Ã— 109/L. Offer fresh frozen plasma to bleeding patients who have either a prothrombin time or activated partial thromboplastin time greater than 1.5 times normal; and cryoprecipitate or fibrinogen concentrate to those with a fibrinogen level of less than 1 g/L. Offer prothrombin complex concentrate to patients who are taking warfarin and actively bleeding. Treat patients who are taking warfarin and whose upper gastrointestinal bleeding has stopped in line with local warfarin protocols.

Question 12 of 191

A 65-year-old man has been admitted with worsening abdominal pain, hypotension and altered mental state. He is currently being treated for intra-abdominal sepsis secondary to peritoneal dialysis for chronic renal failure secondary to diabetic nephropathy. Previous medical history includes type 2 diabetes mellitus, angina, hypertension, hyperlipidaemia, and diabetic retinopathy. The patient is not anti-coagulated but does take aspirin.

He is started on intravenous antibiotics and intravenous fluid. His results are:

Hb	91 g/L	Male: (135-180)Female: (115 - 160)
Platelets	60 * 109 /L	(150 - 400)
WBC	24.5 * 10 /L 9	(4.0 - 11.0)
Na +	128 mmol/L	(135 - 145)
K +	5.8 mmol/L	(3.5 - 5.0)
Urea	31.7 mmol/L	(2.0 - 7.0)
Creatinine	645 µmol/L	(55 - 120)
CRP	317 mg/L	(< 5)
PT	22 seconds	(10-14 seconds)
APTT	56 seconds	(30-40 seconds)

He undergoes a CT scan which shows a spontaneous retroperitoneal haemorrhage and is referred to interventional radiology.

Given the patient's coagulation profile, what blood product is needed?

A. Cryoprecipitate
B. Fresh frozen plasma
C. Protamine
D. Prothrombin complex concentrates
E. Recombinant activated factor 7

B. Fresh frozen plasma

In bleeding patients with DIC and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT), administration of fresh frozen plasma (FFP) may be useful

Fresh frozen plasma is correct. The clinical picture above is that of DIC. There is a prolongation of both PT and APTT. Patients with disseminated intravascular coagulopathy go through a hypercoagulable state followed by a hypo-coagulable state as they use up their reserves of clotting factors. Fresh frozen plasma replaces multiple clotting factors. The disturbed clotting state, as shown with prolongation of PT and APTT, indicates that clotting factor concentrations are below 30% of normal. A typical dose of fresh frozen plasma (15ml/kg) will increase circulating clotting factors by 10%.

Cryoprecipitate is incorrect because this is used to replace fibrinogen in haemorrhaging patients. It also contains Factor VIII and XIII, von Willebrand's Factor and fibronectin. It can be used in patients with von Willebrand's disease and haemophilia.

Protamine is incorrect because this is used to correct the effects of heparin, either unfractionated heparin or low molecular weight heparin. Administration can cause hypotension and high doses can inhibit platelet function.

Prothrombin complex concentrate is incorrect because this is used to reverse warfarin and can be used to reverse some direct oral anticoagulants. This includes clotting factors II, VII, IX and X. It is used for the rapid correction of an acquired coagulation disturbance, commonly warfarin. PT levels are monitored for dose-response. Repeat doses may be required 8-12 hours after the initial dose. An example is Octaplex.

Recombinant activated factor 7 is incorrect because this is used in haemophilia patients and off label in severe multiple trauma, non-traumatic intracranial haemorrhage and some surgeries. It is almost identical to native factor 7.

Question 13 of 191

A 45-year-old man is admitted from a local park. On arrival, he is in respiratory distress with a ventilatory rate of 34 breaths per minute and a peripheral oxygen saturation of 89% on 15L/min oxygen via a non-rebreathe mask. He is grey and sweaty with central cyanosis. Heart rate is 122bpm and blood pressure is 94/66mmHg. Examination of the chest discloses a normal cardiorespiratory examination and there is no clinical indication of heart failure. A chest x-ray shows no acute pathological lesion but background emphysematous changes and an ECG shows only sinus tachycardia with a corrected QT interval approaching the upper limit of normal with no ischaemic lesions.

An arterial blood gas taken on 15L/min oxygen shows:

pH	7.17	HCO3-	13.4	Glucose 6.9 mmol/l	MetHb	35%
pO2	10.9	Base excess	-5.8	Potassium 5.5 mmol/l	COHb	8%
pCO2	6.7	Lactate	4.1 mmol/l			

He is beginning to show signs of tiring and confusion and his GCS has fallen to 13/15 (E3V4M6) but he tells you he has been inhaling Liquid Gold (an alkyl nitrite).

Which of the following interventions is most appropriate in this patient's immediate management?

A. Continuous positive airways pressure ventilation (CPAP) pending transfer to a hyperbaric chamber
B. Reduce inspired oxygen concentration and controlled oxygen therapy via Venturi valve
C. 75mg 1% methylthioninium chloride solution IV over 5 minutes
D. 300mg 3% sodium nitrite solution IV over 10 minutes
E. 50ml 8.4% sodium bicarbonate solution IV over 20 minutes

D. 75mg 1% methylthioninium chloride solution IV over 5 minutes

Methylene blue can be used to treat methaemoglobinaemia. It causes a reduction of Fe3+ (ferric) to Fe2+ (ferrous)

The arterial blood gas in the above clinical description shows a mixed respiratory and metabolic acidosis with a relative hypoxia despite the inspired fraction of oxygen. However, the significant abnormality is the fraction of methaemoglobin on the gas at over 30% which is significantly elevated. The carboxyhaemoglobin level is slightly raised at 8% but levels such as this may be seen in smokers and are not necessarily pathological. In this case, the diagnosis is of acute methaemoglobinaemia which is a rare but potentially fatal consequence of inhalation of poppers (alkyl nitrites).

Poppers are a clear or yellowish, sweet-smelling volatile liquid which is inhaled as a recreational drug of abuse which yields euphoric and anxiolytic effects. It also is a vasodilator and is sometimes used as an adjunct in sexual acts, and previously was a treatment for angina pectoris. However, in some patients, particularly susceptible individuals such as those with sickle cell traits or a G6PD deficiency, inhalation of poppers may rapidly oxidise ferrous iron ions in haemoglobin to their ferric (Fe3+) states creating methaemoglobinaemia (MetHb). MetHb binds oxygen more avidly than haemoglobin and causes a shift in the dissociation curve to the left meaning that oxygen is not liberated in the tissues causing a cellular hypoxia. This manifests in a clinical cyanosis and often a deathly grey pallor to the patient. Oxygen saturations may not be as shocking as the patient appears since many pulse oximeters cannot distinguish between oxyhaemoglobin and methaemoglobin well. However, supplemental oxygen will not improve recorded values (although it should still be given). An impairment in gas exchange is often seen in acute methaemoglobinaemia with raised tensions of CO2 and low tension of O2 and consequent respiratory acidosis. An additional metabolic acidosis occurs due to cellular anoxic respiration. In smokers, this condition may be mistaken for a type 2 respiratory failure due to chronic obstructive lung disease. The methaemoglobin count and low bicarbonate make this unlikely and reducing the inspired oxygen is likely to worsen the situation. CPAP may be tried but will not reverse the underlying problem and hyperbaric oxygen is helpful only in situations of high carboxyhaemoglobin, such as carbon monoxide poisoning, which is not the case here.

The first line treatment for methaemoglobinaemia is the administration of methylthioninium chloride, also known as methylene blue, which reduces the ferric ions back to their ferrous states rapidly. Several administrations may be required, especially in high concentrations of MetHb. Sodium nitrite is a recognised treatment for cyanide poisoning. It actually causes methaemoglobinaemia since cyanide ions are cleared more rapidly when complexed with MetHb. Administration of sodium nitrite is not indicated in this vignette and will make the situation worse. Sodium bicarbonate may well be indicated in this patient due to the profound acidosis but it is not the most pressing concern. Rectification of the oxygen-carrying capacity of the blood may improve the acid-base balance without the need for bicarbonate, and hypoxia is likely to kill the patient more quickly than acidosis with a normal potassium. Remember that 8.4% bicarbonate solution, if given, should ideally be infused through a central vein since it is extremely caustic.

Question 14 of 191

A 74-year-old gentleman presents with shortness of breath on exertion. He denies cough, wheeze, or chest pain. He has a past medical history of Hodgkin's lymphoma. Examination of the cardiopulmonary system is normal.

Blood results are as follows:

Hb	55 g/l
Platelets	346 * 10 /l9
WBC	8.4 * 10 /l9

You decide to transfuse him two units of red cells. What special request will you make?

A. Leukodepleted
B. CMV negative
C. No special request required
D. Irradiated red cells
E. Cell salvage

D. Irradiated red cells

The risk of transfusion associated graft versus host disease in Hodgkin's lymphoma is unrelated to the treatment modality and/or disease stage. Individuals with Hodgkin's lymphoma should therefore receive X- or gamma-irradiated blood for life

If an immunocompromised patient receives red cells that are not irradiated, the donor's T cells can cause transfusion-associated graft-versus-host disease (TA-GvHD), in which the donor T lymphocytes mount an immune response against the recipient's lymphoid tissue causing tissue and organ damage, potentially leading to death.

Typical clinical features of TA-GvHD include fever, an erythematous maculopapular rash, abdominal pain and profuse diarrhoea.

Irradiation of blood products destroys the donors T lymphocytes thereby helping to prevent this potentially fatal complication.

Indications for gamma irradiated blood products include:

- Immunocompromised marrow or organ transplant recipients
- Patients with haematological disorders who will be undergoing allogeneic marrow transplantation imminently
- Intrauterine transfusions
- Patients with Hodgkin's disease
- Patients treated with purine analogue drugs (e.g. fludarabine)

Interestingly, the risk of transfusion associated graft versus host disease in Hodgkin's lymphoma is unrelated to the treatment modality and/or disease stage. Individuals with Hodgkin's lymphoma should therefore receive X- or gamma-irradiated blood for life.

In the UK, all blood products are leukodepleted to prevent Creutzfeldt-Jakob disease transmission.

The use of CMV-seronegative blood products is reserved for CMV-seronegative individuals that are likely to proceed to haematopoietic stem cell transplant, or neonates

Question 15 of 191

A 28-year-old woman presents to the acute medical unit with fatigue, lethargy, and abdominal pain. She is pregnant at 32 weeks gestation.

Blood results are as follows:

Hb	62 g/L	Male: (135-180)Female: (115 - 160)
Platelets	182 * 10 /L 9	(150 - 400)
WBC	8.8 * 10 /L 9	(4.0 - 11.0)

You discuss the case with the obstetrics registrar on call who advises you that they will review the patient in the department and asks you to arrange a blood transfusion.

What special red cell requirements are required?

A. Cytomegalovirus (CMV) negative
B. High titre anti-A and anti -B negative
C. Irradiated
D. Leukodepleted
E. Washed

A. Cytomegalovirus (CMV) negative

The use of CMV-seronegative blood products is reserved for CMV-seronegative individuals that are likely to proceed to haematopoietic stem cell transplant, or neonates

Cytomegalovirus (CMV) negative is the correct answer. CMV is a type of herpes virus. Primary infection is usually asymptomatic but may cause a flu or glandular fever-like illness, leading to a lifelong infection in all age groups. The virus resides in monocytes and can reactivate from its latent state. More severe disease may occur in individuals with impaired immunity such as foetuses, neonates and patients of any age who have been immuno-suppressed by disease or treatment.

Transmission of CMV present in blood components can give rise to primary infection in CMV negative patients or to reinfection in previously infected patients.

With very few stated exceptions (e.g. granulocytes), from November 1999 all allogeneic blood components produced in the UK have been subjected to a leukocyte depletion process. This was primarily a vCJD risk reduction measure, however, it has resulted in other added benefits including reduced incidence of non-febrile haemolytic transfusion reactions, TRALI, and transfer of CMV.

The following groups of patients require **CMV-negative blood**:

Intra-uterine transfusions

Neonates up to 28 days post expected date of delivery Pregnancy

As the patient in this clinical case is pregnant, CMV-negative blood is required.

Historically, immunocompromised patients who have not been infected with CMV (CMV negative) received CMV-negative blood due to the possible life-threatening complication of infection. However recent studies have shown that leukodepletion is just as effective as CMV IgG-negative blood components. Therefore CMV IgG negative donations are no longer required in this cohort.

Irradiated blood is required in individuals with severe immunodeficiencies, those with a history of Hodgkin's lymphoma, patients who have been exposed to certain drugs (e.g. bendamustine and fludarabine), and following stem cell transplant. Pregnancy is not an indication for irradiated blood.

All blood products in the UK are **leukodepleted** (with very few exceptions eg granulocytes). This is therefore not a special requirement.

With transfusion of plasma-rich components (e.g. FFP and platelets), we are more concerned about the passive transfer of antibodies (e.g. Anti-A and Anti-B) in contrast to the transfer of antigens as in red cell transfusions (which contain negligible amounts of plasma). Thus for plasmarich components, group AB is the universal donor and group O is the universal recipient, in stark contrast to packed red cells. **High titre anti-A and anti -B** negative can be requested for incompatible plasma-rich transfusion. This clinical case is regarding red cell transfusions and thus this special requirement is not applicable.

Washed red cells can be requested for patients who have recurrent febrile or allergic reactions to standard packed red cells. Pregnancy is not an indication for washed red cells.

Question 16 of 191

A 35-year-old man presents to the emergency department with generalised weakness, nausea, and joint pain. He has a past medical history of depression for which he has been prescribed sertraline but has not taken it for several months. He is a current smoker and also uses intravenous recreational drugs.

On examination, he has a non-blanching, slightly raised purplish rash over his torso and part of his limbs. He is slightly jaundiced and has mild right upper quadrant tenderness.

Blood tests are taken:

Bilirubin	51 µmol/L	(3 - 17)
ALP	188 u/L	(30 - 100)
ALT	142 u/L	(3 - 40)
Î³GT	82 u/L	(8 - 60)
Albumin	29 g/L	(35 - 50)
HBsAg	Negative	
Anti-HBV	Negative	
Anti-HCV	Positive	
HCV RNA	Positive	
HIV antibodies	Negative	

What is the most likely diagnosis?

A. Cold agglutinin disease
B. Cryoglobulinaemia type 1
C. Cryoglobulinaemia type 2
D. Cryoglobulinaemia type 3
E. Warm autoimmune haemolytic anaemia

C. Cryoglobulinaemia type 2

Hepatitis C + purpuric rash → cryoglobulinaemia

This patient, in summary, has generalised weakness, arthralgia, and a rash consistent with palpable purpura on the background of a diagnosis of hepatitis C. The combination of hepatitis C and purpura is suspicious of cryoglobulinaemia. Meltzer's triad is a combination of palpable purpura, arthralgia, and weakness and are the classical symptoms of cryoglobulinaemia.

There are three types of cryoglobulinaemia. It is **cryoglobulinaemia type 2** that is associated with hepatitis C and therefore this is the correct answer. Other associations of type 2 include rheumatoid arthritis, Sjogren's, and lymphoma.

Cold agglutinin disease is an autoimmune disease caused by the presence of cold-sensitive antibodies which act on red blood cells. It has both primary and secondary forms, of which hepatitis C can be a trigger of secondary cold agglutinin disease. Symptoms can include arthralgia and weakness, but the presence of palpable purpura is not associated. Therefore, this diagnosis is less likely.

Cryoglobulinaemia type 1 is not associated with hepatitic C. Associations include multiple myeloma and Waldenstrom macroglobulinaemia.

Cryoglobulinaemia type 3 is not associated with hepatitic C. Associations include rheumatoid arthritis and Sjogren's.

Warm autoimmune haemolytic anaemia is the most common form of autoimmune anaemia. It is idiopathic in 50% of cases. In others, it is often associated with another autoimmune disease such as rheumatoid arthritis or systemic lupus erythematosus. Therefore, this diagnosis is unlikely in this case.

Question 17 of 191

A 40-year-old man presents to the Emergency Department with non-specific symptoms of lethargy, malaise, headache, body aches, a low-grade fever and a sore throat. The examination is essentially normal aside from multiple limb petechiae. Tympanic temperature is 37.6°C. Blood pressure, heart rate and pulse oximetry are normal.

Blood tests show:

Haemoglobin	112g/L	Sodium	136mmol/L
MCV	82fL	Potassium	4.5mmol/L
Platelets	77x10^9/L	Urea	6.9mmol/L
White cells	32x10^9/L	Creatinine	111µmol/L
Prothrombin time	23secs	CRP	54mg/L
Fibrinogen	0.45g/L	HIV test	Negative
Liver enzymes	normal		

The automated counter is unable to supply differential white cell count.

Manual blood film shows immature granulocytes with bilobed nuclei and Auer rods.

What is the most important immediate therapy to institute?

A. All trans retinoic acid (ATRA) [tretinoin]
B. Methotrexate
C. Imatinib
D. Rituximab
E. Arsenic trioxide

A. All trans retinoic acid (ATRA) [tretinoin]

APML is treated with all-trans retinoic acid (ATRA) to force immature granulocytes into maturation to resolve a blast crisis prior to more definitive chemotherapy

The above vignette gives a classical description of acute promyelocytic leukaemia (APML). This diagnosis is considered a haematological emergency. Approximately 10% of patients with an acute leukaemia are ultimately diagnosed with APML but it is a largely unconsidered diagnosis. If diagnosed, it is one of the most treatable leukaemias, however, in one-third of cases the initial presentation is of catastrophic haemorrhage.

The average age of presentation with APML is 30-40 which distinguishes it from other acute myeloid leukaemias which present in the seventh decade typically. Other presenting symptoms are similar however with fatigue and weakness due to anaemia, coryzal or influenza symptoms and easy bruising due to thrombocytopaenia and coagulopathy. Myeloid leukaemia may cause splenomegaly which is usually absent in APML. Lymphadenopathy does not occur in leukaemias of myeloid line.

A blood film may show characteristic Auer rods in both myeloid leukaemia and APML. The film will show abnormal myeloid precursor cells or granulocytes in APML which are often bilobar or multilobar, whereas leukaemic mature myeloid cells are present in other forms of myeloid leukaemia although distinguishing these is difficult. Automated counters may fail to determine a differential white cell count. Confirmation of AMPL is via polymerase chain reaction or fluorescent in-situ hybridisation (FISH) of the bone marrow which demonstrates translocation of chromosomes 15 and 17. A gene on chromosome 17 codes for the retinoic acid receptor alpha protein and in APML patients with this translocation, administration of all-trans retinoic acid forces the immature myeloid cell to mature and it then undergoes apoptosis. ATRA is considered an emergency treatment for an APML blast crisis in those with coagulopathy or severe anaemia or sepsis. ATRA is considered only an emergency drug to force cell maturation; ongoing chemotherapy is required to maintain remission. Current guidelines recommend arsenic trioxide as the first line agent to achieve remission once ATRA therapy is commenced and also in refractory disease.

Methotrexate may sometimes be used to maintain remission in some APML patients although it is not helpful in the acute presentation.

Imatinib is a tyrosine kinase inhibitor used in the treatment of chronic myeloid leukaemia, particularly those with the Philadelphia translocation. It is not commonly used in this scenario.

Rituximab is a monoclonal antibody against CD20 on B cells. It has many uses in inflammatory diseases, lymphoma and lymphocytic leukaemia but is rarely used in APML or myeloid leukaemia (since B cells are of lymphoid, not myeloid lineage). There are some studies which have suggested a link between rituximab usage and the development of APML.

Question 18 of 191

A 43-year-old man presents to the emergency department with melaena and haematemesis. He has a past medical history of immune thrombocytopenia and is not currently on any treatment. He does not drink alcohol.

Observations:

Heart rate 108 beats per minute Blood pressure 92/58 mmHg Respiratory rate 18/minute Oxygen saturations 96% on room air Temperature 37.1ºC

On examination, there is dried blood around the patient's mouth. Ecchymoses are noted on his arms and abdomen. There is melaena per rectum. There are no signs of chronic liver disease.

Blood tests:

Hb	73 g/L	Male: (135-180)Female: (115 - 160)
Platelets	9 * 10 /L	(150 - 400)
WBC	8.2 * 10 /L	(4.0 - 11.0)
Na	137 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	38 u/L	(30 - 100)
ALT	27 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	38 g/L	(35 - 50)
Prothrombin time	11 seconds	(10-12)

Given the clinical history, what is the most appropriate choice of treatment to raise the platelet count?

A. Azathioprine
B. Intravenous immunoglobulin
C. Prednisolone
D. Rituximab
E. Romiplostin

B. Intravenous immunoglobulin

Human immunoglobulin (IVIG) is an alternative to steroids in treating ITP, particularly if the platelets need to be raised quickly

Intravenous immunoglobulin (IVIG) is correct. The patient presents with life-threatening bleeding and a platelet count of 9. The fastest way to increment the platelet count in ITP is with IVIG, which is indicated in cases of life-threatening bleeding. The expected response time is 1-3 days. In cases of life-threatening bleeding, platelets are typically given in addition.

Prednisolone is incorrect. This is the typical first-line treatment for ITP. However, in cases of lifethreatening bleeding and where the platelet count needs to be incremented quickly, IVIG is more effective. The expected response time is 4-14 days.

Rituximab is incorrect. This is used in refractory cases and takes between 7-56 days to raise the platelet count. It would not be used in the first instance.

Azathioprine is incorrect. This can be used as a steroid-sparing agent in ITP but it takes between 30-90 days to work and would therefore not be used in an emergency such as this case.

Romiplostim is incorrect. This is a fusion protein that activates the thrombopoietin (TPO) receptor and increases platelet production. It takes between 5-14 days to raise the platelet count

Question 19 of 191

A 36-year-old female was referred to the outpatient haematology clinic having been referred by her GP with a falling white cell count. Eight weeks ago she saw her own GP complaining of feeling continuously tired after a viral upper respiratory illness two weeks prior to the onset of her symptoms. She also complained of feeling generally unwell and of having intermittent pains in all her joints and muscles without swelling or stiffness. Her respiratory symptoms had fully resolved and she denied any night sweats or weight loss. Her GP organised a set of screening blood investigations which revealed a white cell count of 2.6 *10^9 g/dl (neutrophil count 2.0 *10^9 g/dl). This was repeated on two further occasions over the next four weeks revealing results of 2.2 and 1.9 respectively (neutrophil counts of 1.5 *10^9 g/dl and 1.2 *10^9 g/dl respectively). Her past medical history included hypothyroidism for which she was treated with levothyroxine 150mcg OD.

Examination at the clinic revealed the presence of a systemically well female. Her blood pressure was 118/74 mmHg, heart rate 82 bpm, respiratory rate 16/min and temperature 36.6ºC. Examination of her cardiovascular system was unremarkable. Similarly, examination of her gastrointestinal system was unremarkable, with no organomegaly identified. No cervical, axillary or inguinal lymph nodes were palpable. Examination of her ENT system was unremarkable.

Initial investigations at the clinic revealed the following results:

Hb	122 g/l
WCC	2.0 * 10 /l
Neutrophils	1.3 * 10 /l
Lymphocytes	0.6 * 10 /l
Monocytes	0.1 * 10 /l
Platelets	224 * 10 /l
Blood film	Neutropaenia
B12	224 (NR 160-900 ng/l)
ESR	15 mm/hr
CRP	9 mg/l
TSH	0.35 (NR 0.4-3.6mu/ml)
FT4	11.6 (NR 4.5-13.6 mcg/dl)
Monospot test	Negative
CMV serology	Negative

What is the single most appropriate management option?

A. Organise bone marrow aspirate and biopsy
B. Organise peripheral blood flow cytometry analysis
C. Repeat full blood count in four weeks
D. Organise CT neck, thorax, abdomen and pelvis
E. Organise blood cytogenetic analysis

C. Repeat full blood count in four weekssss

This is a very common scenario seen in the haematology outpatient clinic. This patient most probably has transient myelosuppression secondary to a viral infection with post viral fatigue and malaise. Although she is symptomatic, she is systemically well and there are no other red flag symptoms or signs including the presence of lymphadenopathy and splenomegaly. Her neutrophil count has been falling but it has remained above 1 and she is not febrile or septic. Her neutrophil count is beginning to improve (albeit very slowly) and therefore a repeat FBC would be justified to ensure that it does return to normal. If it remains low further investigation would be justified.

Question 20 of 191

You are asked to review a 74-year-old man on the haematology ward. He complains of widespread bruising and bleeding gums. He has a past medical history of myelodysplasia. He has required 6 red cell transfusion and 5 platelet transfusions in the past 12 months.

Blood results are as follows:

Hb	95 g/l
Platelets	8 * 10 /l9
WBC	4.2 * 10 /l9

You decide to transfuse him 1 unit of platelets. A repeat blood test the following day is reported below:

Hb	92 g/l
Platelets	12 * 10 /l9
WBC	3.8 * 10 /l9

What investigation will you order next?

A. Anti HLA antibodies
B. Platelet Factor 4 Antibody
C. Von Willebrand factor (vWF) levels
D. Lupus anticoagulant
E. Anti-β2 glycoprotein

A. Anti HLA antibodies

HLA-matched platelets and single-donor platelets are used for individuals that are refractory to platelet transfusions and have developed anti-HLA or antiplatelet antibodies

Platelet refractoriness is a failure to obtain a satisfactory response to a platelet transfusion on two or more occasions. An unsatisfactory response is defined by a platelet rise of less than 10 * 10 /l. When a patient does not have a satisfactory response to a platelet transfusion it is important to establish exactly why this has occurred. There are many mechanisms which can play a role including both immunological (e.g. alloimmunisation) and non-immunological (e.g. splenomegaly, DIC and sepsis).

This patient has had multiple previous platelet transfusions, making alloimmunisation high up in the differential. It is therefore important to check for anti-HLA or antiplatelet antibodies. HLAmatched platelets and single-donor platelets are used for individuals that are refractory to platelet transfusions and have developed anti-HLA or antiplatelet antibodies.

Platelet Factor 4 (PF4) antibodies are checked when heparin induced thrombocytopenia is suspected.

Anti-β2 glycoprotein and lupus anticoagulant are checked when antiphospholipid syndrome is suspected.

Question 21 of 191

The hospital is running low on its stock of cytomegalovirus (CMV) seronegative blood products. All the blood products are routinely leuko-depleted to reduce the risk of transferring CMV. You are asked to prioritise patients for CMV seronegative blood.

From the following options, which patient is the highest priority?

A. Patient having post-partum haemorrhage after delivery of twins
B. Patient on high dose oral steroids for temporal arteritis
C. Patient with HIV with CD4 count 50, not on anti-retroviral therapy
D. Patient with acute myeloid leukaemia who is planned for haematopoietic stem celltransplant next week
E. Patient with previous CMV pneumonitis

D. Patient with acute myeloid leukaemia who is planned for haematopoietic stem celltransplant next week

The use of CMV-seronegative blood products is reserved for CMV-seronegative individuals that are likely to proceed to haematopoietic stem cell transplant, or neonates

The correct answer is patient 4 who is planning for a haematopoietic stem cell transplant. The patient with the post-partum haemorrhage and the patient with severe anaemia secondary to upper GI bleed both require emergency transfusion but do not require CMV negative blood.

Other patients that should receive CMV-negative blood are neonates and pregnant women (other than during delivery). Blood from a patient who is seropositive for CMV is potentially infectious to the recipient due to either infectious virus in the plasma or latent virus in the monocytes in the blood. Blood products are leuko-depleted to remove the white blood cells to reduce the risk of transmission via monocytes. The use of seronegative blood has a lower risk of transfer to CMV but there is still a possible risk of transmission, as the antibodies take time to become positive after the donor has been infected.

Post-partum haemorrhage: pregnant women should be given seronegative blood if possible during pregnancy to prevent CMV infection of the fetus. This does not apply during or after delivery because there is no risk to the fetus, so this patient would not require seronegative blood.

High-dose oral steroids: this patient does not require seronegative blood because immune suppression is not an indication for seronegative blood products.

HIV infection is not an indication for seronegative blood products even in advanced untreated disease.

Previous CMV pneumonitis: this patient has already been infected with CMV and therefore does not require seronegative blood products.

Question 22 of 191

A 23-year-old man presents with diffuse bruising, abdominal pain, and loss of appetite. He feels unwell and has no history of taking any medications, does not use dietary supplements, and does not use illicit drugs. His past medical history is negative for any prior illnesses or hospitalisations. No family history of any bleeding disorders.

On examination, he has a heart rate of 115 bpm with a blood pressure of 130/75mmHg. His respiratory rate is 18 breaths per minute and he is afebrile with a temperature of 37.2ºC. His abdominal exam demonstrates rebound tenderness in the right lower quadrant.

Investigations:

Hb	13.7 g/L	(135-180)
Platelets	48 * 10 /L $_9$	(150 - 400)
WBC	5 * 10 /L $_9$	(4.0 - 11.0)
Haematocrit	41%	(41-50%)
INR	1.1	(0.9-1.2)
Fibrinogen	2.2 g/L	(2 - 4)

A diagnosis of acute appendicitis is made and the general surgical team decides that the patient needs to be taken to theatre for an urgent laparoscopic appendectomy.

What is the next best step in his management?

A. Antithymocyte globulin plus ciclosporin
B. Give intravenous glucocorticoid
C. Haematopoietic stem cell transplant
D. Start intravenous human immunoglobulin
E. Urgent platelet transfusion

D. Start intravenous human immunoglobulin

Human immunoglobulin (IVIG) is an alternative to steroids in treating ITP, particularly if the platelets need to be raised quickly

Primary immune thrombocytopenia (ITP, also called idiopathic thrombocytopenic purpura, immune thrombocytopenic purpura) is acquired thrombocytopenia caused by autoantibodies against platelet antigens leading to platelet destruction and platelet underproduction that is not triggered by an apparent associated condition. The likely diagnosis is ITP here as the patient has normal white cell counts and haemoglobin, no other causes of coagulopathy with normal PT/INR, no family history of bleeding disorder and clinically no organomegaly.

IVIG can raise the platelet count within 12 to 24 hours in many patients with ITP; this effect is reproducible enough that a platelet count response to IVIG has been used as a diagnostic criterion for ITP. The effect of IVIG usually persists for two to six weeks. Thus, IVIG is most useful for patients who require a rapid, temporary increase in platelet count (for urgent management of bleeding associated with thrombocytopenia or before an urgent invasive procedure) or those who are unable to tolerate glucocorticoids and are awaiting initiation of second-line therapy.

IV glucocorticoid therapy is incorrect as it's not preferred therapy in this situation where there is a need for urgent surgery. IVIG may be used either as an adjunct to other therapies in an individual with critical bleeding or need for urgent surgery or as an alternative to glucocorticoids in patients with severe bleeding.

Urgent platelet transfusion will be an ineffective treatment in immune (idiopathic) thrombocytopenic purpura especially when planning for immediate surgery as it is controversial, as transfused platelets are short-lived and platelet transfusion has been linked to arterial thrombosis and mortality in platelet consumptive disorders like ITP.

Antithymocyte globulin plus ciclosporin is not the right option for treatment here as it is used in immune-mediated aplastic anaemia.

Haematopoietic stem cell transplant is not applicable in this situation as it is the best treatment for young patients with aplastic anaemia with the best match available.

Question 23 of 191

A 56-year-old woman presents with lethargy and vomiting to her GP. She is normally fit and well. Blood tests and a urine sample are sent.

Hb	110 g/L /L 9	Female: (115 - 160)
Platelets	160 * 10 /L 9	(150 - 400)
WBC	5 * 10 /L 9	(4.0 - 11.0)
Na +	132 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	11.1 mmol/L	(2.0 - 7.0)
Creatinine	140 µmol/L	(55 - 120)
Calcium	3.0 mmol/L	(2.1-2.6)
Phosphate	1.2 mmol/L	(0.8-1.4)
Magnesium	0.8 mmol/L	(0.7-1.0)

Urine electrophoresis is positive for Bence Jones protein.

Given the likely underlying diagnosis, what imaging is recommended to assess for bony involvement?

A. DEXA scan
B. Isotope bone scan
C. No imaging required at diagnosis
D. Whole body MRI
E. X-rays of spine and pelvis

D. Whole body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

The presence of hypercalcaemia, acute kidney injury and Bence Jones proteins in the urine is highly suggestive of a diagnosis of multiple myeloma. In their 2016 guidelines, NICE recommends whole-body imaging at diagnosis of multiple myeloma to assess for bony involvement. They recommend whole-body MRI as first line. Whole-body CT or positron emission tomography (PET) scans can be used as alternatives if MRI is inappropriate or unavailable. The other options are not recommended as first-line imaging modalities in this circumstance by NICE.

A DEXA scan is used in combination with a FRAX tool assessment to assess for future fracture risk in patients with known or suspected osteoporosis.

Nuclear medicine scans such as an isotope bone scan are not recommended as first-line imaging in this situation. Some indications for isotope bone scans include investigating for Paget's disease, osteomyelitis or in primary bone malignancies.

In their 2016 guidelines, NICE recommends whole-body imaging at the time of diagnosis of myeloma to assess for bony involvement.

X-rays can show typical lytic lesions associated with bony involvement in myeloma. However, Xrays are inadequate to exclude bony involvement and are therefore not recommended as first-line imaging in this circumstance.

Question 24 of 191

A 43-year-old man with acute pancreatitis is being treated in the surgical ward. Whilst an inpatient, he experiences recurrent epistaxis, gingival bleeding, and haematuria.

He is re-examined and multiple petechiae are noted as well as some mild confusion. He is somewhat hypotensive when observations are recorded.

Blood tests are taken:

Platelets	83 * 10 /L 9	(150 - 400)
Prothrombin time (PT)	26 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	48 secs	(25-35 secs)
Fibrinogen	0.3 g/L	(2 - 4)

As well as general resuscitation, what else is most useful, first-line?

A. Cryoprecipitate
B. Fibrinogen concentrate
C. Fresh frozen plasma
D. Platelet transfusion
E. Tranexamic acid

C. Fresh frozen plasma

In bleeding patients with DIC and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT), administration of fresh frozen plasma (FFP) may be useful

This patient has developed disseminated intravascular coagulation (DIC), a syndrome characterised by coagulation pathway activation, leading to intravascular thrombi and depletion of platelets and coagulation factors. It is triggered by an underlying condition - in this scenario, acute pancreatitis. As well as treatment of the underlying disorder, the most useful additional option here is **fresh frozen plasma**. This is the preferred method of replacing coagulation factors when bleeding is present or when fibrinogen levels are low.

Cryoprecipitate is a second-line alternative. Fresh frozen plasma is still preferred with regards to DIC.

Similarly, **fibrinogen concentrate** may be used as second-line alternatives. However, fresh frozen plasma is the first-line choice for DIC.

Platelet transfusion is generally considered when the platelet count is less than 20 * 10 /L, or less than 50 * 10 /L in the presence of active bleeding. In this scenario, therefore, this is not as important a consideration as the administration of fresh frozen plasma.

Tranexamic acid may be used in the management of chronic DIC, under specialist guidance. It should be used with extreme caution as it inhibits fibrinolytic pathways, which may worsen thrombosis. In the acute setting, such as this scenario, it does not play a role.

Question 25 of 191

A 23-year-old man presents to the emergency department acutely unwell for the last 72 hours. He has been fatigued for the last month and has been having night sweats and has had several colds. Over the last 3 days, he has become more unwell, shivery and vomiting. He has noticed bruising on forearms and thighs. On examination, he is drowsy and has a temperature of 38.5ºC. His blood pressure is 90/50 mmHg, heart rate 120/min. He is peripherally shut down with a cap refill time of 5 seconds. He has conjunctival pallor. He is given IV fluids and antibiotics by the emergency department. His blood results show:

Hb	89 g/l
Platelets	43 * 10 /l
WBC	13.0 * 10 /l
Neutrophils	9.0 * 10 /l
D-Dimer	5.8mg/L (<0.5)
INR	8.5
PT	89 seconds (9-12)
APTT ratio	1.7 (0.8-1.2)
Fibrinogen	0.1g/L (1.5 - 4.5)
Blood film	Faggot cells seen

Na	138 mmol/l
K	5.8 mmol/l
Urea	18 mmol/l
Creatinine	195 µmol/l
CRP	170 mg/l

Bilirubin	8 µmol/l
ALP	102 u/l
ALT	300 u/l
Albumin	38 g/l

He is transferred to ITU for ionotropic support. He is treated with fresh frozen plasma which corrects his coagulopathy. Haematology is involved and he has a bone marrow analysis performed. Cytogenetics shows a translocation of chromosomes 15 and 17. ***What is the appropriate treatment to give***?

A. All-trans retinoic acid
B. R-CHOP
C. Chlorambucil
D. High dose prednisolone
E. Ribavirin

A. All-trans retinoic acid

This patient has acute promyelocytic leukaemia (M3 subclass). This can present with DIC in young patients the prolonged prothrombin time, with platelets consumption and low fibrinogen. Faggot cells are hypergranular promyelocytes, so called because the high concentrations of Auer rods in the cytoplasm give the cells a bundle of sticks appearance. The gene translocation of 15:17 results in a fusion gene of PML:RARa (retinoic acid receptor). The exact process by which this gene fusion results in AML is unclear but the condition responds well to retinoic acid therapy hence this is the correct answer here. The other options are for other types of haematological malignancy.

Question 26 of 191

A 37-year-old woman was admitted to the Intensive Care Unit (ICU) two days following chemotherapy. She had received her third of six cycles of chemotherapy for malignant ovarian cancer and without initial complication and was discharged the same day. Two days later she felt unwell and developed a fever. After liaising with the oncology unit she was admitted directly to the Medical Admission Unit. A full septic screen was conducted and she was treated empirically for neutropaenic sepsis with intravenous tazocin and gentamicin. Other than malignant ovarian cancer her past medical history was unremarkable, and there was no known metastasis. She was not taking any other drug therapy and was a non smoker. She did not consume alcohol.

Unfortunately whilst on the Medical Admission Unit she continued to deteriorate, developing fluctuating hemiparesis of initially the left lower limb, and then the right upper limb. Her level of consciousness dropped and her speech had become slurred. An urgent transoesophageal echocardiogram and CT head scan was conducted, pending availability of a MRI scan. She was promptly transferred to the Intensive Care Unit.

Upon arrival at the ICU she appeared very unwell, with a GCS of 12/15. Her blood pressure was 188/96 mmHg, her heart rate was 112, her respiratory rate was 22/min and her temperature was 38.5 degrees celsius. Examination of the cardiovascular system revealed the presence of normal heart sounds, a JVP of 3cm and warm well perfused peripheries. Examination of the respiratory system revealed good air entry in both lungs, with an oxygen saturation of 95% on air. Examination of her gastrointestinal system was unremarkable. Examination of her neurological system revealed localization to pain stimulus, with confusion and eye opening only in response to verbal prompting. Her speech was slurred. There was no other apparent focal neurological deficit, with otherwise normal cranial nerve and peripheral nervous system testing.

The results of the investigations conducted are as follows:

Hb	89g/l
Platelets	38 * 10 /l
WBC	15.2 * 10 /l
Reticulocyte count	4% (ie above normal range)
Blood film	presence of schistocytes, normocytic normochromic anaemia

Na	136 mmol/l
K	6.1 mmol/l
Urea	10.1 mmol/l
Creatinine	154 µmol/l
CRP	22 mg/l
ESR	45 mm/hr
Protein	78 g/l
Albumin	36 g/l
Adj calcium	2.42 mmol/l
Phosphate	0.95 mmol/l
Bilirubin	44 µmol/l
ALT	39 u/l
LDH	1286 u/l
ALP	102 u/l
PTT	14s
APTT	44s
INR	1.1
D-dimer	136 ng/ml

Chest x-ray: normal heart and lung appearances

ECG: heart rate 107bpm normal sinus rhythm, normal QRS and QTc intervals Urinalysis: proteinuria ++, haematuria +, leuc/nit/glu negative

Blood MCS x3: pending result Urine MCS: pending result

CT head: no space occupying lesion, mass shift or intracerebral haemorrhage seen Transoesophageal echocardiogram: normal systolic function, normal appearance of all valves, no evidence of vegetation seen

In the context of the likely underlying diagnosis, what is the best immediate management step?

A. Commence immediate plasma exchange
B. Commence high dose intravenous hydrocortisone
C. Commence platelet infusion
D. Commence IV meropenem and IV antifungal therapy
E. Commence fresh frozen plasma infusion

A. Commence immediate plasma exchange

This patient has developed thrombotic thrombocytopaenia purpura (TTP) secondary to chemotherapy, as manifested by the combination haemolytic anaemia, thrombocytopaenia and acute renal impairment. The presence of a fever and neurological involvement differentiates this condition from haemolytic-uraemic syndrome. Of the above options, plasma exchange holds the best prognosis for this condition and is, therefore, the best option to be initiated without delay, but in practice glucocorticoids and fresh frozen plasma infusions are often given pending arranging plasma exchange.

Question 27 of 191

A 22-year-old man with sickle cell disease is seen in the Emergency Department. He has had worsening pain in his arms and legs for the last 2 days and 5 hours ago developed a painful sustained erection.

He has felt otherwise well recently and has no other past medical history. He is on regular paracetamol, ibuprofen, folate and penicillin. He does not receive regular transfusions and has been admitted with a crisis only once before. He has never had an episode of painful sustained erection.

On examination he has a heart rate of 110 beats per minute and a blood pressure of 132/95 mmHg. His oxygen saturations are 96% on room air and he is afebrile. His chest is clear and abdomen is soft. He has no swelling or erythema of his limbs, though they are generally tender. He continues to have an erection, though there is no sign of ischaemia.

His chest x-ray shows clear lung fields. His blood tests are as follows:

Hb	78 g/l	Na +	141 mmol/l
Platelets	331 * 10 /l 9	K +	3.7 mmol/l
WBC	9 * 10 /l 9	Urea	5 mmol/l
Neuts	7 * 10 /l 9	Creatinine	86 µmol/l
Lymphs	1.6 * 10 /l 9	CRP	14 mg/l

He is treated with intravenous fluids and generous analgesia with diamorphine. His limb pain is improved but he continues to have a painful erection.

What is the next most appropriate step

A. Adrenalin
B. Diethylstilbestrol
C. Exchange transfusion
D. Review by urologist
E. Sildenafil

D. Review by urologist

This gentleman has priapism, a sustained painful erection lasting 4 hours. If left untreated it can result in impotence. Current guidelines recommend initial conservative management with fluids and analgesia. Although any interventions beyond this have variable results, evidence supports prompt urology review to determine the need for surgical management including drainage. There is insufficient evidence to recommend routine exchange transfusions. Sildenafil, diethylstilbestrol and adrenalin may be used in consultation with urology but evidence of benefit is variable.

Question 28 of 191

A 23 year old male of Nigerian descent is referred from the ED with acute shortness of breath associated with fever and dry cough. His shortness of breath has limited him to an exercise tolerance of around 10 yards. He also complains of excruciating right sided chest pain. He is known to have sickle cell anaemia and has had no admissions to the hospital in the last 3 years.

Observations

- heart rate 94bpm regular
- blood pressure 112/74 mmHg
- temperature 38.3
- respiratory rate 22
- urine output under 30ml/hr oxygen saturations 93% on room air

Examination

respiratory system shallow breathing, bronchial breath sounds with crepitations to right base

Blood results:

Hb	7.7 g/dl
Platelets	200 * 10 /l9
WBC	13.2 * 10 /l9
Bilirubin	36 µmol/l
Urea	8.2 mmol/l
Creatinine	146 µmol/l

What is the most important initial steps in management?

A. Oxygen, IV fluids, antibiotics and analgesia
B. 2 unit blood transfusion and analgesia
C. Oxygen and analgesia only
D. Antibiotics and IV fluid only
E. Plasmapheresis and analgesia

A. Oxygen, IV fluids, antibiotics and analgesia

It is important to recognise and treat sickle cell crises (as detailed above) as a matter of urgency. This condition can be quickly fatal. This patient should be treated as per sepsis guidelines. It is crucial to adequately control the pain in this patient cohort as not being able to inhale deeply due to pain will only serve to worsen the lung damage. Early assessment for the involvement of the critical care team is required as acute respiratory distress syndrome is a real possibility. Oxygen saturation levels should be maintained above 95% in a patient where a normal steady state level is not known. Management of this and the haemaglobin level should be specific for the patient and compared to past levels. The question states that the patient has had no admissions to the hospital in the last 3 years and as such the aim should be to keep oxygen saturations above 95%.

Question 29 of 191

A 64-year-old female undergoing chemotherapy treatment with mitomycin for bladder cancer presents to the Emergency Department with confusion, epistaxis and a widespread rash. On examination, she is febrile and has a diffuse petechial rash.

Hb	10.6g/dl
Platelets	54 * 10 /l9
WBC	11.2 * 10 /l9
Urea	11mmol/l
Creatinine	117µmol/l
Bilirubin	58µmol/l
ALP	42u/l

A blood film shows fragmented erythrocytes.

What is the most appropriate treatment for this patient?

A. Renal dialysis
B. Supportive treatment
C. A pool of platelets and fluid resuscitation
D. Urgent plasma exchange
E. IV tazocin, a pool of platelets and fluid resuscitation

D. Urgent plasma exchange

Thrombotic thrombocytopenic purpura (TTP) is characterised by fluctuating neurological signs, fever, renal dysfunction, microangiopathic haemolysis and thrombocytopenia. The key to diagnosis is differentiating between TTP and haemolytic-uraemic syndrome (HUS). The presence of neurological signs in TTP and more severe renal dysfunction in HUS usually helps in distinguishing the two.

Congenital TTP is caused by a deficiency in von Willebrand factor. However, the majority of cases are secondary and can occur in pregnancy, HIV and associated with some drugs. In particular, the chemotherapeutic agents mitomycin C, bleomycin, tamoxifen and gemcitabine are all associated with secondary TTP. Other drugs in association include penicillin, rifampicin and mmunosuppressive drugs eg. ciclosporin A.

The standard treatment for TTP is IV plasma exchange which should be initiated as soon as possible.

Question 30 of 191

A 22-year-old man attends the emergency department with a group of friends from a university party. He complains of worsening shortness of breath and light-headedness. He appears panicked and is clutching his chest. There is no past medical history of note and he has no allergies.

His observations are as follows:

- Temperature 36.2ºC
- Heart rate 112 beats/min
- Blood pressure 120/75mmHg
- Respiratory rate 24 breaths/min
- Oxygen saturations 90% on air

On examination, his lips are cyanosed. His chest is clear with good air entry bilaterally and his heart sounds are normal. Peripheral pulses are present with a capillary refill of <2 seconds and his calves are soft and non-tender.

Arterial blood gas:

pH	7.21	(7.35 - 7.45)
pO_2	12.1 kPa	(11 - 14.4)
pCO_2	2.4 kPa	(4.6 - 6.4)
Bicarbonate	16 mmol/L	(22 - 29)
Chloride	100 mmol/L	(95 - 108)
Lactate	1.2 mmol/L	(0.5 -2.2)
Glucose	5.6 mmol/L	(4 - 7)

Given the likely diagnosis, which of the following is the most appropriate next step in the management of this patient?

A. Fomepizole
B. Hyperbaric oxygen
C. Methylene blue
D. Thrombolysis
E. Intravenous 1.26% sodium bicarbonate

C. Methylene blue

Methylene blue can be used to treat methaemoglobinaemia. It causes a reduction of Fe3+ (ferric) to Fe2+ (ferrous)

This patient has methaemoglobinaemia, likely secondary to drug misuse (e.g. amyl nitrite poppers) at a party. In patients with methaemoglobinaemia, haemoglobin has been oxidised from Fe^{2}+ to Fe^{3}+. This oxidised form of haemoglobin cannot bind to oxygen and therefore symptoms include cyanosis, shortness of breath and headache. In more severe illnesses, investigations may detect metabolic acidosis and arrhythmias. During methaemoglobinaemia, a normal PO may be seen with reduced oxygen saturations, similar to this patient. The treatment of choice for methaemoglobinaemia is intravenous methylene blue, which causes a reduction reaction to convert Fe^{3}+ back to Fe^{2}.

Fomepizole is used in the treatment of ethanol toxicity. Symptoms of ethanol toxicity are initially similar to alcohol excess with confusion, slurred speech and altered gait. Metabolic acidosis and acute kidney injury follow. However, ethanol toxicity does not explain this patient's hypoxia and cyanosis and is less likely to be correct.

Hyperbaric oxygen therapy is used in the treatment of carbon monoxide poisoning. Unlike methaemoglobinaemia, symptoms of carbon monoxide poisoning include headache, confusion and nausea and vomiting. Respiratory symptoms are less predominant compared to methaemoglobinaemia. Carbon monoxide poisoning tends to produce a normal oxygen saturation level with a low PO , unlike this patient. It also does not explain this patient's metabolic acidosis and suggests an alternative diagnosis.

Thrombolysis would be an option for the treatment of a thrombotic cause of this patient's symptoms (e.g. pulmonary embolism). However, patients with a pulmonary embolism are more likely to have a metabolic alkalosis secondary to hyperventilation, in contrast to this patient with metabolic acidosis.

Sodium bicarbonate can be used to treat severe metabolic acidosis. However, it is not used firstline in the treatment of methaemoglobinaemia and the priority should be to reverse the oxidation process of haemoglobin..

Question 31 of 191

A 33-year-old patient presents to the emergency department feeling very lethargic and tired over the last week. He has been increasingly short of breath on exertion and his exercise tolerance has fallen to a few hundred yards before he is out of breath. He is a known sickle cell disease patient who is managed by the Haematology team in your hospital. On examination he is afebrile and heart rate and blood pressure are within normal limits. His respiratory rate is 16/min and his oxygen saturation is 98% on air. He does become noticeably short of breath on minimal movement.

His blood tests show:

Hb	65 g/l
Platelets	46 * 10 /l
WBC	2.5 * 10 /l
Neuts	1.2 * 10 /l
Haptoglobins	1.9 g/L (0.3-2.0)
Reticulocytes	8.9 x10^9/L (25-80)
Na	136 mmol/l
K	3.9 mmol/l
Urea	7.4 mmol/l
Creatinine	78 µmol/l
CRP	<3 mg/L(<10)
LDH	200 IU/L (200-500)
Bilirubin	4 µmol/l
ALP	89 u/l
ALT	34 u/l
Albumin	39 g/l

His chest x-ray is normal.

On further questioning, he tells you that his 5-year-old daughter was unwell 3 weeks ago. He took her to see the GP and was told it was likely to be a viral illness.

What is the most likely cause for his blood results as shown?

A. Parvovirus B19
B. Acute chest crisis
C. Splenic sequestration
D. HIV
E. Legionella pneumoniae

A. Parvovirus B19

This gentleman has had an aplastic sickle cell crisis as a result of parvovirus infection. He has symptomatic anaemia. There is nothing to suggest splenic sequestration and he is too well for an acute chest syndrome. The normal chest x-ray is not in keeping with a pneumonia. HIV is a possibility but less likely given the clinical picture.

Question 32 of 191

A 79-year-old woman has been referred to the clinic due to weight loss, right-sided chest pain, lower back pain, and general fatigue.

Hb	96 g/L	Male: (135-180)Female: (115 - 160)
Platelets	399 * 10 /L 9	(150 - 400)
WBC	10.2 * 10 /L 9	(4.0 - 11.0)
Na +	145 mmol/L	(135 - 145)
K +	4.5 mmol/L	(3.5 - 5.0)
Urea	15.2 mmol/L	(2.0 - 7.0)
Creatinine	190 µmol/L	(55 - 120)
Calcium	3.1 mmol/L	(2.1-2.6)
Phosphate	1.4 mmol/L	(0.8-1.4)
Magnesium	0.7 mmol/L	(0.7-1.0)

Urine Bence Jones: positive

She is usually fit and well with no past medical history.

What would be the first-line imaging to confirm the most likely diagnosis?

A. CT thorax, abdomen, and pelvis
B. Chest radiograph
C. PET CT
D. Skeletal survey
E. Whole-body MRI

A. Whole-body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

The most likely diagnosis here is multiple myeloma given the weight loss, bone pain, anaemia, renal impairment, and hypercalcemia.

Further tests should be sent to clarify this diagnosis including serum free light chains, serum protein electrophoresis, and immunoglobulins.

It is worth noting that guidance regarding the answer to this question may vary from hospital to hospital depending on availability, but national guidance recommends whole-body MRI as firstline imaging.

Whole-body MRI is the correct answer. Part of the diagnostic criteria for multiple myeloma is the presence of 1 or more osteolytic lesions of ≥5 mm. This is most sensitively picked up on MRI scanning, which can also pick up pre-lytic lesions that may be amenable to biopsy.

CT thorax, abdomen, and pelvis is incorrect. CT scanning has a lower sensitivity for osteolytic lesions. There is also higher radiation exposure.

PET CT is incorrect. This type of scanning can be helpful for looking at intramedullary involvement, but the consensus from current best evidence is that MRI is preferable particularly to identify osteolytic lesions.

Skeletal survey is incorrect. It is less sensitive and specific compared to PET CT and MRI scanning. This is the preferred option for patients who are unable to undergo whole-body MRI, PET CT, or CT. It takes less time to perform compared to whole-body MRI (25 minutes as opposed to 60 minutes).

Chest radiograph is incorrect. Although this is a sensible first-line test to perform in the acute setting, this question asks specifically about the first-line test for the most likely diagnosis here - multiple myeloma. Chest radiograph is therefore incorrect.

Question 33 of 191

A 23-year-old female has presented with her first episode of seizure on the labour ward, 2 days after delivering her first child by normal vaginal delivery. She reports a fluctuating generalised headache over the past 3 months but had not previously sought medical attention. In addition, she had spiked 2 fevers over 38ºC over the past 48 hours, with no dysuria, diarrhoea or vomiting, productive cough or signs of meningism. She has no past medical history, is a life-long nonsmoker and has been abstinent from alcohol for 9 months, previously drinking 4 units per week. Her seizure was witnessed and described as tonic-clonic jerking of all 4 limbs, associated with loss of consciousness, terminated after 4mg of intravenous lorazepam after 4 minutes. On examination, she appears post-ictal but responding to voice despite being sleepy. Pupils are reactive and equal. Plantars are downgoing bilaterally. Cardiovascular, abdominal and respiratory examinations are unremarkable. No skin rashes, neck stiffness or photophobia are noted.Her blood results are as follows:

Hb	75 g/l
MCV	87 fl
Platelets	23 * 10 /l9
WBC	9.2 * 10 /l9
Blood film	Schistocytes
Coombs' test	Negative
CRP	30 mg/l
Urea	12.6mmol/l
Creatinine	154 µmol/l
Bilirubin	28 µmol/l
ALP	98 u/l
ALT	28 u/l
γGT	23 u/l

A CT head with contrast demonstrated no areas of ischaemia, haemorrhage or space occupying lesion.

Which is the next most appropriate immediate management?

A. Plasma exchange
B. Intravenous 3rd generation cephalosporin antibiotics
C. Intravenous phenytoin loading
D. MRI head with contrast
E. Intravenous steroids

A. Plasma exchange

This young lady's blood tests demonstrated a normocytic anaemia associated with schistocytes (fragmented red cells) with negative Coombs' test, suggestive of mechanical destruction of red cells. In addition, thrombocytopaenia is present with renal impairment and normal liver function tests. The initial presentation is of first seizure and fluctuating headache, with two unexplained fevers. The pentad of fever, fluctuating neurological symptoms, microangiopathic haemolytic anaemia, thrombocytopaenia and renal impairment represents thrombotic thrombocytopaenic purpura-haemolytic uraemic syndrome spectrum (TTP-HUS), resulting in microvascular thrombus formation. There is little to suggest an underlying epilepsy syndrome and no indication for phenytoin loading after a single seizure without status epilepticus. While meningitis may cause headaches, a fluctuating 3-month history without meningism is unlikely.

Immediate treatment of TTP-HUS is reliant on plasma exchange without delay in order to remove the high-molecular weight von-Willebrand factor (vWF) driving platelet aggregation and replacing ADAMTS-13 protease, a cleavage enzyme of high molecular weight vWF often deficient in TTP patients, resulting in microvascular thrombi formation. High dose steroids may be appropriate in the setting of refractory disease despite plasma exchange but is an adjunct to plasma exchange, not in place of. Persistent recurrent or refractory TTP-HUS despite plasma exchange and steroids should be considered for the addition of rituximab or increased frequency of plasma exchange. TTP-HUS is a medical emergency and invariably results in death secondary to progressive renal failure if not treated immediately.

Question 34 of 191

A 22-year-old man presents to the emergency department with shortness of breath. He takes no regular medicines and denies the use of herbal, or over-the-counter medications. However, he does admit to using amyl nitrites recreationally.

Observations are as follows: heart rate 125 beats per minute, respiratory rate 24 breaths per minute, blood pressure 125/75 mmHg, temperature 37.2 ºC, and SpO2 92%. His chest is clear on auscultation.

He is started on 15L O2 via a non-rebreather mask. Blood gas analysis results are as follows:

pH	7.26	(7.35 - 7.45)
PaO2	72.4 kPa	(10.3 - 13.3 kPa)
PaCO2	2.9 kPa	(4.7 - 6 kPa)
HCO3	18 mmol/L	(22 - 28 mmol/L)
SaO2	48%	(94 - 98%)
Lactate	3.2 mmol/L	(<1.0)

What treatment is indicated?

A. Ascorbic acid
B. Dicobalt edetate
C. Hydroxocobalamin
D. Hyperbaric oxygen
E. Methylthioninium chloride

A. Methylthioninium chloride

Methylene blue can be used to treat methaemoglobinaemia. It causes a reduction of Fe3+ (ferric) to Fe2+ (ferrous)

The striking feature, in this case, is the significant discrepancy between the PaO2 and SaO2 on arterial blood gas analysis.

Given the patient is on 15L O2, the PaO2 is at a level expected indicating that gas exchange at the level of the alveoli is not impaired. There are various formulas for predicting the expected PaO2 for any given inspired O2 concentration. The Advanced Life Support (ALS) guidelines suggest that the PaO2 for any given inspired concentration should be approximately 10 less than the inspired concentration (%). For example, in this case, 15L O2 is equivalent to approximately 80-85% so we would expect the PaO2 to be around 70 kPa.

However, it is important to note that the SaO2 (oxygen saturation of haemoglobin) is markedly low at 48% indicating impaired oxygen binding to haemoglobin. It is also important to note that the peripheral SpO2 is 92% which is clearly discrepant with the SaO2.

The two main causes of this picture are methaemoglobinaemia and carboxyhaemoglobinaemia. Because standard pulse oximeters are not capable of differentiating between different forms of bound haemoglobin, the SpO2 is usually falsely high in these conditions.

Tissue hypoxia can be a consequence of 4 main causes:

1. Hypoxaemia (low PaO2 due to poor gas exchange at the alveoli)

2. Toxic haemoglobin (low SaO2 due to methaemoglobinaemia or carboxyhaemoglobinaemia)

3. Perfusional (e.g. shock, or localised causes such as compartment syndrome or bowel

ischaemia)

4. Severe anaemia

Regardless of the cause, tissue hypoxia will result in lactic acidosis. Therefore, in patients with lactic acidosis, all the aforementioned causes should be considered. The patient in this case most certainly has lactic acidosis as a consequence of toxic haemoglobin-induced tissue hypoxia. He is acidotic with low serum bicarbonate since this acts as a buffer for lactic acid.

Methylthioninium chloride is correct. The patient has a diagnosis of acquired methaemoglobinaemia. As discussed above, the biochemical results are suggestive of toxic haemoglobin. The history of nitrate exposure favours the diagnosis of acquired methaemoglobinaemia. The treatment of choice is IV methylthioninium chloride (methylene blue).

Ascorbic acid is incorrect. This drug can be used to treat congenital methaemoglobinaemia. Although this remains within the differential diagnosis, the absence of previous episodes and the presence of a known risk factor (e.g. nitrate exposure) favours the acquired form.

Dicobalt edetate and **Hydroxocobalamin** are incorrect. These drugs can be used to treat cyanide poisoning. Cyanide binds the ferric (Fe3+) ion of cytochrome oxidase causing 'histotoxic hypoxia' and lactic acidosis. It would not cause a marked reduction of SaO2 as seen in this case unless it was associated with coexistent carbon monoxide poisoning (e.g. due to smoke inhalation). There is nothing in this clinical case to suggest that this is the case.

Hyperbaric oxygen is incorrect. This can be used to treat severe carboxyhaemoglobinaemia.

Although carbon monoxide poisoning presents similarly and remains within the differential diagnosis, the history of nitrate exposure favours the diagnosis of methaemoglobinaemia.

Question 35 of 191

A 31-year-old lady presents to the emergency department with abdominal pain.

Her medical and surgical history is unremarkable other than mild depression and hay fever. Medications include paroxetine and PRN loratadine.

She complains of generalised colicky abdominal pain and has vomited once in the department.

On examination blood pressure is 155/86mmHg, heart rate is 95bpm and temperature is 37.9ºC. Digital rectal examination reveals hard stool in the rectum.

Investigations reveal:

Hb	131 g/l
Platelets	362 * 10 /l9
WBC	7.3 * 10 /l9
Na +	121 mmol/l
K +	3.3 mmol/l
Urea	6.2 mmol/l
Creatinine	87 µmol/l
Urine dipstick	protein ++, leucocytes ++

What is the most likely diagnosis?

A. Cholecystitis
B. Acute porphyria
C. Intestinal obstruction
D. Pyelonephritis
E. Systemic lupus erythematosus

B. Acute porphyria

The normal white cell count make infective diagnoses such as pyelonephritis and cholecystitis less likely. Intestinal obstruction usually presents with an empty rectum.

The history of neuropsychiatric symptoms along with hypertension and hyponatraemia are suggestive of acute porphyria.

Systemic lupus erythematosus doesn't tend to present with abdominal pain.

Question 36 of 191

A 34-year-old woman is rushed to the emergency department by her husband. Her husband says that she has been lethargic for the last 2 days and this morning has become increasingly more confused and behaving differently to normal. She has no past medical history of note. She is 16 weeks pregnant.

On examination, she is febrile with a temperature of 38.5ºC. She is tachycardic with a heart rate of 125 bpm and has a blood pressure of 115/95mmHg. On auscultation, her chest is clear with normal heart sounds. Her abdomen is soft and non-tender with a palpable uterus in keeping with 16 weeks gestation.

Investigations:

Hb	92 g/L	Male: (135-180)Female: (115 - 160)
Platelets	43 * 10 /L 9	(150 - 400)
WBC	6.3 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	11.2 mmol/L	(2.0 - 7.0)
Creatinine	185 µmol/L	(55 - 120)
Bilirubin	32 µmol/L	(3 - 17)
ALP	35 u/L	(30 - 100)
ALT	85 u/L	(3 - 40)
Albumin	37 g/L	(35 - 50)
CRP	< 1 mg/L	(< 5)

Urinalysis: negative.

Pregnancy test: positive. What is the next immediate treatment for this patient?

A. Intravenous antibiotics
B. Intravenous immunoglobulin
C. Magnesium sulphate
D. Plasma exchange
E. Platelet transfusion

D. Plasma exchange

TTP - plasma exchange is first-line

The pentad of symptoms: AKI, fever, cerebral dysfunction, thrombocytopenia and microangiopathic haemolytic anaemia should point towards a diagnosis of thrombotic thrombocytopenic purpura (TTP). TTP is a serious condition that causes dysregulation of the clotting cascade. The underlying mechanism is not completely understood but a deficiency in the enzyme ADAMTS13 has been identified. If left untreated, TTP has a high mortality. Pregnancy is a known cause of TTP although it does not have to be present to make the diagnosis. If TTP is suspected, the first-line treatment of choice is plasma exchange. Plasma exchange removes any antibodies which inhibit ADAMTS13 whilst also replacing the functioning version of the enzyme. Steroids and rituximab have also been used to suppress the patient's immune system from producing enzymes to ADAMTS13.

Intravenous antibiotics are an appropriate consideration, given that this patient is febrile. In the absence of raised inflammatory markers, it seems more likely that fever is a symptom of TTP rather than an underlying infection. Nevertheless, even if given, antibiotic administration will not treat TTP.

Intravenous immunoglobulin is used in the treatment of refractory TTP. However, it is not the firstline treatment of choice.

Magnesium sulphate is used in the treatment of eclampsia. It is not used in the treatment of TTP.

Platelet transfusion is not recommended in TTP. Transfusion is associated with an increased risk of thrombosis and mortality.

Question 37 of 191

A 28-year-old man is admitted to the Medical Admissions Unit with a 2-day history of itching, right upper quadrant pain, and abdominal distension. The pain started as a dull ache but became constant and severe over the course of several hours.

His past medical history is remarkable only for a left lower limb DVT diagnosed at age 20. He takes no regular medications and he is a non-smoker. He drinks 2-3 units of alcohol per week and denies intravenous drug use.

Examination reveals a jaundiced young man with pale conjunctivae. He appears deeply uncomfortable. His abdomen is moderately distended with marked right upper quadrant tenderness. His liver and spleen are both palpable 2cm below the costal margin. Shifting dullness is demonstrable on percussion of the abdomen.

His blood results are as follows:

Hb	101 g/l	Na +	139 mmol/l	Bilirubin	109 µmol/l
MCV	102.4 fl	K +	4.2 mmol/l	ALP	284 u/l
Platelets	63 * 10 /l 9	Urea	6.7 mmol/l	ALT	684 u/l
WBC	12.9 * 10 /l 9	Creatinine	108 µmol/l	γGT	179 u/l
Neuts	10.8 * 10 /l 9	Albumin	27 g/l		
Lymphs	0.9 * 10 /l 9	LDH	759 u/l		

His abdominal ultrasound scan is consistent with hepatic vein thrombosis and the patient is started on low molecular weight heparin. Following a review by the Haematologists, a diagnosis of paroxysmal nocturnal haemoglobinuria is made and the patient is advised to start treatment with eculizumab.

Given the proposed treatment strategy, which of the following vaccinations should the patient be offered?

A. Hepatitis B
B. Neisseria meningitidis
C. Varicella zoster virus
D. Streptococcus pneumoniae
E. Haemophilus influenzae type b

B. Neisseria meningitidis

Eculizumab is a recombinant humanised monoclonal antibody that specifically binds to terminal complement protein C5. Patients with C5 deficiency are at elevated risk of serious meningococcal infections and all patients being treated with eculizumab should receive a quadrivalent vaccine against the meningococcal strains A, C, W, and Y

Question 38 of 191

A 32-year-old male presents with a progressive worsening non-specific lethargy. 9 months ago, he had returned from an active holiday from New Zealand and now feels lethargic to the point that he can no longer work in his job as a computer programmer. In this period, he has been treated for two deep vein thromboses with low molecular heparin, the first initially attributed to his return flight from New Zealand. He reports three episodes of rose coloured urine over the past 4 months and intermittent episodes of abdominal cramps that his GP had diagnosed to be irritable bowel syndrome.

On examination, you note mild conjunctival pallor and jaundiced sclera. Respiratory, cardiovascular and abdominal examinations are unremarkable. His blood results are as follows:

Hb	76 g/l
MCV	92 fl
Platelets	276 * 10 /l9
WBC	4.1 * 10 /l9
Reticulocytes	18%
Haptoglobin	2 (normal range 41-165 mg/dL)
LDH	2128 (normal range 140-280 units/L)
Coombs' test	negative at 4 and 37 degrees

What is the definitive treatment for the underlying condition?

A. Packed red blood cell transfusion

B. Anti-retroviral treatment
C. Bone marrow transplant
D. R-CHOP chemotherapy
E. Intravenous iron replacement

C. Bone marrow transplant

This is a tricky clinical scenario with a number of red herrings: a young man in his 30s has presented with recurrent DVTs, episodes of haematuria, abdominal cramps and a blood picture suggestive of intravascular haemolysis (low haptoglobin, raised LDH) not secondary to an autoimmune cause (Coombs negative): there is thus an underlying red cell fragility predisposing to thrombosis, strongly suggestive of paroxysmal nocturnal haemoglobinuria (PNH). Note that haemoglobinuria is not restricted to night-time alone. The majority of patients present in their 30s with thromboses being the most common cause of death.

PNH is caused by an underlying reduced CD 59 on the red cell surface, leading to increased susceptibility to complement lysis. Complications can present following the release of haemoglobin, such as pulmonary hypertension, dystonia and renal impairment while PNH can overlap with aplastic anaemia and myelodysplasia. PNH patients are managed by blocking complement lysis with eculizumab and red cell transfusions but the only curative solution is allogenic bone marrow transplantation.

Question 39 of 191

A 24-year-old female presents with severe abdominal pain. This is her fourth presentation this year. She was previously told that the abdominal pain was medically unexplained. On examination you note peripheral neuropathy of her lower limbs. Her blood pressure is 160/110 mmHg and heart rate 125 beats per minute.

Blood results are as follows:

Hb	115 g/l	Na^+	132 mmol/l
Platelets	468 * 10 /l 9	K^+	3.8 mmol/l
WBC	14.2 * 10 /l 9	Urea	8.6 mmol/l
Neuts	10.8 * 10 /l 9	Creatinine	72 µmol/l
Lymphs	1.6 * 10 /l 9	CRP	28 mg/l
Eosin	0.2 * 10 /l9		
Urine	Increased levels of delta aminolevulinic acid and porphobilinogen		

What treatment is indicated?

A. Dimercaprol
B. Penicillamine
C. Dimercaptosuccinic acid (DMSA)
D. Haem arginate
E. Supportive management

D. Haem arginate

IV haem arginate can be used to treat flares of acute intermittent porphyria

The clinical features and laboratory data are suggestive of acute intermittent porphyria (AIP). This is one of the hereditary hepatic porphyrias. Its inheritance is autosomal dominant. The deficient enzyme is porphobilinogen deaminase (PBGD). A deficiency of PBGD is not sufficient by itself to produce AIP, and other activating factors must also be present. These include hormones, drugs and dietary changes.

Hematin and heme arginate is the treatment of choice during an acute attack of AIP. Heme is not a curative treatment, but can shorten attacks and reduce the intensity of an attack.

Dimercaprol, penicillamine and dimercaptosuccinic acid (DMSA) can be used to treat lead toxicity. Lead toxicity can present similarly to AIP (e.g. abdominal pain and peripheral neuropathy). In lead poisoning we would expect increased urinary coproporphyrin.

Question 40 of 191

A 30-year-old woman presents to the emergency department with severe, progressive abdominal pain over the past day. The pain is accompanied by nausea, vomiting and diarrhoea. The patient recalls similar episodes in the past that progressed over a few days and lasted for a week. Temperature is 37°C, blood pressure is 140/100 mmHg, pulse is 120/min and respirations are 16/min.

On examination: minimal abdominal tenderness and rebound tenderness. She has a history of abdominal surgery for suspected appendicitis and biliary disease, neither of which was confirmed once inside the abdomen.

Which of the following will help to confirm the diagnosis?

A. Erythrocyte porphyrins
B. Faecal porphyrins
C. Plasma porphyrins
D. Urine porphobilinogen
E. Urine porphyrins

D. Urine porphobilinogen

In acute intermittent porphyria, urinary porphobilinogen is typically raised

This patient has acute intermittent porphyria, which classically presents with neurovisceral symptoms which can mimic an acute abdomen. This mimicry occurs because the abdominal pain is produced by a nerve problem rather than inflammation, hence why exploratory surgery is uneventful. In long-standing cases, patients may have damage to their motor nerves resulting in upper limb weakness.

Question 41 of 191

A 40-year-old woman of Mediterranean descent was found to be anaemic during a workup for fatigue. Past medical history includes hypothyroidism, which is currently well controlled on 125mcg levothyroxine, and hypertension for which she takes amlodipine 5mg.

She denies any recent weight loss or change in bowel habits and her periods remain regular and are no heavier than normal. Blood tests results showed:

Hb	85g/l	115-165g/l
MCV	60fL	79-95fL
Iron	32nmol/L	13-32nmol/l
Ferritin	250µg/l	11-307µg/l

TIBC	50µmol/l	45-70µmol/l
Folate	2.5µg/l	3.1-19.9µg/l
B12	253ng/l	145-910ng/l

Which test is most likely to identify the underlying cause of her anaemia?

A. Anti-tissue transglutaminase (anti-tTG) antibodies
B. Colonoscopy
C. Prussian blue stain
D. Haemoglobin electrophoresis
E. Blood film

D. Haemoglobin electrophoresis

Disproportionately low MCV think thalassaemia

The differential diagnosis for microcytic anaemias includes iron deficiency anaemia (IDA), thalassaemia, and sideroblastic anaemia. Colonoscopy is used to investigated unexplained IDA but serum iron and ferritin levels were raised in this patient, thus excluding IDA.

The disproportionately low MCV compared with haemoglobin levels points towards thalassaemia where iron and ferritin levels can often be normal or high. Whilst a blood film would aid the diagnosis, HbA2 >3.5% on haemoglobin electrophoresis is diagnostic.

Prussian blue stains are used in the diagnosis of sideroblastic anaemia but one would expect significantly raised iron levels and reduced TIBC.

Anti-tTGs are used in the diagnosis of coeliac disease which often causes a mixed iron and folate deficiency. Whilst folate levels are low in this patient, this can also be explained by a chronic background level of haemolysis in thalassaemia and the other results are not in keeping with a coeliac picture.

Question 42 of 191

A 46-year-old man with a diagnosis of chronic hepatitis C is reviewed in hepatology clinic. He complains of 3 weeks of lethargy and generalised muscle pain.

On examination there are erythematous macules and purpuric papules on both lower limbs with some small areas of ulceration. Light touch and pain sensation is reduced in the toes bilaterally.

What is the most likely cause of these symptoms?

A. Eosinophilic granulomatosis with polyangiitis
B. Leukocytoclastic vasculitis
C. Granulomatosis with polyangiitis
D. Cryoglobulinaemia
E. Microscopic polyangiitis

D. Cryoglobulinaemia

Hepatitis C is associated with mixed (type II) cryoglobulinaemia

A vasculitic rash and neuropathy in a patient with hepatitis C is suggestive of cryoglobulinaemia.

Small-vessel vasculitides can all cause neuropathy, however the association with hepatitis C makes cryoglobulinaemia most likely.

Patients with eosinophilic granulomatosis with polyangiitis (formerly known as Churg-Strauss syndrome) typically present with a history of allergic rhinitis and asthma. The disease progresses to eosinophilic infiltrative disease (eg, eosinophilic pneumonia or gastroenteritis) and systemic medium- and small-vessel vasculitis with granulomatous inflammation.

Granulomatosis with polyangiitis (GPA), formerly known as Wegener's granulomatosis has a spectrum of presentations but often includes chronic sinusitis (failure to respond to conventional treatment is suggestive). Rhinitis and epistaxis occur in 22% and 11% of patients with GPA, respectively.

Question 43 of 191

A 65-year-old man attends the Emergency Department with a one-month history of persistent left-sided chest pain that is unresponsive to analgesia. He describes the pain as a constant ache, which does not worsen with exertion or radiate elsewhere. His medical background includes hypertension and diabetes, and he has a significant smoking history. His current medication regimen comprises enalapril, metformin, vildagliptin, and glimepiride.

Hb	110 g/L	Male: (135-180)
Platelets	210 * 10 /L $_9$	(150 - 400)
WBC	6.4 * 10 /L $_9$	(4.0 - 11.0)
Calcium	2.8 mmol/L	(2.1-2.6)
Na $^+$	138 mmol/L	(135 - 145)
K $^+$	4.4 mmol/L	(3.5 - 5.0)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	235 µmol/L	(55 - 120)

No cardiac abnormalities were detected on ECG or echocardiography.

What is the most appropriate imaging modality for this patient?

A. Bone scan
B. Chest x-ray
C. PET-CT
D. Skeletal survey
E. Whole body MRI

A. Whole body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

Whole body MRI is the correct answer. The constellation of symptoms, including left-sided chest pain (bony aches), anaemia, hypercalcaemia, and renal impairment, should prompt consideration of multiple myeloma. Whole-body MRI is the recommended modality for diagnosis when multiple myeloma is suspected, as per NICE and BSH guidelines. Diagnostic features of myeloma on MRI include a diffuse pattern of bone marrow involvement and numerous focal lesions throughout the skeleton. These lesions typically present with a 'salt-and-pepper' appearance due to varying signal intensities caused by active myeloma cells and fatty marrow replacement.

Bone scan is not the appropriate choice. Although bone scans use a radioactive tracer to evaluate bone metabolism, they are limited in detecting small focal lesions and do not adequately assess bone marrow involvement in multiple myeloma. Furthermore, they may demonstrate nonspecific uptake in other conditions affecting bone remodelling and repair.

Chest x-ray, while capable of revealing osteolytic lesions, does not provide sufficient information to differentiate between multiple myeloma and metastatic disease; thus, it is not advocated for definitive diagnosis.

PET-CT, although an alternative diagnostic tool for patients with newly diagnosed nonsecretory or oligo secretory multiple myeloma or those presenting with the extramedullary disease, lacks sufficient evidence to support its routine use in all cases of newly diagnosed multiple myeloma. One limitation is the potential for high false positive and false negative findings rates.

Skeletal survey is less sensitive than CT, MRI, and PET/CT; therefore, it is considered suboptimal and is not advisable in this clinical scenario.

Question 44 of 191

An 18-year-old woman presents to the emergency department with dark urine. She had recently been diagnosed with 'mono' following a sore throat confirmed by swab testing, originally becoming unwell nine days ago. She had been recovering and was starting to feel well but then noticed passing dark urine after having a walk outside in the park but she started to return after it started to rain heavily and she became very cold. She also had abdominal cramping sensation. She has no other past medical history, takes no medication apart from the oral contraceptive pill, and has no allergies.

Blood tests:

Hb	101 g/l
Platelets	379 * 10 /l9
WBC	5.1 * 10 /l9
Bilirubin	43 µmol/l
ALP	161 u/l
ALT	15 u/l
Blood film	spherocytes

What is the most appropriate investigation to establish a diagnosis?

A. Hepatitis C serology
B. Syphilis serology
C. Anti-nuclear antibody
D. Direct Coombs test
E. ESO titre

D. Direct Coombs test

Paroxysmal cold haemoglobinuria should be confirmed with urinary heamosiderin

This is a young patient who has developed dark urine associated with exposure to going outside, implying exposure to cold. This has been associated with abdominal cramps and following a recent viral infection, most likely with Ebstein-Barr virus. In addition, blood tests show anaemia, elevated bilirubin and spherocytes. This implies haemolysis, and the history suggests that the haemolysis is associated after cold exposure. This history suggests is typical for paroxysmal cold haemoglobinuria. Paroxysmal cold haemoglobinuria is due to cold-reacting IgG causing complement fixation leading to haemolysis. Diagnosis is best established with direct Coombs test to demonstrate the intravascular nature of haemolysis. Further testing can demonstrate the presence of temperature specific IgG antibodies which react to red blood cells below 37 degrees C and cause hemolysis on re-warming. Syphilis was historically associated with this condition, but only in tertiary syphilis which such a young patient is unlikely to have. Determining ESO titre to establish the viral infection is unlikely to be helpful in the current situation, and whilst hepatitis C is associated with cryoglobulinaemia it is not associated with paroxysmal cold haemoglobinuria. In older patients, paroxysmal cold haemoglobinuria can be associated with auto-immune conditions, making ANA a useful screening test, but there is no chronic history suggesting a prolonged autoimmune condition.

Question 45 of 191

A 74-year-old man attends with worsening fatigue and shortness of breath. A systematic enquiry was otherwise unremarkable. He was treated with radical chemo-radiotherapy for metastatic squamous cell carcinoma 5 years ago.

Blood results are as follows:

Hb	72 g/L	Male: (135-180)Female: (115 - 160)
Platelets	42 * 10 /L 9	(150 - 400)
WBC	2.1 * 10 /L 9	(4.0 - 11.0)
Neuts	0.4 * 10 /L 9	(2.0 - 7.0)
Lymphs	0.6 * 10 /L 9	(1.0 - 3.5)
Mono	1.0 * 10 /L 9	(0.2 - 0.8)
Eosin	0.1 * 10 /L 9	(0.0 - 0.4)
Blood film	Occasional hypogranular and hypolobulated neutrophil; Blasts 8% of all nucleated cells	

What is the most likely diagnosis?

A. Acute lymphoblastic leukaemia
B. Acute myeloid leukaemia
C. Metastatic infiltration
D. Myelodysplastic syndrome
E. Myelofibrosis

D. Myelodysplastic syndrome

Pancytopaenia 5 years post-chemotherapy/radiotherapy → ?myelodysplastic syndrome

Myelodysplastic syndrome is correct. The patient most likely has therapy-related myelodysplastic syndromes (t-MDS) which is defined as MDS occurring as a complication of cytotoxic chemotherapy and/or radiation. The median onset of occurrence is 5 years post-chemotherapy (however this can vary widely with the type of chemotherapy given). The blood film appearances of hypogranular and hypolobulated neutrophils are classic of MDS. The presence of myeloblasts is also in keeping with this condition, and since the blast count is < 20% on peripheral blood the diagnosis is MDS rather than acute myeloid leukaemia. The patient requires an urgent bone marrow aspirate and trephine for morphology, cell markers, and cytogenetics.

Acute lymphoblastic leukaemia is incorrect. Acute lymphoblastic leukaemia (ALL) is rare in adults. It is predominantly a disease of children. The blood film appearances are not in keeping with ALL which would present with lymphoblasts and the absence of dysplasia in the myeloid lineage.

Acute myeloid leukaemia is incorrect. The peripheral blast count is < 20% confirming a diagnosis of MDS. Acute myeloid leukaemia (AML) is characterised by a peripheral blast count > 20%. It is important to note that the main risk of MDS is transformation to AML.

Metastatic infiltration is incorrect. Metastatic infiltration would be characterised by leukoerythoblastosis and teardrop poikilocytes on the blood film.

Myelofibrosis is incorrect. Myelofibrosis would also be characterised by leukoerythoblastosis and teardrop poikilocytes on the blood film.

Question 46 of 191

A 45-year-old gentleman has a diagnosis of renal cell carcinoma and is booked for a nephrectomy in four days time. He presents with an acutely swollen, tender left calf and a diagnosis of deep vein thrombosis is made, with the ultrasound report describing a clot extending to the femoral vein.

Which management is most appropriate?

A. Low molecular weight heparin and IVC filter insertion
B. Low molecular weight heparin
C. Warfarin
D. Apixiban
E. None

A. Low molecular weight heparin and IVC filter insertion

If a diagnosis of DVT is made less than 7 days before surgery, an IVC filter must be inserted pre-op

This gentleman has a malignancy that needs urgent operative management. An IVC filter should be inserted pre-operatively to bridge the operative period when low molecular weight heparin will be held.

The British Society of Haematology recommends that 'IVC filters should be considered in any preoperative patient with recent VTE (within 1 month) in whom anticoagulation must be interrupted'.

Whilst DOACs such as apixaban are now recommended first-line for venous thromboembolism they would be less suitable as surgery is planned in 4 days time.

Question 47 of 191

A 34-year-old woman presents to the emergency department with fever and bruising. She has no past medical history and does not take any regular medications. She does not smoke or drink alcohol and works as an accountant.

Observations:

- Heart rate 94 beats per minute
- Temperature 38.1ºC
- Blood pressure 170/101 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air

On examination, there is no meningism. You note that she is jaundiced but there are no signs of chronic liver disease. There are scattered petechiae on her arms, legs and abdomen.

Bloods tests:

Hb	72 g/L	Male: (135-180)Female: (115 - 160)
MCV	104fL	(80-96)
Platelets	33 * 10 /L	(150 - 400)
WBC	4.6 * 10 /L	(4.0 - 11.0)
Na	136 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	155 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	53 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	24 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
Prothrombin time	11 seconds	(10-14)
Blood film		schistocytes
ADAMTS13 enzyme		absent

Urinalysis:

Protein	++
Blood	++
Leucocytes	+
Nitrites	-ve
Glucose	-ve

Based on the likely diagnosis, what treatment is most likely to be effective?

A. Antibiotics
B. Antiplatelet therapy
C. High dose intravenous steroids
D. Intravenous labetalol
E. Plasma exchange

E. Plasma exchange

TTP - plasma exchange is first-line

Plasma exchange is correct. The patient has thrombotic thrombocytopenic purpura as evidenced by fever, thrombocytopenia, renal failure, microangiopathic haemolytic anaemia (jaundice, schistocytes) and absent ADAMTS13 enzyme activity. Haematoproteinuria is also common in this condition. The first-line treatment for this condition is plasma exchange (PEX), which removes inhibitory antibodies and replenishes the deficient protease.

Antiplatelet therapy is incorrect. While this is a thrombotic condition, there is a risk of haemorrhage with antiplatelet treatment.

High dose intravenous steroids is incorrect. Steroids are sometimes administered in this condition but have no proven benefit over PEX alone.

Intravenous labetalol is incorrect. While the patient is hypertensive, the blood pressure is not so high that we would label this as malignant hypertension, which is a differential for a cause of microangiopathic haemolytic anaemia.

Antibiotics are not the right answer. While no one would criticise someone for administering antibiotics to someone with a petechial rash and fever, on the basis that it could be meningococcal septicaemia, antibiotics have no role in the management of TTP and may even worsen the condition.

Question 48 of 191

A 24-year-old female presents to the emergency department with severe abdominal pain which had developed over for the last few hours. The pain was central, severe and stabbing in nature associated with vomiting. She was in hysterics and was extremely agitated and confused. Past medical history included asthma and depression. Two days earlier she had seen her GP for dysuria and been prescribed trimethoprim.

She was a student studying chemistry at university and had recently been out late several nights drinking excess alcohol to celebrate passing her exams. On examination, she was unwell, extremely clammy, distressed with generalised abdominal tenderness and weakness in both legs with areflexia. Heart sounds and chest were clear. Observations showed a blood pressure 190/100 mmHg, heart rate 126/min, regular and temperature 37.9ºC.

Which investigation is most likely to be diagnostic?

A. Urinary catecholamines
B. Abdominal ultrasound
C. Urinary porphobilinogen
D. Lumbar puncture
E. Blood cultures

C. Urinary porphobilinogen

In acute intermittent porphyria, urinary porphobilinogen is typically raised

This patient has acute intermittent porphyria (AIP). AIP is the most common type of porphyria. AIP is an autosomal dominant condition caused by a genetic mutation in the gene encoding the enzyme porphobilinogen (PBG) deaminase on chromosome 11. The condition is more common in females than males and usually occurs between the ages 14-30 years. Porphyrias occur due to a problem within the haem biosynthesis. Defective PBG deaminase causes PBG to accumulate and this can be found in the urine. Attacks are usually precipitated by drugs, alcohol, fasting and sepsis. This patients attack has been caused by a combination of antibiotic use and alcohol intake.

Patients most commonly present with gastrointestinal symptoms (most commonly severe abdominal pain) neurological symptoms (autonomic dysfunction, peripheral motor neuropathies, areflexia, delirium, seizures, coma) and psychiatric symptoms such as common. Observations commonly show tachycardia and hypertension. Fever can be present. Most patients are completely free of symptoms between attacks.

The treatment for acute attacks of porphyria is to decrease haem synthesis and reduce the production of porphyrin precursors. Withdrawal of culprit medication is essential. A high-calorie intake and high doses of glucose can help inhibit haem synthesis and are useful for the treatment of mild attacks. In severe attacks, intravenous haematin is used. Pain is treated with narcotics. Beta blockers can be used to treat tachycardia and hypertension.

Advice can be obtained from National Acute Porphyria Centres: Cardiff, Kings College Hospital, London and Cambridge.

Question 49 of 191

A 22-year-old man attends with progressive tiredness over the past week. A systematic enquiry was otherwise unremarkable. He has a past medical history of hereditary spherocytosis. His regular medications include folic acid however he states that he often forgets to take this. On examination, you note 5cm splenomegaly.

Blood results are as follows:

Hb	55 g/L	Male: (135-180)Female: (115 - 160)
Platelets	142 * 10^9/L	(150 - 400)
WBC	14.2 * 10^9/L	(4.0 - 11.0)
Reticulocytes	0.2 %	(0.5 - 1.5)
Direct antiglobulin test (DAT)	Negative	
Bone marrow examination	Marked erythroid hypoplasia and occasional giant erythroblasts	

Blood results from the clinic 3 months ago are as follows:

Hb	105 g/L	Male: (135-180)Female: (115 - 160)
Reticulocytes	5.8 %	(0.5 - 1.5)

What is the most likely explanation?

A. Acute erythroblastic leukaemia
B. Folic acid deficiency
C. Haemolytic crisis
D. Parvovirus infection
E. Splenic sequestration crisis

D. Parvovirus infection

Parvovirus infection may trigger an aplastic crisis in patients with hereditary spherocytosis

Parvovirus infection is correct. Of note, the patient has significant reticulocytopaenia suggestive of bone marrow failure. Two of the commonest causes of this would include infection (e.g. Parvovirus) and megaloblastic anaemia (e.g. B12 and folate deficiency). In health, the usual life span of a red cell is approximately 120 days. However in conditions such as hereditary spherocytosis (HS), due to premature destruction by the spleen, the lifespan could be as low as 10- 30 days. Thus acute insults to the bone marrow can manifest much more rapidly in the peripheral blood. Acute parvovirus B19 infection can cause a transient erythroid hypoplasia as demonstrated on the bone marrow results in this case. In healthy populations this would unlikely cause more than mild anaemia, however, in patients with chronic haemolytic states (e.g. red cell membrane disorders and haemoglobinopathies), the effects can be much more rapid and profound as demonstrated in this case.

Acute erythroblastic leukaemia is incorrect. The giant erythroblasts within the bone marrow are indicative of acute parvovirus infection, not leukaemia.

Folic acid deficiency is incorrect. Patients with HS have chronic low-grade haemolysis and therefore an increased red cell turnover. Since folic acid is essential for haematopoiesis, all patients with HS should continue on lifelong folic acid replacement. This is even more essential in a haemolytic crisis. Importantly this remains the case even when folic acid levels are normal. Although the patient, in this case, has poor compliance with folic acid, the bone marrow examination is more suggestive of acute parvovirus infection rather than megaloblastic anaemia.

Haemolytic crisis is incorrect. The presence of a marked reticulocytosis would be suggestive of a haemolytic crisis. However, it would be important to compare this to the patient's baseline reticulocyte count since patients with hereditary spherocytosis will often have chronic reticulocytosis due to low-grade haemolysis of spherocytes. In this case, the patient's reticulocyte count is low, making a haemolytic crisis less likely.

Splenic sequestration crisis is incorrect. Although the patient has mild splenomegaly, this would be expected due to the chronic haemolytic state associated with hereditary spherocytosis. A splenic sequestration crisis would present with a marked and painful enlargement of the spleen.

Question 50 of 191

A 35-year-old male Caucasian presents to the emergency department. He was asked to come to hospital after his GP noticed that his recent community blood tests showed severe anaemia. He attended his GP two days ago due to feeling increasingly tired and therefore the GP did routine blood tests for him. Apart from increasing fatigue and shortness of breath on exertion he had noticed nothing wrong. He had no past medical history apart from appendectomy when he was 20 years old and has recently significantly increased his exercise in an attempt to loose weight, and developed severe muscle aches, for which he has started to take diclofenac regularly. He denies any pain currently. On examination he is mildly jaundiced, has no stigmata of liver disease and his abdomen is soft without tenderness.

Blood tests:

Hb	96 g/l
Platelets	357 * 10 /l$_9$
WBC	4.8 * 10 /l$_9$
Blood film	spherocytosis
Na $^+$	138 mmol/l
K $^+$	4.9 mmol/l
Urea	4.7 mmol/l
Creatinine	79 µmol/l
Bilirubin	58 µmol/l
ALP	188 u/l
ALT	26 u/l

Further investigations are pending.

What is the most likely diagnosis?

A. G6PD deficiency
B. Warm autoimmune haemolytic anaemia
C. Peptic ulcer disease
D. Sickle-cell anaemia
E. Thalassaemia

B. Warm autoimmune haemolytic anaemia

Warm autoimmune haemolytic anaemia can be confirmed with the presence of anaemia, spherocytes on blood film and positive direct Coombs test for IgG or C3d

This is a patient who has developed symptomatic anaemia and jaundice following taking diclofenac, and has no symptoms of gastric irritation or signs of epigastric tenderness. Furthermore, the presence of elevated bilirubin suggests a haemolytic cause for the anaemia. These factors make peptic ulcer disease less likely.

Warm autoimmune haemolytic anaemia is the most likely explanation due to the evidence of haemolysis occurring following the administration of a drug known to cause this problem, and the presence of spherocytes supports this as well, but confirmation would be with a positive direct Coombs test.

G6PD deficiency is a cause for acute haemolytic anaemia but is more common in those of African ancestry and occurs typically after oxidating drugs such as primaquine.

Sickle-cell anaemia is very unlikely in a Caucasian patient and is also unlikely to be diagnosed at this age, and also would likely have a history of sickle-cell crisis.

Thalassemia is a disorder of globin genes causing ineffective erythropoiesis and haemolysis, endemic in the Mediterranean region and Africa. The blood film would be expected to show microcytosis and target cells rather than spherocytosis, and there is no evidence of extramedullary haematopoiesis.

Question 51 of 191

A 65-year-old man attends the clinic with a three-month history of generalised, dull-aching bone pain and increased fatiguability. He has a history of hypertension, which is well-controlled with amlodipine 10 mg daily. On examination, he exhibits pallor and has bruises and petechiae on his shins and forearms. Laboratory results are attached.

Hb	7.6 g/L	Male: (135-180)
Platelets	39 * 10 /L $_9$	(150 - 400)
WBC	3.1 * 10 /L $_9$	(4.0 - 11.0)
Calcium	3.1 mmol/L	(2.1-2.6)
Creatinine	140 µmol/L	(55 - 120)

What is the most appropriate next investigation to determine the cause of this patient's bone pain?

A. MRI spine
B. Whole body MRI
C. Whole body isotope bone scan
D. Whole body low dose CT scan
E. X-ray skull and spine

B. Whole body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

Whole body MRI is the preferred initial imaging modality for detecting myeloma-related bone disease and extra-medullary plasmacytomas. The clinical features of bone pain, fatigue, anaemia, thrombocytopenia, deranged creatinine, and hypercalcaemia in an older man are suggestive of multiple myeloma. It is standard practice to offer imaging to all patients with a suspected diagnosis of myeloma to investigate potential bone involvement, and a whole-body MRI is the most suitable investigation. This imaging modality can detect both lytic lesions and bone marrow infiltration, which are characteristic of multiple myeloma.

Whole body low dose CT scan is recommended as the first-line alternative for imaging in patients with myeloma in instances where an MRI is contraindicated due to the presence of a pacemaker, metallic heart valves, or aneurysm clips. For comprehensive assessment in this context, a whole-body MRI would be necessary rather than just an **MRI spine**.

A **whole body isotope bone scan** is not indicated for initial screening of myeloma-related bone disease. An isotope bone scan relies on osteoblastic activity and may yield a false negative result, particularly in cases where bone turnover is not high.

An **x-ray skull** is not a primary imaging choice for evaluating myeloma-associated bone pathology. While a raindrop skull on an x-ray can support the diagnosis of multiple myeloma, it is not sensitive or specific enough to be used as a primary diagnostic tool.

Question 52 of 191

A 20-year-old female complains of feeling tired. She has no past medical history and takes no regular medications.

The following blood tests were obtained:

Hb	84g/L
MCV	70fL
WBC	8x10^9/L
Platelets	460x10^9/L

Blood film analysis comments on hypochromic anaemia with pencil cells, target cells, acanthocytes and Howell Jolly bodies.

What is the most likely diagnosis?

A. Sickle cell anaemia
B. Hereditary spherocytosis
C. Thalassaemia trait
D. Iron deficiency anaemia
E. Coeliac disease

E. Coeliac disease

The blood film shows hypochromic anaemia with the presence of pencil cells that indicates the patient has iron deficiency anaemia. Target cells, acanthocytes and Howell Jolly bodies are features of hyposplenism. Iron deficiency and functional hyposplenism are both seen in coeliac disease, which is therefore the most likely unifying diagnosis. Thalassaemia trait is associated with mild reduction in haemoglobin, low MCV and low MCH; there would not be evidence of hyposplenism on the film in thalassaemia trait. Hereditary spherocytosis is due to a deficiency in spectrin, which leads to an abnormal red blood cell cytoskeleton. The film would show spherocytic red blood cells and reticulocytes. In sickle cell anaemia MCV is usually normal and sickle cells would be seen on the blood film.

Question 53 of 191

A 34-year-old man presents to the emergency department with abdominal pain. He has a background of multiple previous attendances with similar symptoms, which typically last for 3-7 days and then resolve. On a previous occasion, he underwent an exploratory laparoscopy, which did not identify a cause. He has a past medical history of depression. He takes citalopram. He does not smoke cigarettes or drink alcohol. He is a ceramicist. He has been under a lot of stress at work recently.

His observations are heart rate 111 beats per minute, blood pressure 153/74 mmHg, respiratory rate 18/minute, oxygen saturation 96% on room air and temperature 37ºC.

Examination reveals a soft and non-tender abdomen with normal bowel sounds. There are no abnormalities of the external genitalia. A bilateral foot drop is noted on neurological examination.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	5.6 * 10 /L 9	(4.0 - 11.0)
Na +	129 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	8.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	23 mg/L	(< 5)
Lactate	1.2 mmol/L	(0-2)

A urine sample is requested and it is noted to turn dark red when left standing. Porphobilinogen is increased in the urine.

Plain radiography of the abdomen and chest are normal.

Based on the likely diagnosis, what is the most appropriate treatment?

A. Chelation therapy
B. IV hydrocortisone
C. Supportive treatment only
D. 5% dextrose
E. Haem arginate and 10% dextrose

E. Haem arginate and 10% dextrose

IV haem arginate can be used to treat flares of acute intermittent porphyria

Haem arginate and 10% dextrose is the correct answer. This presents with features suggestive of acute intermittent porphyria (unexplained abdominal pain, depression, neuropathy, hyponatraemia, hypertension, tachycardia, red urine) and increased levels of urine porphobilinogen. Intravenous glucose inhibits the activity of aminolaevulinic acid synthase (an enzyme in the haem pathway). This reduces the overproduction of porphyrins. More hypotonic dextrose infusions should be avoided as they may worsen hyponatraemia. Haem arginate itself inhibits 5-aminolevulinic acid, which is another component in the porphyrin synthesis pathway. While the randomized control evidence of is lacking for this treatment, it is felt that patients typically respond well to this treatment and it should be given early in a severe attack.

5% dextrose is incorrect. Hypotonic dextrose solutions should be avoided as they may worsen hyponatraemia.

Chelation therapy is incorrect. Lead poisoning is a mimic of acute intermittent porphyria and can cause unexplained abdominal pain and neuropathy. However, the key distinction is that urine levels of porphobilinogen will not be increased in this condition. The diagnosis is typically confirmed by measuring levels of lead in the blood.

IV hydrocortisone is incorrect. Addison's disease can cause abdominal pain and hyponatraemia but you would expect hypotension rather than hypertension and the urinary findings are not typical of this condition.

Supportive treatment only is incorrect. This patient has a significant attack of acute intermittent porphyria with evidence of raised urinary porphobilinogen and motor neuropathy. This indicates a need for treatment with the above regimen.

Question 54 of 191

A 70-year-old man is referred to the haematology clinic by his general practitioner with anaemia. He has experienced progressive fatigue and shortness of breath for four months. On further questioning he also describes waking up at night soaked in sweat on one or two nights per week for the last month. His weight is stable. He has a past medical history of hypertension and COPD.

On examination he is pale. His heart sounds are normal and his chest is clear.. He has no ankle oedema and JVP is not raised. His abdomen is soft and he has splenomegaly 3cm below the costal margin with no hepatomegaly.

Test results sent with him by his GP are a follows:

Hb	92 g/l	Na +	143 mmol/l
Platelets	143 * 10 /l 9	K +	3.7 mmol/l
WBC	4 * 10 /l 9	Urea	7 mmol/l
Neuts	2 * 10 /l 9	Creatinine	86 µmol/l
Lymphs	1 * 10 /l 9	CRP	5 mg/l

Blood film: Anisocytosis with mild hypochromia. Tear drop cells. Mild thrombocytopenia with no platelet clumping.

Chest x-ray: Mildly hyperexpanded lung fields. No focal consolidation. No masses or lymphadenopathy.

Upper GI endoscopy & colonoscopy: Normal

Presence of which mutation is required to confirm the likely diagnosis?

A. BCR-ABL
B. BCL2
C. C-MYC
D. JAK2
E. TP53

D. JAK2

This gentleman has B symptoms, anaemia and splenomegaly in the presence of characteristic tear drops cells on the blood film, making myelofibrosis the most likely diagnosis. The British Committee for Standards in Haematology list several mutations which together with these symptoms and fibrosis on bone marrow form the diagnostic criteria. The most common of these is JAK2.

Presence of BCR-ABL is diagnostic for CML. BCL2 and TP53 mutations are seen in diffuse large B cell lymphoma.

C-MYC mutations are seen in Burkitt's lymphoma.

Use of JAK inhibitors in the management of myelofibrosis: a revision of the British Committee for Standards in Haematology Guidelines for Investigation and Management of Myelofibrosis 2012.

British Journal of Haematology, 2014;:167;418438.

Question 55 of 191

A 48-year-old male with hepatitis C is admitted to the acute medical assessment unit having noticed a significant reduction in his urine output over the last few days. Urinalysis revealed haematoproteinuria, and his blood results are as follows:

Hb	9.8 g/dl
Platelets	75 * 10 /l9
WBC	12.1 * 10 /l9
Na +	143 mmol/l
K +	5.4 mmol/l
Urea	18.9 mmol/l
Creatinine	205 µmol/l

A renal biopsy was subsequently performed and microscopy of the sample showed generally enlarged and hypercellular glomeruli with an increase in mesangial cellularity and matrix. A histological diagnosis of membranoproliferative glomerulonephritis is made.

What is the most likely underlying pathology for this finding?

A. Cryoglobulinaemia
B. Haemolytic uraemic syndrome
C. Hepato-renal syndrome
D. Systemic lupus erythematosus
E. Thrombotic thrombocytopaenic purpura

A. Cryoglobulinaemia

Hepatitis C is associated with mixed (type II) cryoglobulinaemia

This gentleman presents with acute kidney injury secondary to membranoproliferative glomerulonephritis. All of the listed options are recognised causes of membranoproliferative glomerulonephritis, but the key to this question is the patient's history of hepatitis C which is known to be closely associated with cryoglobulinaemia.

Question 56 of 191

A 77-year-old man presents with a general decline in mobility, extreme lethargy, and weight loss. His admission blood tests show:

Hb	98 g/L	Male: (135-180)Female: (115 - 160)
Platelets	119 * 10 /L 9	(150 - 400)
WBC	3.8 * 10 /L 9	(4.0 - 11.0)

Na +	137 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Urea	6.1 mmol/L	(2.0 - 7.0)
Creatinine	73 µmol/L	(55 - 120)
Calcium	2.46 mmol/L	(2.1-2.6)

A CT TAP is performed:

No evidence of solid organ malignancy or bony lesions. Splenomegaly noted - clinical correlation advised.

Given the ongoing concern for malignancy, a myeloma screen is sent:

IgA	0.56 g/L	(0.64-2.97)
IgG	4.7 g/L	(5.8-15.4)
IgM	12.52 g/L	(0.71-2.3)
Serum electrophoresis	Shows a paraprotein band	
Paraprotein level	44g/L	
Serum immunofixation	IgM type kappa paraprotein	
Serum free kappa light chains	13.65mg/L	(3.30-19.40)
Serum free lambda light chains	18.09 mg/L	(5.71-26.30)
Serum kappa / lambda ratio	0.75	(0.26-1.65)

What is the most likely diagnosis?

A. Acute lymphoblastic leukaemia
B. Monoclonal gammopathy of uncertain significance
C. Multiple myeloma
D. Smouldering myeloma
E. Waldenstrom's macroglobulinaemia

A. Waldenstrom's macroglobulinaemia

IgM paraproteinaemia - ?Waldenstrom's macroglobulinaemia

Waldenstrom's macroglobulinaemia is the correct diagnosis. The patient presents with relatively non-specific symptoms; however, initial findings of pancytopenia and radiological evidence of splenomegaly are concerning for a haematological malignancy. Subsequent serological investigations revealing elevated serum free light chains and electrophoresis indicating a raised IgM level, alongside an IgM-type kappa paraprotein, strongly suggest Waldenstrom's macroglobulinaemia.

Acute lymphoblastic leukaemia (ALL) is not the appropriate diagnosis. ALL is characterised by the malignant proliferation of lymphoid progenitor cells and typically presents with lymphadenopathy and signs consistent with bone marrow infiltration by malignant clones, such as anaemia and thrombocytopenia. While initial blood tests may show leukocytosis, anaemia, and thrombocytopenia, elevated IgM levels (12.52 g/L) and an associated IgM-type kappa paraprotein indicate a monoclonal gammopathy rather than ALL. Lymphoid progenitor cells in ALL do not secrete immunoglobulins in large quantities; thus, the detection of a paraprotein band, specifically an IgM-type kappa paraprotein on serum electrophoresis, does not align with ALL but instead suggests plasma cell disorders such as Waldenstrom's macroglobulinaemia or multiple myeloma.

Monoclonal gammopathy of uncertain significance (MGUS) is also incorrect. Although MGUS with an IgM paraprotein could yield similar serum electrophoresis and immunofixation results to those observed in this case, MGUS is asymptomatic by definition—contrary to our patient who exhibits symptomatic anaemia. Furthermore, diagnostic criteria for MGUS stipulate that the paraprotein concentration must be below 30g/L; this patient's level exceeds this threshold at 44g/L. The combination of symptomatic presentation and a higher paraprotein level excludes MGUS as a diagnosis.

Multiple myeloma does not fit this clinical picture either. Defined by CRAB features (hypercalcaemia, renal failure, anaemia, bony lesions), multiple myeloma involves monoclonal plasma cell proliferation detectable via serum electrophoresis showing a paraprotein presence. However, an IgM-type kappa paraprotein is more indicative of Waldenstrom's macroglobulinaemia than multiple myeloma; the latter more commonly involves IgG or IgA production. Additionally, splenomegaly is less common in multiple myeloma cases. The absence of skeletal lesions further argues against multiple myeloma as a diagnosis here. While multiple myeloma can present with variable levels of serum free light chains depending on disease burden and subtype—a finding not prominent in this patient—the normal range kappa/lambda ratio observed supports Waldenstrom's macroglobulinaemia over multiple myeloma.

Smouldering myeloma, like smouldering forms of other malignancies, presents without symptoms or end-organ damage—which includes CRAB features or any indication of organ impairment—and typically involves either IgG or IgA rather than IgM paraproteins. Given that our patient has symptomatic anaemia, smouldering myeloma is ruled out as a diagnosis in favour of Waldenstrom's macroglobulinaemia which accounts for both the symptomatology and laboratory findings observed.

Question 57 of 191

A 35-year-old patient with known sickle cell disease presents to the emergency department with new onset of left arm and facial weakness. The symptoms began earlier in the day. He is normally very careful with his sickle disease and ensures he is well hydrated and avoids the cold. His wife admits that over the last few days he has been suffering from nausea and vomiting and diarrhoea after he had a takeaway meal 3 days ago, On examination he his observations are within normal parameters. He has slurred speech and an obvious left facial droop with forehead sparing. He has power of 0/5 in his left arm but is otherwise neurologically intact.

His blood test show:

Hb	100 g/l
Platelets	330 * 10 /l9
WBC	8.9 * 10 /l9
INR	1.0
Na +	138 mmol/l
K +	3.5 mmol/l
Urea	9.9 mmol/l
Creatinine	135 µmol/l
CRP	19 mg/L(<10)
Bilirubin	12 µmol/l
ALP	89 u/l
ALT	39 u/l
Albumin	39 g/l

He is seen by the stroke team who arrange an urgent CT head which is reported as normal.

What is the appropriate treatment for this gentleman?

A. Thrombolysis
B. Aspirin
C. Plasmapheresis
D. Methylprednisolone
E. Exchange transfusion

A. Exchange transfusion

Exchange transfusions are a way of reducing the number of sickle red cells and increasing the number of normal red cells, in order to improve oxygenation

This gentleman has a cerebral vaso-occlusive episode as a result of his sickle cell disease. The treatment of choice in these situations is urgent and aggressive exchange transfusion followed by transfusions to maintain HbS <30%. Thrombolysis and aspirin are not in the management guidelines for acute stroke in this situation.

Question 58 of 191

A 29-year-old man who is known to be HIV positive is reviewed. He has been taking anti-retroviral therapy for the past 2 years and has remained relatively well. Over the past few weeks however he has developed abdominal distension with some discomfort in the right iliac fossa. On examination a mass can be felt in the right lower quadrant. A biopsy shows a B cell lymphoma. Sheets of a medium sized lymphoid cells with high proliferative activity, forming a 'starry sky' appearance, are noted.

What cytogenic abnormality is most likely to be found?

A. t(11;14)
B. t(14;18)
C. t(8;14)
D. t(9;22)
E. t(11;18)

C. t(8;14)

Burkitt's lymphoma - t(8:14)

This patient has an immunodeficiency-associated Burkitt lymphoma

Question 59 of 191

A 27-year-old woman is admitted after developing dyspnoea associated with pleuritic chest pain. A D-dimer taken on admission is elevated and subsequent CTPA shows a pulmonary embolism. Her past medical history includes a giving birth to her son 12 months ago (full term, vaginal delivery) and anxiety. She reports that her 47-year-old mother has had two deep vein thromboses in the past 10 years.

Which one of the following is the most likely underlying cause?

A. Factor V Leiden
B. Antithrombin III deficiency
C. Antiphospholipid syndrome
D. Protein C deficiency
E. Prothrombin gene mutation

A. Factor V Leiden

Activated protein C resistance (Factor V Leiden) is the most common inherited thrombophilia

NICE would recommend testing for thrombophilia given the unprovoked venous thromboembolism and family history

Question 60 of 191

A 19-year-old man with hereditary spherocytosis is reviewed in the clinic. He was last admitted to the hospital some 6 months earlier for an acute haemolytic crisis related to parvovirus infection. He complains that he feels chronically tired and has persistent left upper quadrant pain and discomfort. Abdominal examination confirms splenomegaly.

Investigations:

Abdominal ultrasound scan reveals splenomegaly and a solitary gallstone visualised within the gallbladder.

Hb	90 g/l
MCV	101 fL
Platelets	301 * 10 /l9
WBC	7.1 * 10 /l9

Which of the following is the most appropriate intervention for him?

A. Prednisolone
B. Splenectomy
C. Cholecystectomy
D. Oral iron supplementation
E. IV iron supplementation

B. Splenectomy

Elective splenectomy is appropriate in a patient with hereditary spherocytosis who has recurrent anaemia

This patient has hereditary spherocytosis with evidence of chronic haemolysis. Although this patient doesn't yet have symptoms of cholecystitis they have evidence of possible pigment gallstone formation on the ultrasound scan and symptomatic splenomegaly. Coupled with the anaemia and raised MCV (suggestive of increased reticulocytes), this clinical picture points to elective splenomegaly as the most appropriate option, with vaccination at least against pneumococcus before the procedure is carried out.

Cholecystectomy is carried out where patients present with cholecystitis related to hereditary spherocytosis. Prednisolone may help stimulate red cell production in situations where there is an acute haemolytic crisis. There is no role for iron supplementation here. IV iron supplementation is usually considered for patients with chronic renal impairment.

Question 61 of 191

A 60-year-old woman presents to the clinic with a one-year history of generalised body pain and fatigue. She intermittently experiences epistaxis and bleeding gums. She underwent a fundoscopy for blurred vision, which showed retinal haemorrhages and dilated retinal veins. Examination reveals pallor and hepatosplenomegaly. Serum protein electrophoresis demonstrates a sharp, narrow spike of monoclonal IgM. A skeletal survey is normal. A bone marrow biopsy is scheduled.

What are the expected findings of the bone marrow biopsy for this patient?

A. <10% infiltration of bone marrow with lymphoplasmacytic cells
B. <10% monoclonal plasma cells
C. >10% infiltration of bone marrow with lymphoplasmacytic cells
D. >10% monoclonal plasma cells with clock-face chromatin
E. Abnormal B cells

C. >10% infiltration of bone marrow with lymphoplasmacytic cells

IgM paraproteinaemia - ?Waldenstrom's macroglobulinaemia

> 10% infiltration of the bone marrow with lymphoplasmacytic cells is the typical bone marrow finding observed in patients with Waldenstrom's macroglobulinemia, which is the case here. The patient's presentation and investigations are consistent with Waldenstrom's macroglobulinaemia, a lymphoplasmacytic malignancy characterised by the secretion of a monoclonal IgM paraprotein. The disease typically presents with systemic symptoms such as fatigue and weight loss, hyperviscosity syndrome (e.g., blurred vision due to retinal haemorrhages), and hepatosplenomegaly.

< 10% infiltration of bone marrow with lymphoplasmacytic cells is typically observed in monoclonal gammopathy of undetermined significance (MGUS). The features such as anaemia, hepatosplenomegaly and hyperviscosity symptoms outlined in this scenario are rarely associated with MGUS; hence, this option is not applicable.

< 10% monoclonal plasma cells is incorrect because it is < 10% monoclonal plasma cells can be seen in MGUS. It is important to distinguish this condition from multiple myeloma. The lack of bony lesions and normal skeletal survey findings exclude multiple myeloma in this case. Additionally, IgM myeloma is exceedingly uncommon. **> 10% monoclonal plasma cells with clock-face chromatin** typify multiple myeloma; therefore this choice is incorrect.

Chronic lymphocytic leukaemia (CLL) represents another differential diagnosis characterised by **abnormal B cells** within the bone marrow. Monoclonal gammopathy is uncommon in CLL. Serum protein electrophoresis typically appears normal in CLL cases and only demonstrates abnormal protein spikes in approximately 15% of instances.

Question 62 of 191

A 28-year-old Afro-Caribbean male presents with a two-hour history of sudden onset left sided weakness. He denies any sensory involvement, dysarthria or dysphasia. He has a known history of sickle cell disease, with two previous episodes of transient ischaemic attacks and an episode of acute chest syndrome attack 10 days ago. On examination, he displays power of 1/5 in his left arm, 2/5 in his left leg, 5/5 in his right side. He reports no sensory disturbances, plantar responses are downgoing bilaterally, he is unable to perform finger-nose testing. He denies any illicit drug use, is a non-smoker and does not drink alcohol. He has no other past medical history. A hyperacute CT head demonstrates an area of acute ischaemia in the right internal capsule region.

What is the most appropriate immediate treatment?

A. Intravenous thrombolysis
B. Aspirin 300mg
C. Intravenous thrombolysis and mechanical thrombectomy
D. Exchange transfusion
E. Clopidogrel 300mg

D. Exchange transfusion

Exchange transfusions are a way of reducing the number of sickle red cells and increasing the number of normal red cells, in order to improve oxygenation

This patient has presented with an acute vaso-occlusive crisis on a background of known sickle cell disease. He is at high risk of an infarctive stroke given the background of previous TIAs (increased relative risk by 56 times) and a recent chest crisis within the past 2 weeks (increased relative risk by 7 times). The other risk factors include a high systolic pressure (RR 1.3 increase per 10mmHg) and

a low steady state haemoglobin (RR 1.9 per 1g/dL decrease)1. The management of an acute sickle infarct is different to that of thromboembolic stroke or atheromatous disease. The immediate aim is to reduce the proportion of HbS, either with immediate transfusion or optimally, with exchange transfusion. The latter reduces the concentration of HbS faster with a lower risk of transfusional volume overload, possibly resulting in increased blood viscosity and consequent pulmonary oedema.

Question 63 of 191

A 25 year old man presented to the Emergency Department with acute onset, rapidly progressive weakness in all the four limbs following a bout of severe colicky abdominal pain which lasted for 10 days but eventually subsided. The abdominal pain was located around the umbilicus, stabbing in nature, radiated towards the back, and was associated with nausea and intermittent constipation. Patient reports weakness originating in both arms then affecting both the lower limbs. He also complains of difficulty in closing his lips and eyes, and has uncontrolled salivation from the angles of the mouth. He denied any history of paraesthesia, sphincteric disturbances, epileptic fits or dark colored urine during any of the episodes. No definite history of any drug intake prior to both the episodes could be ascertained.

Physical examination revealed bilateral facial palsy of lower motor neuron (LMN) type together with flaccid quadriparesis which was more marked distally with bilateral wrist drop. Deep tendon reflexes were diminished in both upper and lower limbs. There was no sensory loss.

Initial lab values showed WBCs 8.9x10^9/L, Hemoglobin of 12g/L, Sodium of 132mmol/L, and ESR of 35mm/Hr. His temperature was 36.5 C and pulse 83/min. His blood pressure was 130/83 mm/Hg and oxygen saturations were 98% on air. A lumbar puncture was performed and CSF studies were normal.

Which of the following is most likely to be diagnostic?

A. CT scan with contrast of abdomen
B. MRI brain with contrast
C. Urine screen for Vanillylmandelic acid (VMA)
D. Urine screen for Aminolevulinic Acid (ALA) and Porphobilinogen (PBG)
E. Measurement of urinary and stool porphyrins

D. Urine screen for Aminolevulinic Acid (ALA) and Porphobilinogen (PBG)

n acute intermittent porphyria, urinary porphobilinogen is typically raised

Acute attacks of Acute Intermittent Porphyria (AIP) are often precipitated by drugs like barbiturates, sulfonamides, chloroquin, griseofulvin, diphenyl hydantoin and many other drugs, acute infections and over-indulgence in alcohol. Acute attacks are due to greatly increased activity of delta-aminolaevulinic acid synthetase. During acute attacks, the urine contains large amounts of porphobilinogen (PBG) and delta-aminolaevulinic acid (ALA) which, on standing, gives dark 'portwine' colour to the urine. Mental disturbances during acute episodes are of metabolic origin whilie neurological weakness of the extremities is due to focal demyelination and/or axonal degeneration of peripheral and autonomic nerves.

Onset of symptoms usually occurs in adolescence. Females are more commonly affected than males. The clinical picture is dominated by gastrointestinal and neurological manifestations. Symptoms during acute episodes usually comprise of severe colicky pain in the abdomen which may be diffuse or localized- usually to the umbilical or epigastric region and is often associated with nausea and vomiting and occasionally diarrhea. Diagnosis in such patients may be missed, unduly delayed or confused with acute surgical abdomen especially if neurological manifestations are lacking. Gastrointestinal manifestations are related to severe intestinal spasm due to autonomic dysfunction. Neurological manifestations comprise of flaccid paralysis, neuropsychiatric disturbances and rarely generalized epileptic fits. Paralysis may be confined to lower or upper extremities or may affect all the four limbs. It may be more marked proximally or distally or may be generalized and is due to predominant motor neuropathy. Sensory symptoms may also occur but objective sensory loss is unusual. Epileptic fits in AIP have been reported in about 15 to 20% cases. Bulbar paralysis and respiratory involvement can also occur and may threaten the life of the patient. Sphincteric disturbances are uncommon. Skin lesions are seldom seen.

Diagnosis of AIP should be suspected in any patient presenting with rapidly progressive flaccid paralysis with severe abdominal pain and history of passing dark reddish urine. Examination of the urine during acute attacks for PBG and ALA will help in establishing the diagnosis. In the patient in the above case, the diagnosis of AIP was based on clinical and urinary findings.

There is no specific treatment for porphyria and it is therefore very important to prevent the onset of acute attack. Treatment during acute episodes usually comprises symptomatic and general supportive measures for bulbar and respiratory paralysis, if it occurs. Chlorpromazine has been reported to be beneficial in relieving pain and other symptoms. Approximately 25% siblings of patients of AIP may be expected to have PBG in urine and therefore screening of siblings and other family members should be done. Prophylaxis in such cases as well as those known to clinically manifest AIP includes the avoidance of drugs known to precipitate the acute attacks as enlisted above.

Question 64 of 191

A 55-year-old man is referred by her GP to the haematology clinic. He reports a four-week history of night sweats and early satiety. On questioning, he elaborates and says that he has been feeling unwell for some time, but that he had just started work as a managing director and had attributed this to the added stress of his promotion.

On examination, he is pale with an unremarkable cardiovascular and respiratory exam. There is a fullness in the left upper quadrant which moves with inspiration and widespread small volume lymphadenopathy.

His blood tests are shown below:

Hb	100 g/L	Male: (135-180)Female: (115 - 160)
Platelets	117 * 10 /L 9	(150 - 400)
WBC	30.1 * 10 /L 9	(4.0 - 11.0)
Neuts	4.0 * 10 /L 9	(2.0 - 7.0)
Lymphs	25.0 * 10 /L 9	(1.0 - 3.5)
Mono	0.8 * 10 /L 9	(0.2 - 0.8)
Eosin	0.3 * 10 /L 9	(0.0 - 0.4)
Blood Film	lymphocytosis with smudge cells	

A bone marrow biopsy shows lymphocytosis in a diffuse growth pattern.

Chromosomal analysis is performed to guide further management.

Given the likely diagnosis,

which of the following findings would suggest a poor prognosis?

A. Wild-type TP53
B. >2% mutated immunoglobulin heavy chain variable region
C. Deletion of 13q
D. Mutated TP53
E. < 20% expression of CD38 lymphocytes

D. Mutated TP53

TP53 mutation is associated with a poor prognosis in CLL

This patient has aggressive chronic lymphocytic leukaemia (CLL) with both constitutional symptoms and bone marrow failure, indicating the need for treatment. The chromosomal analysis may be used to guide treatment offers significant insights into prognostication.

The presence of a mutated TP53 is a poor prognostic marker, where a 'wild type' refers to an unmutated form and is a good prognostic marker. A >2% mutated immunoglobulin heavy chain variable region, deletion of 13q or < 20% expression of CD38 lymphocytes are good prognostic markers.

Question 65 of 191

A 26-year-old gentleman presents to haematology clinic one week prior to starting chemotherapy for acute myeloid leukaemia (AML). He is currently feeling fatigued, suffering from night sweats, and has chronic lower back pain. He is anxious to start treatment.His past medical history includes ankylosing spondylitis and a clavicular fracture. His current medications include paracetamol and ibuprofen.

Blood tests:

Hb	113 g/l
Platelets	156 * 10 /l9
WBC	57 * 10 /l9
Na +	140 mmol/l
K +	3.6 mmol/l
Urea	4.2 mmol/l
Creatinine	63 µmol/l

What measure is the least useful to prevent tumour lysis syndrome?

A. IV fluids prior to chemotherapy
B. Urine alkalization
C. Prophylactic allopurinol
D. Prophylactic rasburicase
E. Stopping NSAID use

B. Urine alkalization

This patient has AML with a high white cell count and is about to start chemotherapy, and is therefore at high risk of tumour lysis syndrome (TLS).The key is to prevent TLS, which is done by ensuring good renal perfusion. Commonly this can be done by aggressive intravenous hydration prior to the start of treatment and stop NSAIDs, such as ibuprofen for this patient. Allopurinol and rasburicase both prevent uric acid accumulation and can, therefore, be used as well. Urine alkalization has not shown to be effective.

Question 66 of 191

A 50 year old woman was referred to haematology clinic for management of a persistent erythrocytosis that had been monitored by her General Practitioner over the previous 6 months. The patient was asymptomatic and in particular reported no headaches or visual changes. Past medical history was remarkable only for internal fixation of a tibial fracture sustained in a car accident 5 years previously. There is no strong family history of venous thrombosis or ischaemic heart disease. The patient took no regular medications and worked as an accountant. She is a lifelong non-smoker and drinks approximately 10 units of alcohol per week.

Following assessment at haematology, further investigations were requested as listed below.

Hb	# g/dl
Platelets	# * 10 /l
WBC	# * 10 /l
Haemoglobin	18.7 g / dL
White cell count	6.1* 10 /l
Neutrophils	3.5 * 10 /l
Lymphocytes	1.0 * 10 /l
Monocytes	0.7 * 10 /l
Eosinophils	0.4 * 10 /l
Basophils	0.5 * 10 /l
Platelets	276 * 10 /l
Packed cell volume	0.57
Urea	4.5 mmol / L
Creatinine	95 micromol / L
Sodium	142 mmol / L
Potassium	4.5 mmol / L
Ferritin	56 ng / mL
Albumin	35 g / L
Alkaline phosphatase	80 U / L
ALT	20 U / L
Bilirubin	18 micromol / L
JAK 2 V617F mutation	Postive
Serum erythropoietin	3 U / L (reference 0-19)

Blood film: no abnormality detected

Abdominal ultrasound: liver, hepatic duct system and gallbladder unremarkable; mild-moderate splenomegaly; kidneys and renal tract unremarkable

What is the appropriate management for the patient's erythrocytosis?

A. Aspirin and venesection with target PCV < 0.45
B. Aspirin and venesection with target PCV 0.45-0.50
C. Aspirin
D. Venesection with target PCV 0.45-0.50
E. Hydroxyurea

A. Aspirin and venesection with target PCV < 0.45

This patient has polycythemia vera as evidenced by the positive JAK 2 mutation, normal blood film, splenomegaly and low serum erythropoietin.

Management of polycythemia depends on the patient's risk of thrombosis. This patient has a low risk of thrombosis based on her age, absence of cardiac risk factors, normal white cell and platelet count and absence of hyperviscosity symptoms.

The mainstay of treatment of polycythaemia vera is aspirin and venesection. A target PCV < 0.45 has been shown to have a significantly lower rate of death from cardiovascular disease and major thrombosis than target PCV 0.45-0.50. Treatment with aspirin reduces the risk of non-fatal myocardial infarction, non-fatal stroke, pulmonary embolus, major venous thrombosis or death from cardiovascular cause compared to placebo. Aspirin does not increase the incidence of major bleeding episodes compared to placebo.

Cytoreductive treatments such as hydroxyurea are used to treat high-risk polycythaemia vera.

Question 67 of 191

A 65-year-old male presents with a 2 year history of fatigue. Over the past year he has had progressive early satiety, vomiting and weight loss. On examination you note 10cm splenomegaly.

Investigation results are as follows:

Hb	84g/l	Na +	138 mmol/l	Bilirubin	22 µmol/l
Platelets	65 * 10 /l 9	K +	3.7 mmol/l	ALP	88 u/l
WBC	2.2 * 10 /l 9	Urea	4.5 mmol/l	ALT	22 u/l
Neuts	0.8 * 10 /l 9	Creatinine	68 µmol/l	γGT	96 u/l
Lymphs	0.4 * 10 /l 9	Albumin	28 g/l		

Blood film: Tear-drop poikilocytes

What is the most likely diagnosis?

A. Myelodysplasia due to bone marrow metastases
B. Chronic myeloid leukaemia
C. Acute myeloid leukaemia
D. Myelofibrosis
E. Megaloblastic anaemia

D. Myelofibrosis

Massive splenomegaly may early satiety and vomiting which can mimic gastric cancer

The blood results confirm pancytopenia with tear drop cells, suggestive of a primary marrow problem. Teardrop cells may be seen in the setting of marrow infiltration (by fibrosis, granulomatous inflammation, haematological or metastatic malignancy), splenic abnormalities, megaloblastic anaemia, and thalassemia.

In this case, the differential is clearly between gastric cancer (with bone marrow metastases resulting in myelodysplasia), and myelofibrosis. Early satiety and vomiting can be a feature of both gastric cancer, and massive splenomegaly. The presence of splenomegaly, and the duration of symptoms are more suggestive of myelofibrosis.

Question 68 of 191

A 56-year-old man presents to the clinic with a 1-week history of yellowing of his skin. He also complains of itching. A systematic inquiry was otherwise unremarkable. He drinks approximately 160 units of alcohol per week. Observations are within normal limits. On examination, there is palpable hepatosplenomegaly.

Blood results are as follows:

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	52 * 10 /L 9	(150 - 400)
WBC	4.8 * 10 /L 9	(4.0 - 11.0)
Reticulocytes	195 * 10 /L 9	(50 - 100)
Urea	2.8 mmol/L	(2.0 - 7.0)
Creatinine	42 µmol/L	(55 - 120)
LDH	520 units/L	(140 - 280)
Haptoglobins	<0.5 g/L	(0.5 - 2.2)
Triglycerides	4.2 mmol/L	(<2.3)

Prothrombin time (PT)	16 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	38 secs	(25-35 secs)
Fibrinogen	2.8 g/L	(2 - 4)
D-Dimer	360 ng/mL	(< 400)

Bilirubin	58 µmol/L	(3 - 17)
ALP	580 u/L	(30 - 100)
ALT	126 u/L	(3 - 40)
Î³GT	860 u/L	(8 - 60)
Albumin	28 g/L	(35 - 50)
Direct antiglobulin test (DAT)		Negative

What is the treatment of choice?

A. Abstinence from alcohol
B. Eculizumab
C. Intravenous immunoglobulin (IVIg)
D. Plasma exchange
E. Prednisolone

A. Abstinence from alcohol

Zieve syndrome usually resolves with abstinence from alcohol

The presence of anaemia with reticulocytosis is suggestive of bleeding or haemolysis. The suppressed haptoglobins, raised bilirubin, and raised LDH are highly suggestive of haemolytic anaemia. The causes of haemolytic anaemia are wide and include hereditary (e.g. membranopathies, enzymopathies, haemoglobinopathies), immunological (e.g. autoimmune haemolytic anaemia), infective (e.g. malaria), and microangiopathic haemolytic anaemias (e.g. TTP, DIC).

It is also important to note that the patient is thrombocytopenic. The cause of this most likely relates to cirrhosis with portal hypertension and splenomegaly, given the significant alcohol history and the presence of hepatosplenomegaly. However, it may also be due to a recent alcohol binge since ethanol is toxic to platelets and can cause transient thrombocytopenia which should resolve within a few days following the binge. However, in the context of haemolytic anaemia, it would also be important to consider microangiopathic haemolytic anaemias (e.g. TTP, HUS, HELLP) which can cause thrombocytopenia due to platelet consumption.

The patient is also coagulopathic which is most certainly related to cirrhosis with decreased production of liver-derived clotting factors.

Abstinence from alcohol is correct. The most likely diagnosis is Zieve's syndrome (ZS) which is characterised by a triad of cholestatic jaundice (high ALP/GGT/bilirubin), DAT-negative haemolytic anaemia, and hyperlipidaemia that develops secondary to alcohol-induced liver injury (most commonly following a binge). The patient fulfils all the criteria of this triad favouring this diagnosis. The treatment for Zieve's syndrome is abstinence from alcohol. Abstinence from alcohol would also be essential for preventing the progression of cirrhosis.

Eculizumab is incorrect. Eculizumab is a terminal complement inhibitor that specifically binds to the complement protein C5 with high affinity, thereby inhibiting its cleavage to C5a and C5b and preventing the generation of the terminal complement complex C5b-9. This drug is used to treat paroxysmal nocturnal haemoglobinuria (PNH). PNH presents with pancytopenia, intravascular haemolytic anaemia, and arterial/venous emboli. Although it remains within the differential diagnosis, the clinical and laboratory features are more in keeping with Zieve's syndrome.

Intravenous immunoglobulin (IVIg) is incorrect. IVIg can be used to treat autoimmunehaemolytic anaemia (AIHA). The patient clearly has haemolysis, however, the negative DAT makes AIHA an exceptionally unlikely diagnosis. Although DAT-negative haemolysis can occur it is exceedingly rare.

Plasma exchange is incorrect. Plasma exchange can be used to treat thrombotic thrombocytopenic purpura (TTP). Thrombotic thrombocytopenic purpura (TTP) is a microangiopathic haemolytic anaemia classically characterised by the pentad of fever, haemolytic anaemia, thrombocytopenia, and renal and neurologic dysfunction. Although it remains within the differential diagnosis, the clinical and laboratory features are more in keeping with Zieve's syndrome.

Prednisolone is incorrect. Prednisolone can be used to treat autoimmune haemolytic anaemia (AIHA). The patient clearly has haemolysis, however, the negative DAT makes AIHA an exceptionally unlikely diagnosis. Steroids can also be used to treat alcoholic hepatitis, however, the liver function tests are predominantly cholestatic in this case.

Question 69 of 191

A 44-year-old woman presents to the clinic with bruising. This has progressively worsened over the past week. She has also been having frequent nose bleeds which self-terminate. Her past medical history includes rheumatoid arthritis for which she takes weekly methotrexate. She drinks approximately 64 units of alcohol per week.

Her observations are within normal limits. She is noted to have widespread petechia and purpura. On abdominal examination, there is palpable hepatosplenomegaly.

Blood results are as follows:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	2 * 10 /L 9	(150 - 400)
WBC	8.0 * 10 /L 9	(4.0 - 11.0)
Neuts	6.0 * 10 /L 9	(2.0 - 7.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	75 µmol/L	(55 - 120)

Bilirubin	16 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	146 u/L	(3 - 40)
Î³GT	582 u/L	(8 - 60)
Albumin	32 g/L	(35 - 50)

Prothrombin time (PT)	10 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	28 secs	(25-35 secs)
Fibrinogen	3.4 g/L	(2 - 4)
D-Dimer	360 ng/mL	(< 400)

What is the most likely cause of this patient's thrombocytopenia?

A. Disseminated intravascular coagulation (DIC)
B. Felty's syndrome
C. Immune thrombocytopenic purpura (ITP)
D. Portal hypertension
E. Thrombotic thrombocytopenic purpura (TTP)

C. Immune thrombocytopenic purpura (ITP)

ITP should be considered in the presence of symptoms that suggest isolated thrombocytopenia e.g. epistaxis, menorrhagia

The causes of thrombocytopenia are wide and include decreased production (e.g. bone marrow failure), increased consumption (e.g. MAHA), and sequestration (e.g. portal hypertension with splenomegaly).

Immune thrombocytopenic purpura (ITP) is correct. ITP is an acquired autoimmune disorder characterised by a low platelet count resulting from peripheral platelet destruction by autoantibodies. It can often be precipitated by malignancy, drugs, vaccinations, or infections. It is often commonly associated with other autoimmune disorders. A single-figure platelet count, with otherwise normal full blood count and a normal coagulation screen, is most likely a consequence of ITP.

Felty's syndrome is incorrect. Felty's syndrome is a rare, extra-articular manifestation of rheumatoid arthritis (RA), characterised by persistent, idiopathic neutropenia and, in some cases, splenomegaly. The absence of neutropenia makes this an unlikely diagnosis.

Disseminated intravascular coagulation (DIC) is incorrect. The normal coagulation profile excludes this diagnosis. DIC presents with prolonged PT, prolonged APTT, low fibrinogen and very high D-dimers.

Thrombotic thrombocytopenic purpura (TTP) is incorrect. Thrombotic thrombocytopenic purpura (TTP) is a microangiopathic haemolytic anaemia classically characterised by the pentad of fever, haemolytic anaemia, thrombocytopenia, and renal and neurologic dysfunction. The absence of any of the other criteria makes this an unlikely diagnosis.

Portal hypertension is incorrect. The patient certainly has features to suggest portal hypertension namely the significant alcohol history, deranged LFTs, and the presence of hepatosplenomegaly. Thrombocytopenia is a common complication in liver disease as a result of multiple factors, including splenic sequestration, reduced activity of the haematopoietic growth factor thrombopoietin, and bone marrow suppression by chronic hepatitis C virus infection. However, it is important to remember that the platelet count is rarely < 50 *10 /L in this setting. Therefore, although this may be a contributing factor in this clinical case, an alternative diagnosis should be considered, and indeed ITP is the most likely diagnosis.

Question 70 of 191

An 82-year-old man attends the clinic with a 6-month history of drenching night sweats and 10kg weight loss. He also complains of headaches and blurred vision. His observations are within normal limits. On examination, he has bulky bilateral cervical and inguinal lymphadenopathy.

Blood results are as follows:

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	185 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	85 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Total protein	110 g/L	(60-80)

What is the most likely diagnosis?

A. Burkitt's lymphoma
B. Diffuse large B-cell lymphoma
C. Mantle cell lymphoma
D. Marginal zone lymphoma
E. Waldenstrom's macroglobulinaemia

E. Waldenstrom's macroglobulinaemia

Weight loss, raised total protein, hyperviscosity symptoms (headache, blurring) → ? Waldenstrom's macroglobulinaemia

Waldenstrom's macroglobulinaemia is correct. The clinical features are suggestive of lymphoma (e.g. B symptoms and lymphadenopathy). The presence of headaches, and visual impairment, in the context of a raised total protein, is suggestive of hyperviscosity. Although formal serum electrophoresis and immunofixation are required to confirm and classify the paraprotein, it is usually IgM paraproteins that are implicated in hyperviscosity. This is because the IgM molecule is a massive pentameric structure. IgM paraproteins can be associated with many types of lymphoma, however, the classic cause is Waldenstrom's macroglobulinaemia, making this the most likely diagnosis.

Burkitt's lymphoma is incorrect. Burkitt's lymphoma is a highly aggressive high-grade lymphoma. It is the fastest-growing tumour seen in humans with a doubling time of between 24 and 48 hours. Thus the chronicity of the patient's symptoms makes this an exceptionally unlikely diagnosis.

Diffuse large B-cell lymphoma is incorrect. Diffuse large B cell lymphoma (DLBCL) is a highly aggressive high-grade lymphoma. Although not as rapidly growing as Burkitt's, the chronicity of the patient's symptoms makes this a less likely diagnosis.

Mantle cell lymphoma is incorrect. Although mantle cell lymphoma looks like a low-grade lymphoma under the microscope, it often behaviours more like a high-grade lymphoma (e.g. rapid growth). Although it can occasionally produce an IgM paraprotein, it is Waldenstrom's macroglobulinaemia which is more commonly associated with IgM paraproteins making this the more likely diagnosis.

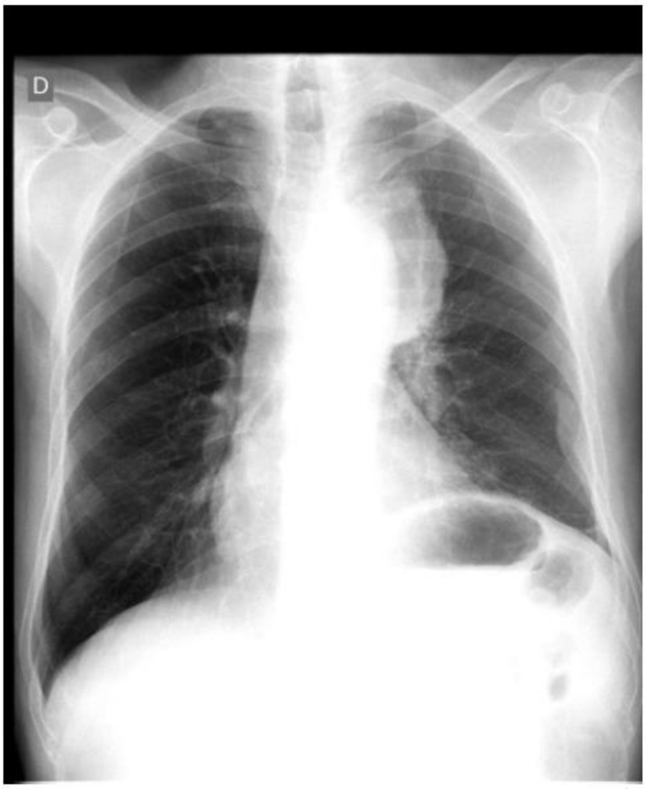
Marginal zone lymphoma is incorrect. There are three types of marginal zone lymphomas (MZL): extranodal MZL of mucosa-associated lymphoid tissue (MALT or gastric GALT), splenic MZL, and nodal MZL. Although IgM paraproteins are occasionally associated with MZL, they are much closer associated with Waldenstrom's macroglobulinaemia making this the favoured diagnosis.

Question 71 of 191

A 70-year-old man is investigated for dysphagia and chest pain. These symptoms have been getting progressively worse for the past 3 months and have not responded to a trial of a proton pump inhibitor. There is no history of weight loss or anorexia.

On examination you note a left-sided partial ptosis. The patient also complains of double vision when you are assessing eye movements. Sustained upward gaze exacerbates his ptosis.

A chest x-ray is requested:



What is the most likely diagnosis?

A. Lung cancer
B. Cardiac myxoma
C. Tuberculosis
D. Sarcodoisis
E. Thymoma

E. Thymoma

Anterior mediastinal mass + symptoms of myasthenia = thymoma

The chest x-ray shows is a partially delineated mediastinal mass (anterior mediastinum) with regular borders, bulging the left upper mediastinal contour. These findings are consistent with a thymoma.

The history is highly suggestive of myasthenia gravis which is seen in around a third of patients with a thymoma. Note how the ptosis worsened with sustained upward gaze, a demonstration of fatigability.

Question 72 of 191

A 53-year-old man presents to the emergency department with a rash and ulceration on his lower limbs. He has a past medical history of untreated hepatitis C virus. He is not on any regular medications. He is homeless. He is an intravenous drug user.

On examination, there is a purpuric rash on his lower limbs with ulceration of the digits. There is no clinical evidence of synovitis.

Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	422 * 10 /L	(150 - 400)
WBC	5.2 * 10 /L	(4.0 - 11.0)
Na	138 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	141 µmol/L	(55 - 120)
CRP	55 mg/L	(< 5)
Rheumatoid factor	654 IU/ml	(0-20)
Complement (C3)	0.81 g/L	(0.75 - 1.65)
Complement (C4)	.02 g/L	(0.16 to 0.48)
Antinuclear antibody	negative	(negative)
ESR	101 mm/Hr	(0-20)
IgA	10.2 g/L	(6.60 - 15.90)
IgG	24.1 g/L	(6-16)
IgM	4.2 g/L	(0.53-2.47)

Urinalysis:

Leucocytes	negative
Nitrites	negative
Blood	+++
Protein	++
Glucose	negative

What is the likely diagnosis?

A. Rheumatoid vasculitis
B. Systemic lupus erythematosus
C. Type I cryoglobulinaemia
D. Type II cryoglobulinaemia
E. Type III cryoglobulinaemia

D. Type II cryoglobulinaemia

Hepatitis C is associated with mixed (type II) cryoglobulinaemia

Type II cryoglobulinaemia is correct. This patient presents with a purpuric rash on the lower limbs with distal ulceration in association with hypocomplementaemia and a positive rheumatoid factor on a background of hepatitis C. This suggests a diagnosis of cryoglobulinaemia. Hepatitis C is associated with Type II cryoglobulinaemia. The haematoproteinuria and deranged renal function suggest glomerulonephritis. Rheumatoid factor may be very high in this condition.

Rheumatoid vasculitis is incorrect. This may cause a rash, ulceration and positive rheumatoid factor. However, it tends not to cause low complement and glomerulonephritis and is, therefore, less likely. Additionally, it tends to occur in longstanding rheumatoid, which is absent here.

Systemic lupus erythematosus is incorrect. This can be associated with rash, low complement, rheumatoid factor and ulceration. However, a negative ANA essentially excludes the diagnosis.

Type I cryoglobulinaemia is incorrect. This form of cryoglobulinaemia is typically associated with a monoclonal IgM or IgG rather than a polyclonal picture. It is associated with multiple myeloma and Waldenstrom's macroglobulinaemia.

Type III cryoglobulinaemia is incorrect. This type of cryoglobulinaemia is typically associated with rheumatoid arthritis and Sjogren's rather than hepatitis C. The absence of joint symptoms and the negative ANA make rheumatoid arthritis and Sjogren's unlikely.

Question 73 of 191

A 19-year-old African male was referred by his GP to the medical assessment unit with a complaint of dark coloured urine, abdominal pain and jaundice. He does not have any other co-morbidities and there is no family history of haemolytic anaemias. He recently tried a new Mediterranean diet containing fava beans. On examination, there is moderate splenomegaly.

Hb	70 g/l	Na +	137 mmol/l	Bilirubin	107 µmol/l
Platelets	280 * 10 /l 9	K +	4.3 mmol/l	ALP	98 u/l
WBC	8.7* 10 /l 9	Urea	5.6 mmol/l	ALT	25 u/l
Neuts	5.6 * 10 /l 9	Creatinine	77 µmol/l	γGT	37 u/l
Lymphs	1.3 * 10 /l 9	Albumin	35 g/l		
Eosin	0.9 * 10 /l9				

Serum haptoglobin was undetectable, and serum lactate dehydrogenase (LDH) was 1987 units/l. Peripheral blood film showed Heinz bodies. A direct Coombe's test was negative. G6PD levels return as normal.

What investigation should be performed next to confirm the diagnosis?

A. Repeat G6PD level immediately as the first specimen may have been inadequate
B. Ultrasound abdomen
C. Hepatitis serology
D. Bone marrow examination
E. G6PD analysis in few weeks when symptoms improved

E. G6PD analysis in few weeks when symptoms improved

G6PD deficiency: G6PD level may be normal during an acute haemolytic episode

G6PD testing should be performed when patients are in remission as the result may be falsely negative during acute haemolysis. The reason for this is that during an acute haemolytic episode, older erythrocytes with low G6PD levels are destroyed and there is a compensatory increase in immature erythrocytes and reticulocytes that have increased G6PD levels. Although ultrasound abdomen may be useful in assessing for splenomegaly and gallstones in this patient, it's not diagnostic of G6PD deficiency.

Hepatitis serology is more useful in the setting of jaundice secondary to hepatobiliary disease. Bone marrow examination is not an investigation of choice in G6PD deficiency.

Question 74 of 191

A 72-year-old man is brought into the emergency department following a fall. He was found by his daughter unresponsive on the floor after hearing a loud bang. His daughter tells you that he has been more unsteady on his feet for the last few days and is recovering from a urinary tract infection. There is a past medical history of benign prostatic hyperplasia and atrial fibrillation for which he takes tamsulosin, finasteride and rivaroxaban.

On examination, he is drowsy with a GCS of 12 (E3V4M5). He has a heart rate of 85bpm and blood pressure of 210/118mmHg. On auscultation, his chest is clear with normal heart sounds. Oxygen saturations are 90% on air. There is a deep laceration over the left side of his forehead which is oozing blood and there is bruising down the left side of his body. Pupils are equal and reactive to light.

CT Head: Evidence of a moderate intracranial haemorrhage in the left frontal lobe. There is no evidence of a mass effect.

What is the most appropriate next step in the management of this patient?

A. Andexanet alfa
B. Cryoprecipitate
C. Dexamethasone
D. Idarucizumab
E. Protamine

A. Andexanet alfa

Rivaroxaban and apixaban can be reversed by andexanet alfa

Important for me Less im This patient has had a traumatic intracranial haemorrhage. Initial treatment should be to maintain a patent airway and attempt to stop the bleeding in order to prevent raised intracranial pressures. With patients taking anticoagulant therapy, actions should be taken to reverse their action. Andexanet alfa is a recombinant form of factor Xa which binds specifically to apixaban or rivaroxaban to reverse their anticoagulant effects.

Cryoprecipitate is derived from fresh frozen plasma and contains factor VIII, factor XIII, fibrinogen, vWF and fibronectin. It is used to treat fibrinogen deficiency in cases of disseminated intravascular coagulation, trauma, invasive procedures or haemorrhage. It is more commonly used to treat an intracranial haemorrhage secondary to tissue plasminogen activator use for an acute ischaemic stroke.

Dexamethasone can be given in the case of increased intracranial pressure, which can be secondary to intracranial haemorrhage and subsequent mass effect. However, the current investigations do not show evidence of cerebral oedema or midline shift and therefore dexamethasone is not the next initial treatment to be given.

Idarucizumab is a specific reversal agent for dabigatran. As this patient is not taking dabigatran therapy, the use of idarucizumab is not indicated.

Protamine is used in the reversal of heparin. As this patient is not taking heparin therapy, the use of protamine is not indicated.

Question 75 of 191

A 24-year-old female presents to her GP with a 2 month history of tiredness. On further questioning she admits she has also been experiencing pain in the centre of her chest and in the lymph nodes in her neck when drinking alcohol.

What is the likely underlying cause?

A. Hodgkin's lymphoma
B. Somatisation disorder
C. GORD (gastro-oesophageal reflux disease)
D. Hiatus hernia
E. Pancreatitis

A. Hodgkin's lymphoma

Lymph node pain when drinking alcohol is very specific for Hodgkin's lymphoma (although it occurs rarely)

Lymph node pain when drinking alcohol is very specific for Hodgkin's lymphoma. It is however a rare symptoms and most patients do not experience it.

None of the other conditions mentioned cause pain in lymph nodes

Question 76 of 191

You are the medical registrar on call. The surgical registrar contacts you for a patient he has just seen in clinic who requires an elective cholecystectomy. The patient is a 65-year-old woman who has atrial fibrillation for which she takes rivaroxaban. The patient is otherwise well. The bloods performed in clinic that day are as follows:

Hb	131 g/l
Platelets	352 * 10 /l9
WBC	5.5 * 10 /l9
INR	1.5
Na +	137 mmol/l
K +	3.6 mmol/l
Urea	3.2 mmol/l
Creatinine	67 µmol/l

The surgical registrar would like to know how long the patient should omit their anticoagulation before the procedure?

A. 1 day
B. 2 days
C. 3 days
D. 5 days
E. 7 days

A. 1 day

The new oral anticoagulant drugs (NOACs) are being used increasingly in patients who require anticoagulation. They have the advantage of once or twice daily dosing regimes, oral formulation and do not require therapeutic monitoring like warfarin. They are particularly useful in patients that may have issues with warfarin compliance or those with erratic international normalised ratio (INR) readings. NOACs have been shown to convey equivalent efficacy to warfarin in most contexts the main exception being anticoagulation in patients with prosthetic heart valves where NOACs were not as effective as warfarin.

Rivaroxaban is one of the most commonly used agents. It acts as a direct factor Xa inhibitor. It is absorbed from the gut and has maximum factor Xa inhibition four hours post dose. It is indicated for anticoagulation in atrial fibrillation and in the treatment of venous thromboembolism. It has a half-life of 7-9 hours and is metabolised in the liver. Factor Xa levels do not return to normal for just over 24 hours so once daily dosing is appropriate.

The following table outlines how long anticoagulants need to be withheld before surgery:

Drug	Duration to withhold before procedure
Dabigatran	1-2 days with creatinine clearance >50ml/min
Rivaroxaban	1 day if creatinine clearance >90 ml/min
Apixaban	1-2 days if creatinine clearance >60
Fondaparinux	36-48 hours
LMWH	12 hrs for prophylactic dose, 24 hours for therapeutic dose
Warfarin	1-8 days, check INR
UFH	IV 4-6 hrs, SC 12-24 hrs

Question 77 of 191

A 45-year-old worker on demolition sites comes to the Emergency department for review. He has suffered increasing tiredness, lethargy, headache, and abdominal pains over the past 2 months. On examination he is hypertensive with a blood pressure of 155/90 mmHg, his pulse is 85 beats per minute and regular. He looks pale.

Investigations

Hb	97 g/l
MCV	78 fl
Platelets	175 * 10 /l9
WBC	6.2 * 10 /l9
Lead	5 µmol/l

Blood film reveals basophilic stippling

Which of the following is the most appropriate initial intervention?

A. Activated charcoal
B. Disodium EDTA
C. DMSA
D. Haemodialysis
E. Vitamin C

C. DMSA

DMSA is an oral chelation therapy that can be used for chronic lead poisoning, the diagnosis here. A lead level above 3.4 µmol/l indicates significant occupational exposure and that the patient should be withdrawn from work. 500mg twice per day is a usual initial therapeutic dose.

Given his lead exposure represents chronic exposure, there is no role for activated charcoal. Disodium EDTA is used in the management of acute lead poisoning and is given intravenously. Human trials of vitamin C with respect to treatment of lead toxicity are so far equivocal, and there is no role for haemodialysis in chronic lead poisoning.

Question 78 of 191

A 65-year-old man is seen in the haematology clinic for review of test results. He has been fatigued for the last three months and has experienced night sweats. On examination he is pale with a palpable spleen 4cm below the costal margin, mildly tender on palpation. His only other past medical history is of osteoarthritis.

His results are as follows:

Hb	89 g/l	Na +	140 mmol/l
Platelets	205 * 10 /l 9	K +	4.0 mmol/l
WBC	5 * 10 /l 9	Urea	5.8 mmol/l
Neuts	3.6 * 10 /l 9	Creatinine	72 µmol/l
Lymphs	1.2 * 10 /l 9	CRP	3 mg/l

Blood film: Anisocytosis with mild hypochromia. Tear drop cells. CT chest/abdomen/pelvis: Splenic enlargement. No suspicious mass lesions seen. 1cm simple right renal cyst. No lymphadenopathy.

Bone marrow biopsy: Fibrosis

Which initial therapy should be used to treat this gentleman?

A. Chlorambucil
B. Fludarabine
C. Hydroxycarbamide
D. Interferon alpha
E. Lenalidomide

C. Hydroxycarbamide

This gentleman has myelofibrosis as evidenced by bone marrow fibrosis, tear drop cells on blood film and constitutional symptoms. He has symptomatic splenomegaly and anaemia. First line treatment for this would be hydroxycarbamide.

Chlorambucil is used in chronic lymphocytic leukaemia and non-Hodgkin lymphoma. Fludarabine is used to treat acute myeloid leukaemia. Interferon alpha is used for myelosuppression in myelofibrosis in the presence of thrombocytosis or leucocytosis. Lenalidomide is used in the treatment of multiple myeloma

Question 79 of 191

A 30-year-old lady presents with shortness of breath and facial flushing. She had been to a restaurant that evening and noticed the symptoms when rushing home. She also had itchy skin and tingling lips. On examination she was tachycardic with a wheeze. She had no history of food allergies and reported eating lasagne for dinner alongside a glass of wine.

What is the most likely diagnosis?

A. Acute asthma attack
B. Carcinoid syndrome
C. Exercise induced wheat angioedema
D. Shellfish anaphylaxis
E. Thyrotoxicosis

C. Exercise induced wheat angioedema

Exercised induced anaphylaxis is now well described and is most associated with wheat ingestion. The clinical manifestations usually occur around 10 minutes after exercise and follow a sequence of pruritus, widespread urticaria and then subsequently respiratory distress and vascular collapse. The condition usually resolves on stopping exercise and is managed in the same manner as anaphylaxis. The patients can usually eat the causative food without problems so long as they do not exercise afterwards. The physiology of the condition remains slightly unknown, but it may be related to endorphin release during exercise. The endocrines cause excessive histamine release from mast cells in susceptible individuals.

The tingling lips and facial flushing are not in keeping with an asthma attack and there is no history of shellfish consumption. Thyrotoxicosis could explain some of the symptoms but not the wheeze. Carcinoid syndrome can cause episodes of flushing, shortness of breath and tachycardia and thus represents a plausible option, especially as exercise, food and stress can trigger these episodes. However these patients often have diarrhoea and abdominal symptoms alongside their other symptoms.

Question 80 of 191

A 54-year-old man presents to the emergency department with shortness of breath. He has a history of heart failure and takes ramipril, bisoprolol, eplerenone and isosorbide mononitrate.

Observations are as follows: heart rate 135 beats per minute, respiratory rate 26 breaths per minute, blood pressure 135/82 mmHg, temperature 37.4 ºC, and SpO2 92%. His chest is clear on auscultation.

The doctors initiate the patient on 15L O2 via a non-rebreather mask. Blood gas analysis results are as follows:

pH	7.24	(7.35 - 7.45)
PaO2	72.4 kPa	(10.3 - 13.3 kPa)
PaCO2	2.9 kPa	(4.7 - 6 kPa)
HCO3	16 mmol/L	(22 - 28 mmol/L)
SaO2	44%	(94 - 98%)
Lactate	3.4 mmol/L	(<1.0)

What is the most likely diagnosis?

A. Acquired methaemoglobinaemia
B. Carboxyhaemoglobinaemia
C. Congenital methaemoglobinaemia
D. Cyanide poisoning
E. Pulmonary embolism

A. Acquired methaemoglobinaemia

Nitrates, including recreational nitrates such as amyl nitrite ('poppers') may cause methaemoglobinaemia

The striking feature, in this case, is the significant discrepancy between the PaO2 and SaO2 on arterial blood gas analysis. Given the patient is on 15L O2, the PaO2 is at a level expected indicating that gas exchange at the level of the alveoli is not impaired. There are various formulas for predicting the expected PaO2 for any given inspired O2 concentration. The Advanced Life Support (ALS) guidelines suggest that the PaO2 for any given inspired concentration should be approximately 10 less than the inspired concentration (%). For example, in this case, 15L O2 is equivalent to approximately 80-85% so we would expect the PaO2 to be around 70 kPa.

However, it is important to note that the SaO2 (oxygen saturation of haemoglobin) is markedly low at 44% indicating impaired oxygen binding to haemoglobin. It is also important to note that the peripheral SpO2 is 92% which is clearly discrepant with the SaO2. The two main causes of this picture are methaemoglobinaemia and carboxyhaemoglobinaemia. Because standard pulse oximeters are not capable of differentiating between different forms of bound haemoglobin, the SpO2 is usually falsely high in these conditions.

Tissue hypoxia can be a consequence of 4 main causes:

1. Hypoxaemia (low PaO2 due to poor gas exchange at the alveoli)
2. Toxic haemoglobin (low SaO2 due to methaemoglobinaemia or carboxyhaemoglobinaemia)
3. Perfusional (e.g. shock, or localised causes such as compartment syndrome or bowel ischaemia)
4. Severe anaemia

Regardless of the cause, tissue hypoxia will result in lactic acidosis. Therefore, in patients with lactic acidosis, all the aforementioned causes should be considered. The patient in this case most certainly has lactic acidosis as a consequence of toxic haemoglobin-induced tissue hypoxia. He is acidotic with low serum bicarbonate since this acts as a buffer for lactic acid.

Acquired methaemoglobinaemia is the correct answer. As discussed above, the biochemical results are suggestive of toxic haemoglobin. The history of isosorbide mononitrate use favours the diagnosis of acquired methaemoglobinaemia. Nitrate-containing drugs are commonly implicated in this condition.

Carboxyhaemoglobinaemia is incorrect. Although carbon monoxide poisoning presents similarly and remains within the differential diagnosis, the history of nitrate exposure favours the diagnosis of methaemoglobinaemia.

Congenital methaemoglobinaemia is incorrect. Although this remains within the differential diagnosis, the absence of previous episodes and the presence of a known risk factor (e.g. nitrate exposure) favours the acquired form.

Cyanide poisoning is incorrect. Cyanide binds the ferric (Fe3+) ion of cytochrome oxidase causing 'histotoxic hypoxia' and lactic acidosis. It would not cause a marked reduction of SaO2 as seen in this case unless it was associated with coexistent carbon monoxide poisoning (e.g. due to smoke inhalation). There is nothing in this clinical case to suggest that this is the case.

Pulmonary embolism is incorrect. As stated above, the blood gas analysis confirms hypoxaemia as a consequence of toxic haemoglobin rather than poor gas exchange at the level of the alveolar. Therefore a pulmonary embolism is a less likely diagnosis.

Question 81 of 191

A 75-year-old man presents to the emergency department with a reduced level of consciousness after a recent fall and head injury. He has a past medical history of atrial fibrillation. His medications include apixaban and bisoprolol.

On examination, his Glasgow coma scale is 12/15 (E 3 V4 M5). There is evidence of an external head injury with bruising and laceration in the right occipital area.

An urgent CT head is arranged, which demonstrates a large right-sided subdural haematoma.

What is the most appropriate medication to administer?

A. Andexanet alfa
B. Fresh frozen plasma
C. Vitamin K
D. Prothrombin complex
E. Idarucizumab

A. Andexanet alfa

Rivaroxaban and apixaban can be reversed by andexanet alfa

Andexanet alfa is the correct answer. The patient has sustained a traumatic subdural haematoma. Clinically he has a low GCS. The method of anticoagulation needs to be reversed. The most appropriate reversal agent for apixaban is andexanet alfa.

Vitamin K is incorrect. This can be used as a reversal agent for warfarin. It is not the most appropriate agent to use given this patient's method of anticoagulation.

Fresh frozen plasma is incorrect. This is mainly used to replace coagulation factors in cases of excessive bleeding or in those with abnormal coagulation. It is not the most appropriate reversal agent available to choose in this case.

Prothrombin complex is incorrect. This can be used to rapidly reverse the effects of warfarin in those patients that are bleeding. It is under investigation currently to see if it is effective in reversing agents such as apixaban Idarucizumab is incorrect. This is a monoclonal antibody that can reverse the effects of dabigatran

Question 82 of 191

You are looking after a 35-year-old man who is in the oncology day unit receiving his second round of chemotherapy for a low grade non-Hodgkin's lymphoma. His lymphoma is confined to two lymph node groups in his anterior cervical chain and right inguinal region. In total there are 6 nodes with the largest being 4cm in size. He had no issues during his first round of chemotherapy apart from some nausea a week afterwards. He has no other medical problems and is on no other medications. His bloods pre-chemotherapy are as shown below:

Na +	137 mmol/l
K +	3.8 mmol/l
Urea	2.8 mmol/l
Creatinine	55 µmol/l
Corrected Calcium	2.39 µmol/l
Phosphate	1.05 µmol/l

What regimen would be most appropriate for prevention of tumour lysis syndrome in his case?

A. Allopurinol (200mg BD)
B. Fluids and allopurinol (200mg BD)
C. Fluids and rasburicase (0.2mg/kg)
D. Reduced dose chemotherapy
E. Fluids, allopurinol (200mg BD) and rasburicase (0.2mg/kg)

B. Fluids and allopurinol (200mg BD)

The British Society of Haematology suggest that patients undergoing chemotherapy can be categorised into three different risk groups for tumour lysis syndrome. While you are not required to know how to do this in detail it would be important clinically to be able to recognise factors that put people at increased risk:

- High tumour burden
- High grade tumours with rapid cell turnover
- Pre-existing renal impairment or renal involvement by the tumour Increased age
- Treatment with highly active, cell-cycle specific agents
- Concomitant use of drugs that increase uric acid levels (the list is available on the guidance)

Risk Group	Prophylaxis
Low Risk	Adequate hydration (consider IV fluids and allopurinol prophylaxis)
Intermediate Risk	Allopurinol (7 days) and IV fluids
High Risk	Rasburicase and IV fluids (consider low dose chemotherapy)

This patient has no high risk features in his history and is therefore considered low risk, so the closest answer is fluids and allopurinol.

It is important to know that allopurinol and rasburicase should not be used together, as allopurinol reduces the effectiveness of rasburicase. Allopurinol reduces the production of urate, allowing elimination of upstream compounds, which are more water soluble and thus more easy to excrete through the kidneys. Rasburicase, on the other hand, converts urate into more easily excreted downstream compounds.

In addition rasburicase cannot be given to patients with G6PD as it can precipitate haemolysis.

Question 83 of 191

A 24-year-old man is brought into the resuscitation room. They were struggling to walk across the emergency department reception area due to severe dyspnoea.

They admit to inhaling some substances at a party earlier in the evening but cannot recall what it was.

On examination, they have blue-tinged peripheries with blue lips and tip of nose but appear relatively undistressed. Their observations show oxygen saturations of 90% on 6 litres of oxygen and a heart rate of 120 beats per minute.

An arterial blood gas is taken while they are on 6 litres of oxygen. The results are below.

pH	7.40	(7.35-7.45)
paO2	18	(11-13)
paCO2	4.6	(4.5-6)
methaemoglobin	38%	(1-3%)

What is the most likely substance that they have ingested?

A. Amyl nitrite
B. Glyceryl trinitrate
C. Sodium nitroprusside
D. Aniline dye
E. Dapsone

A. Amyl nitrite

Nitrates, including recreational nitrates such as amyl nitrite ('poppers') may cause methaemoglobinaemia

The answer is amyl nitrite otherwise known as 'poppers' which is a drug of abuse. It induces a short lived euphoric high but can result in methaemoglobinaemia. The other answers all cause methaemoglobinaemia but are unlikely to be used in the above context.

Question 84 of 191

You are called to see a 55-year-old gentleman who is having a blood transfusion for symptomatic anaemia secondary to colon cancer. The nurses have been doing regular observations as documented below.

10am:

Baseline observations prior to blood transfusion

- Respiratory rate 20 breaths/min
- Saturations 96% on air
- Temperature 37.5 ºc
- Blood pressure 145/78 mmHg
- Heart rate 74 beats/min

10:15 am: repeat observations after 15 mins of transfusion

- Respiratory rate 19 breaths/min
- Saturations 97% on air
- Temperature 38.2 ºc
- Blood pressure 150/80 mmHg
- Heart rate 72 beats/min

The nurses have already stopped the blood transfusion by the time you arrive to see the patient. On questioning the patient he feels well with no complaints of pain, itch or rashes. On examination his heart sounds are pure and chest is clear. He has no previous documented reactions to blood transfusions although the patient informs you he is allergic to penicillin.

What instructions do you give the nurses?

A. Take blood cultures and commence antibiotics
B. Dispose of the remaining blood in the bag
C. Restart the blood transfusion after giving the patient paracetemol
D. Take blood cultures, repeat chest x ray and perform urinalysis
E. Restart the blood transfusion an hour after giving the patient paracetemol

C. Restart the blood transfusion after giving the patient paracetemol

Blood transfusion reaction are common and can be serious. This patient is well and has no clinical evidence of haemodynamic compromise. He has an isolated pyrexia which is likely to be secondary to commencement of the blood transfusion. After confirming this his blood transfusion should be restarted as soon as possible and paracetemol given for symptomatic relief. Disposal of the blood should be considered if a serious adverse reaction occurs. Septic screen and antibiotics should be considered if any underlying infection is suspected. Blood transfusion should be completed within 4 hours and waiting an hour prior to restarting is a waste of valuable time.

Question 85 of 191

A 55-year-old lady presents to her general practitioner with a painful rash on her breasts. The rash has developed over the last 24 hours and although initially diffuse and red is now well demarcated and a much darker red. She was started on warfarin five days ago for a deep vein thrombosis diagnosed on ultrasound doppler. She has a past medical history of hypothyroidism, type two diabetes mellitus, thromboembolism and obesity. She remembers having been on warfarin at least once before for previous deep vein thrombosis but does not remember ever having had this rash. Her blood tests today are as follows.

Prothrombin time	21.4 seconds
INR	2.1 ratio

What is the most likely diagnosis?

A. Protein S deficiency
B. Idiosyncratic drug reaction
C. Stevens Johnson syndrome
D. Warfarin toxicity
E. Protein C deficiency

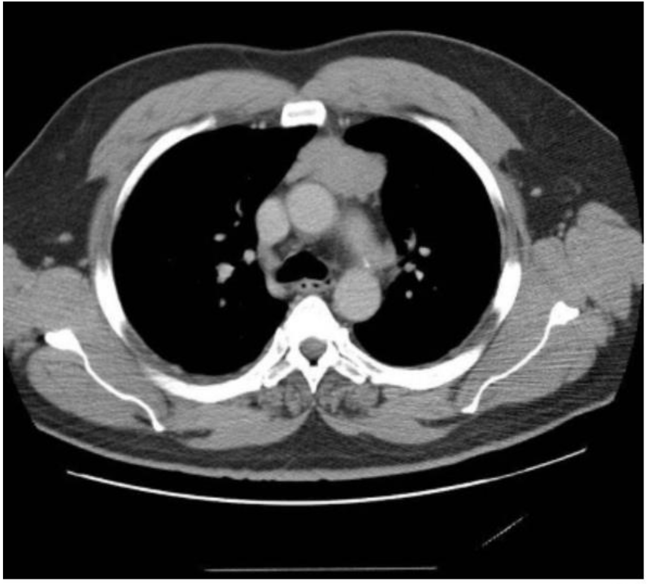
E. Protein C deficiency

Warfarin-induced skin necrosis is a symptom of the hypercoagulable state that can be seen in the first week of warfarin therapy. This is explained by the fact that warfarin inhibits both procoagulant factors (2, 7, 9, 10) as well as anti-coagulant factors (protein C). Protein C has the shortest half-life and therefore there is a short period of time during the initiation of warfarin therapy where the patient is hypercoagulable despite a therapeutic INR. Warfarin-induced skin necrosis is more likely to occur in patients with pre-existing protein C deficiency, which is a rare congenital condition associated with recurrent venous thromboembolic disease.

Question 86 of 191

A 41-year-old woman presents to her general practitioner with a three-month history of shortness of breath and cough. Her symptoms have been progressive and she is otherwise asymptomatic. She has no relevant medical comorbidities but a 30 pack-year smoking history.

Examination of the respiratory systems is unremarkable. She has a CT thorax which is displayed below:



What is the most likely cause for this woman's symptoms?

A. Bronchial cancer

B. Chronic pulmonary emboli
C. Lung fibrosis
D. Thymoma
E. Thyroid cancer

D. Thymoma

This woman's CT scan demonstrates a large mass representing a thymoma in the anterior mediastinum. Thymomas can commonly cause shortness of breath and cough, as well as retrosternal chest pain, dysphagia, and vocal changes. Although bronchial cancer could cause this woman's symptoms, there is no evidence of this pathology on the CT and therefore this answer is incorrect.

There is no evidence on this CT scan of a pulmonary embolus despite this not being a pulmonary angiogram. As the scan does identify a thymoma, chronic pulmonary emboli are therefore less likely and incorrect.

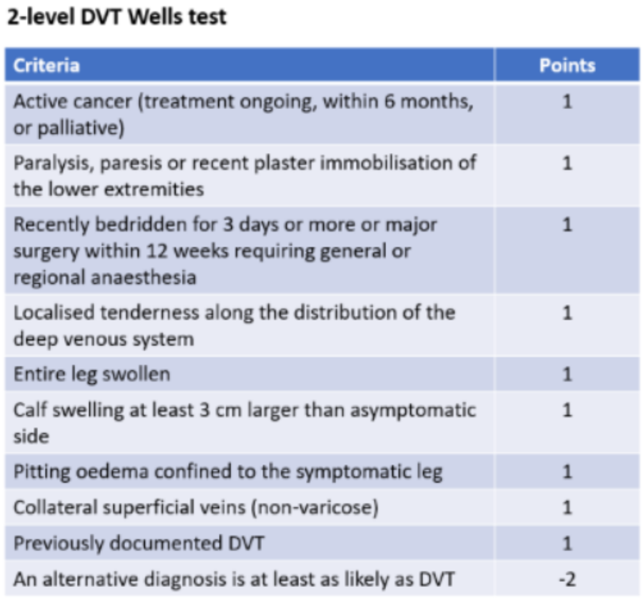
Although not a high-resolution scan, there is no evidence of fibrosis within the lung fields and therefore this answer is incorrect.

The anterior mediastinal mass shown on this CT scan is too inferior to be a thyroid cancer which would typically present as a lump in the neck. Therefore the diagnosis of thymoma is more likely and thyroid cancer is incorrect.

Question 87 of 191

A 64-year-old woman presents to her general practitioner with a one-day history of swollen left leg associated with pain. She has a past medical history of heart failure and hypertension and takes bisoprolol, ramipril, amlodipine, and furosemide. She is significantly limited in her mobility.

On examination, the left calf is red and 4cm larger than the right. There is tenderness over the deep venous system. There is bilateral, symmetrical pedal oedema. The left thigh is unremarkable.



2-level DVT Wells test

Criteria	Points
Active cancer (treatment ongoing, within 6 months, or palliative)	1
Paralysis, paresis or recent plaster immobilisation of the lower extremities	1
Recently bedridden for 3 days or more or major surgery within 12 weeks requiring general or regional anaesthesia	1
Localised tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than asymptomatic side	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented DVT	1
An alternative diagnosis is at least as likely as DVT	-2

What is the most appropriate next step?

A. CT pulmonary angiogram
B. D-dimer
C. Inferior vena cava filter
D. Lower limb venous ultrasound
E. VQ scan

D. Lower limb venous ultrasound

This woman has a 2-level Wells' score of 2 (calf swelling, tenderness over the deep venous system) for deep vein thrombosis (DVT). NICE guidance states that a score of 2 or above should be investigated by **lower limb venous ultrasound** rather than high sensitivity d-dimer testing. **CT pulmonary angiography** (CTPA) could be considered to check for a pulmonary embolus (PE) once a DVT is confirmed however this is not indicated at this stage.

High-sensitivity **d-dimer** testing is the first-line investigation for patients who have a 2-level Wells' score of less than 2. As this patient scores 2, a lower limb ultrasound should be performed and therefore this is an incorrect answer.

An **inferior vena cava filter** is a treatment for DVT, particularly in cases where anticoagulation is not an option. As a DVT has not been confirmed, this would not be the most appropriate next step.

A **VQ scan** is an alternative imaging modality to CTPA for PE however as previously discussed, prior to confirmation of a DVT and with no clinical indication, this test would not be indicated at this stage.

Question 88 of 191

A 19-year-old man presents to your clinic. For as long as he can remember, he has had a dusky discolouration that is not in keeping with the skin colour of any of his relatives, and he feels that it is becoming gradually duskier with time. He tells you that. The only medication he is taking is oral isotretinoin, for acne, which he has been taking on-and-off for four years. Auscultation of his chest was unremarkable. Oxygen saturation by pulse oximetry showed saturation of 91% and an arterial blood gas was done which showed a pO2 of 10.6kPa, FO2Hb of 65% and metHb of 30%.

What is the most appropriate treatment for this man?

A. Ascorbic acid
B. Corticosteroids
C. Methylene blue
D. Nocturnal CPAP
E. Vitamin A

Question 89 of 191

A 24 year-old medical student of Italian extraction returns from elective in India. One week after his return he presents with fever, headache, and myalgia.

Investigations are as follows:

Hb	10.1 g/dl
MCV	101.2 fl
Platelets	43 x10^9/l
WCC	6.1 x10^9/l
Na	134mmol/l
K	4.6 mmol/l
Urea	3.8 mmol/l
Creatinine	80 mol/l

ALT	44 IU/l
ALP	78 IU/l
Bilirubin	33 mol/l
Albumin	38 g/l
Thick and thin blood films	Plasmodium ovale parasites with red cells

What other blood test will be essential for the management of this condition?

A. Coomb's test
B. G6PD enzyme assay
C. Chloroquine resistance test
D. Ham's test
E. Reticuloctye count

B. G6PD enzyme assay

Primaquine can precipitate haemolysis in individuals with G6PD (glucose-6-phosphate dehydrogenase) deficiency. G6PD activity should be tested before commencing treatment. If deficient, expert advice should be sought.

Coomb's test, also known as the direct antiglobulin test (DAT), detects antibody bound to the surface of red cells and is a test for autoimmune haemolytic anaemia. A variable degree of haemolysis occurs in malaria, but is not typically autoimmune. Rather it is due predominantly to destruction of infected red cells during parasite replication and breakdown in the spleen.

Chloroquine is the first-line treatment for non-falciparum malaria. Chloroquine resistance in *Plasmodium ovale* and *malariae* is extremely rare, but has been reported for vivax. Chloroquine is inadequate for the treatment of falciparum malaria as resistance is widespread.

Ham's test was previously used for the diagnosis of paroxysmal nocturnal haemoglobinuria, a condition which causes intravascular haemolysis.

Reticulocytes are red cell precursors, which are prematurely released from the marrow in response to haemolysis. Their large size accounts for the macrocytosis which often accompanies haemolytic anaemia. An elevated reticulocyte count is an appropriate response to haemolysis in the presence of an adequately functioning bone marrow.

Question 90 of 191

A 61-year-old woman comes for review. Around one year ago she finished a 6 month course of warfarin after being diagnosed with an unprovoked, proximal deep vein thrombosis. For the past few weeks she has been experiencing 'heaviness' and 'aching' in the the same leg. This is associated with an itch and some swelling, although this seems to go down each night. Past medical history of note includes osteoarthritis and type 2 diabetes mellitus.

On examination prominent varicose veins are seen on the affected leg with some brown discolouration of the skin above the medial malleolus. There is no difference in the circumference of the calves. Her temperature is 36.9ºC, pulse 78/min and blood pressure 108/82 mmHg.

What is the most likely diagnosis?

A. Recurrence of deep vein thrombosis
B. Post-thrombotic syndrome
C. Cellulitis
D. Ruptured Baker's cyst
E. Necrobiosis lipoidica

B. Post-thrombotic syndrome

Post-thrombotic syndrome is the correct diagnosis. This chronic condition develops in approximately 20-50% of patients following deep vein thrombosis (DVT) and typically presents with symptoms including leg heaviness, aching, pruritis, and oedema that improves with elevation (such as overnight). The presence of varicose veins and skin changes (particularly brown discolouration or hyperpigmentation) above the medial malleolus are classical signs. The pathophysiology involves damage to venous valves during the initial DVT, leading to chronic venous insufficiency.

Recurrence of DVT would be less likely in this case. While unprovoked DVT does carry a higher risk of recurrence, the clinical features are different. Acute DVT typically presents with more significant unilateral leg swelling, warmth, and tenderness. The improvement in symptoms overnight and chronic skin changes point away from acute DVT.

Cellulitis can be excluded based on the presentation. Cellulitis typically presents with acute onset erythema, warmth, tenderness, and often systemic symptoms such as fever. The patient's normal temperature and chronic nature of symptoms make this diagnosis unlikely.

Ruptured Baker's cyst typically presents with acute calf pain and swelling, often following activity. The pain is usually localised to the popliteal fossa and posterior calf. The chronic nature of symptoms and venous changes make this diagnosis unlikely.

Necrobiosis lipoidica is a rare condition associated with diabetes mellitus that presents with welldemarcated, waxy, atrophic plaques, typically on the anterior shin. While this patient does have diabetes, her presentation with venous symptoms and characteristic post-thrombotic changes makes necrobiosis lipoidica an unlikely diagnosis.

Question 91 of 191

A 62-year-old gentleman with a background of Rheumatoid Arthritis, on maintenance sulfasalazine, is referred to the medical take from his GP with severe unremitting flu-like symptoms and deranged blood tests.

On examination, his temperature is 38.3 degrees celsius, heart rate 104bpm, respiratory rate 31/min and oxygen saturations 92% on room air.

His blood test reveals the following:

Hb	82 g/l
Platelets	52 * 10 /l9
WBC	18 * 10 /l9
Ferritin	50,000ng/ml
EBV Monospot test +ve	

He is initially treated as neutropaenic sepsis, with broad spectrum antimicrobials, and transferred to the intensive care unit for organ support. Unfortunately, he does not make any improvement. He is then seen by haematology who organise a bone marrow aspirate, revealing haemophagocytosis

. What is the most likely underlying diagnosis?

A. Macrophage activation syndrome
B. Drug-induced pancytopaenia
C. Atypical infection
D. Parvovirus infection
E. Felty syndrome

A. Macrophage activation syndrome

Macrophage activation syndrome is a condition characterised by excessive immune stimulation and cytokine storm in a rheumatological patient with an intercurrent EBV infection.

There is no suggestion in the question that there is a parvovirus infection and Felty syndrome would be characterised by a neutropaenia and splenomegaly. Drug-induced pancytopaenia and atypical infections would not commonly show haemophagocytosis in the bone marrow.

Question 92 of 191

A 45-year-old woman is reviewed shortly after being diagnosed with having a pulmonary embolism. Around two weeks ago she was admitted with a severe community-acquired pneumonia which resulted in her being ventilated and admitted to ITU. She responded well to intravenous antibiotics but shortly before discharge became more short-of-breath again. A CTPA was requested which showed a pulmonary embolism. She is started immediately on dalteparin.

What is the most appropriate next step?

A. Stop dalteparin. Start a direct oral anticoagulant for 6 weeks
B. Stop dalteparin. Start a direct oral anticoagulant for 3 months
C. Stop dalteparin. Start a direct oral anticoagulant for 6 months
D. Keep on dalteparin for 6 weeks
E. Keep on dalteparin for 3 months

B. Stop dalteparin. Start a direct oral anticoagulant for 3 months

As this patient developed a pulmonary embolism secondary to something (in this case severe illness with associated immobility) an anticoagulation period of 3 months is generally recommended

Question 93 of 191

A 68-year-old gentleman with known chronic lymphocytic leukaemia (CLL) is reviewed in the Haematology Clinic.

He is normally an active gentleman who enjoys playing golf 3 times per week, but he complains that he has been feeling increasingly fatigued since his last appointment 6 months previously. He states that he has not been able to play golf for several weeks and his wife tells you that he has started napping during the afternoons. His past medical history is otherwise unremarkable and he takes no regular medications.

Examination reveals a tired gentleman with marked axillary and inguinal lymphadenopathy. His abdomen is soft with mild upper abdominal tenderness. A liver edge is palpable 3cm below the costal margin and his spleen is markedly enlarged.

His full blood count today is as follows:

Hb	114 g/l
Platelets	173 * 10 /l9
WBC	30.4 * 10 /l9
Neutrophils	5.8 * 10 /l9
Lymphcytes	23.1 * 10 /l9

His lymphocyte count 2 months ago was 15.3 * 10 /l and a decision to start the patient on fludarabine, cyclophosphamide, and rituximab (FCR) chemotherapy is taken.

Given the proposed treatment strategy, which of the following prophylactic medications is it most important to start?

A. Co-trimoxazole
B. Aciclovir
C. Entecavir
D. Fluconazole
E. Penicillin V

A. Co-trimoxazole

Fludarabine is a purine analogue that prevents DNA synthesis through the inhibition of ribonucleotide reductase and DNA polymerase. It is associated with profound lymphopenia, and significantly increases the risk of opportunistic infections. Patients treated with fludarabine are at particular risk of morbidity and mortality secondary to pneumocystis pneumonia. It is essential that these patients receive regular prophylactic co-trimoxazole.

Purine analogues can lead to herpes simplex, herpes zoster, and cytomegalovirus reactivation and aciclovir is often given as prophylaxis against this. Fluconazole is also frequently given as fungal prophylaxis.

Entecavir is given to patients who are hepatitis B surface antigen (HBsAg) positive. Penicillin V is given to patients with asplenia and is not routinely used in this setting.

Pneumocystis pneumonia is the most severe complication described. Co-trimoxazole is, therefore, the most essential of the medications listed above.

Question 94 of 191

A 77-year-old lady was seen in the haematology outpatient clinic for her monthly follow-up. She has been seen in the haematology clinic for the last six months having been referred by her GP following an anomaly on her blood investigations. Overall she has been feeling well though for the last three weeks she has been feeling increasingly tired. She has noted that her appetite has been reduced for the last three months though she has not lost any weight during this time. In spite of the tiredness she is still able to lead an active life, regularly enjoying long distance rambling and gardening. She denied the presence of other symptoms, including the absence of fever or night sweats. She has a past medical history comprising asthma, hypertension, type 2 diabetes mellitus and hypercholesterolaemia for which she has been prescribed felodipine 5mg M/R OD, atorvastatin 20mg ON, Clenil modulite 2 puffs BD and metformin 500mg TDS.

Examination revealed the presence of a well elderly lady who was independently mobile. Her blood pressure was 122/82 mmHg, heart rate 82bpm and temperature 36.9 Celsius. Examination of her cardiovascular and respiratory systems revealed the presence of normal heart and breath sounds and a JVP of 3cm. Examination of her gastrointestinal and lymphatic systems revealed the presence of a smooth edge 2 fingerbreadths below the left subcostal margin and bilateral small

cervical lymphadenopathy, with the maximum node size less than 1cm. Investigations reveal the following:

Results from clinic three months ago:

Hb	112 g/l
Platelets	242 * 10 /l
WBC	22.6 * 10 /l
Neutrophils	2.1 * 10 /l
Lymphocytes	19.9 * 10 /l
Eosinophils	0.4 * 10 /l
Monocytes	0.2 * 10 /l

Renal and liver function tests were normal.

Blood film: lymphocytosis with atypical lymphocytes Bone marrow aspirate: infiltration with 25% lymphocytes

Peripheral blood flow cytometry: presence of circulating clonal B-lymphocytes expressing CD5, CD19, CD20, CD 23, and an absence of FMC-7 staining

Results from clinic on this occasion:

Hb	106 g/l
Platelets	162 * 10 /l9
WBC	34.2 * 10 /l9
Neutrophils	2.3 * 10 /l9
Lymphocytes	31.5 * 10 /l9
Eosinophils	0.3 * 10 /l9
Monocytes	0.1 * 10 /l9

What is the single next best step management step?

A. Commence prednisolone therapy
B. Commence chlorambucil therapy
C. Commence fludarabine therapy
D. Commence rituximab therapy
E. Observe in clinic and repeat tests in one month

A. Commence prednisolone therapy

This lady has chronic lymphocytic leukaemia (CLL) as manifested by the high lymphocyte count, lymphocyte marrow infiltration and evidence clinically of splenomegaly and lymphadenopathy. 70% of patients are asymptomatic and patients with stage A leukaemia as with this lady [no anaemia or thrombocytopaenia and less than 3 areas of lymphoid enlargement] have a median survival of 8 years. Treatment is therefore not indicated.

Accepted indications for treatment include:

The development of anaemia +/ thrombocytopaenia

Progressive or massive splenomegaly (6cm) +/ lymphadenopathy (10cm)

Progressive lymphocytosis [50% increase in 2 months or doubling time of less than 6 months] Systemic symptoms [fever, night sweats, weight loss >10% in 6 months, extreme fatigue]

Although this lady has been complaining of tiredness, this does not in itself constitute a 'systemic symptom' given the absence of other symptoms and her strong performance status. Her lymphocyte count is rising but does not meet the criteria for treatment at present. Should treatment be indicated, this comprises chemotherapeutic agents such as chlorambucil and fludarabine, immunological agents such as rituximab and steroids in advanced disease.

Question 95 of 191

A 32-year-old patient who is 10 weeks pregnant attends for her antenatal booking clinic. This is her first pregnancy, and she tells you she has been feeling lethargic and has a poor appetite. She has no past medical history of note.

On examination, she looks pale and appears comfortable at rest. Her chest is clear, heart sounds I&II are present and her abdomen is soft non-tender. She has some oedema of both ankles bilaterally. Her blood pressure is 111/75 mmHg and her heart rate is 79/min.

Investigations in clinics are as follows:

Hb	94 g/l
MCV	69 fl
Platelets	168 * 10 /l9
WBC	9.1 * 10 /l9
Hb electrophoresis	positive HbA2
Rhesus	negative
Blood Group	AB
Na +	139 mmol/l
K +	3.9 mmol/l
Urea	7.6 mmol/l
Creatinine	99 µmol/l

What is the single most likely underlying condition?

A. Alpha thalassaemia trait
B. Beta thalassaemia trait
C. Beta thalassemia major
D. Iron deficiency anaemia
E. Sideroblastic anaemia

B. Beta thalassaemia trait

The two main differentials in this patient who has been identified as having a symptomatic microcytic anaemia during pregnancy are iron deficiency anaemia and beta thalassaemia trait. The clue that this is beta thalassaemia trait rather than iron deficiency anaemia is that the MCV is surprisingly low for the level of haemoglobin. In iron deficiency anaemia you would expect the MCV to be much higher for a fairly modest decrease in haemoglobin.

In addition, the Hb electrophoresis shows +ve HbA2 which supports the diagnosis of beta thalassaemia trait. Of course, it would be wise to send off iron studies in this patient to assess for a coexistent iron deficiency anaemia.

Question 96 of 191

A 54-year-old gentleman is reviewed 48 hours after being admitted to his local hospital with neutropaenic sepsis. He measured his temperature at home found it to be 38.2ºC. Because of this, he called the chemotherapy helpline and he was advised to attend the emergency department who promptly admitted him under the care of the medical team.

He has a background of metastatic colorectal cancer and he has had chemotherapy ten days ago. He was started on piperacillin with tazobactam on admission. His temperature settled within 12 hours and investigations, including blood cultures, a chest X-ray, urine testing and a thorough examination did not find any source of infection. His initial neutrophil count was 0.4* 10 /l. Recent blood tests demonstrate a neutrophil count of 0.5* 10 /l. His vital parameters have all been normal since his temperature settled and he has not noticed any symptoms at any point.

What is the most appropriate management plan?

A. Convert patient to oral antibiotics and discharge
B. Keep on IV antibiotics in hospital until full course completed
C. Monitor neutrophil count in hospital and discharge when greater than 1* 109/l
D. Arrange for outpatient IV antibiotics
E. Change piperacillin with tazobactam to meropenem

A. Convert patient to oral antibiotics and discharge

The correct answer is to convert patient to oral antibiotics and discharge. This is a patient who was admitted with a fever and a low neutrophil count and therefore he was managed with empirical IV antibiotics for neutropenic sepsis. Many of these patients will not look or feel significantly unwell and in the majority of them identifying a source of the temperature can be impossible. If neutropenic they should be treated with urgent IV antibiotics and waiting for a full blood count to confirm the low neutrophil count would be inappropriate. At 48 hours the antibiotic should be reviewed and if still febrile then escalation of antibiotics should be considered If they have improved and the temperature has settled then there can be a consideration of an oral switch or if completely well can stop antibiotics altogether. NICE does not recommend keeping patients in hospital whilst waiting for their neutrophil count to improve.

Question 97 of 191

A 67-year-old gentleman presents to the emergency department following a fall. He tripped on the carpet and landed on his back. Following this he has been complaining of lower back pain, but this pain was present prior to his fall and only slightly worsened with the accident. He undergoes a CT scan which unfortunately demonstrates lytic lesions in his lumbar vertebrae. He is suspected of having multiple myeloma. He undergoes blood and urine tests which unfortunately raises further suspicion of the diagnosis. He is due to undergo a bone marrow biopsy.

What investigation prior to the biopsy can give prognostic information?

A. Serum immunofixation
B. B2 microglobulin
C. Serum corrected calcium
D. Protein electrophoresis
E. Urine electrophoresis

B. B2 microglobulin

The correct answer is B2 microglobulin. This is a patient who has unfortunately found to have multiple myeloma and is awaiting further investigation to obtain histology. B2 microglobulin elevation and fall in albumin are associated with a poor prognosis. Serum immunofixation and electrophoresis studies are useful diagnostic tools but are not as useful in terms of prognosis.

Question 98 of 191

A 45-year-old man undergoing chemotherapy mentions to the nurses that he has been feeling unwell for the last two days. He has currently having treatment for metastatic lung cancer. The nurses find that his temperature is 38.2ºC. His other observations are stable. He has been having chemotherapy via a peripherally inserted central catheter (PICC). On examination his line site appears normal, his chest his clear and his abdomen is soft and non-tender.

What is the most appropriate next step in his management plan?

A. Send a full blood count to tests neutrophil levels
B. Remove the PICC line and then observe if temperature settles
C. Remove the PICC line then discharge with IV antibiotics
D. Take blood cultures from the PICC line and peripherally then treat with IV antibiotics
E. Discharge with oral antibiotics

D. Take blood cultures from the PICC line and peripherally then treat with IV antibiotics

The correct answer is to take blood cultures from the PICC line and peripherally then treat with IV antibiotics. This is a patient on chemotherapy who has developed an asymptomatic fever at 38.2ºC. As he may be neutropenic, he should be admitted to hospital and given IV piperacillin and tazobactam, but blood cultures should be taken from any central lines that he has before doing so. If a line has more than one port then blood cultures should be taken from each port. Peripherally inserted lines should only be removed if they are shown to be the cause of infection, which is why blood cultures from these lines are important.

Question 99 of 191

A 50-year-old man is diagnosed with high-grade non-Hodgkin's lymphoma and starts his regimen of R-CHOP chemotherapy. Two days after his chemotherapy he complains of feeling increasingly weak, lethargic and generally unwell. He has developed persistent vomiting and is unable to tolerate oral fluids.

He has a history of recurrent gout but has been unable to tolerate allopurinol.

On examination, he looks unwell and pale. He seemed short of breath with a respiratory rate of 28 per minute. His temperature is 36.5ºC, heart rate 110 bpm, blood pressure 100/60 mmHg.

His heart sounds were normal. His JVP was raised by 4cm lying at 45 degrees in the bed. Examination of the chest revealed fine bibasal inspiratory crepitations. Pitting oedema was present to mid-shins bilaterally.

Abdominal examination was unremarkable.

On neurological examination, there was normal tone and sensation to all limbs. General weakness was noted.

The house officer has taken bloods:

Na+	137 mmol/L
K+	6.2 mmol/L
Urea	15 mmol/L (previously 8)
Creatinine	240 µmol/L (previously 100)
Hb	100 g/L
WBC	10.0x10^9/L
Corrected Calcium	1.95 mmol/L
Phosphate	2.3 mmol/L
Uric acid	640 mmol/L
LFTs	Normal

Chest x-ray shows congested lung fields.

ECG demonstrates tall T waves.

In view of the diagnosis which of the following is most likely to treat the hyperuricaemia? IV calcium gluconate, insulin and

A. dextrose infusion
B. Allopurinol
C. Rasburicase
D. IV fluids
E. IV electrolyte replacement

C. Rasburicase

This man has lymphoma and has presented with physical and biochemical markers suggesting established tumour lysis syndrome. He has severe electrolyte disturbance: hyperkalaemia, hypocalcaemia, hyperphosphataemia. The chest x-ray suggests pulmonary oedema and ECG indicates a degree of cardiac toxicity from the hyperkalaemia. There is also acute renal failure and hyperuricaemia.

The question asks what treatment should be used to treat the underlying condition of tumour lysis syndrome. The answer is rasburicase as he has previously been intolerant of allopurinol in the context of gout prophylaxis. All the other answers are entirely reasonable and are part of the treatment of tumour lysis syndrome but do not answer this question specifically

Question 100 of 191

An 85-year-old male is referred by the anaesthetic registrar after abnormal blood test results were noted during pre-assessment for an elective hip replacement. He is otherwise fit and well, independent with all activities of daily living and continues to drive. His past medical history includes diet controlled type 2 diabetes mellitus and hypertension. On examination, he is alert and well, reports no discomfort, pain, or non-specific malaise. No skin bruises or conjunctival pallor are noted. You note a rubbery, non-tender and firm 3cm lymph node in the left cervical chain and non-tender splenomegaly at 8cm below the costal margin. His chest is clear and normal heart sounds are noted. His blood tests are as follows, with blood tests from his GP 6 months ago in brackets:

Hb	89 (95) g/l
Platelets	78 (76) * 10 /l9
WBC	67 (32) * 10 /l9
Blood film	mature lymphocytes and smudge cells

What is the most appropriate treatment?

A. Monitor and repeat blood count in 6 months
B. Fludarabine, cyclophosphamide and rituximab treatment immediately
C. Delayed chlorambucil treatment in 6 months
D. Platelet transfusion
E. Intravenous immunoglobulin

B. Fludarabine, cyclophosphamide and rituximab treatment immediately

This patient is on the cusp of requiring immediate treatment for chronic lymphocytic leukaemia. The latest guidelines are provided by the British Committee for Standards in Haematology (BCSH) 2012 , recommending immediate treatment to commence if the patient demonstrates signs of progressive marrow failure, massive or symptomatic splenomegaly greater than 6cm below the costal margin, massive or symptomatic nodes greater than 10cm in longest diameter, progressive lymphocytosis with doubling in 6 months, autoimmune thrombocytopaenia or anaemia, or significant constitutional symptoms within the previous 6 months. It is important to note that doubling of lymphocytosis is calculated only if the initial count is greater than 30 x 109/l.

Asymptomatic patients not meeting these criteria do not benefit in long term survival when receiving immediate chlorambucil therapy versus delayed treatment . Regular blood test monitoring is more appropriate for this group of patients. Be aware that despite increased white cell counts, the mature lymphocytes are non-functional and patients are hence at increased risk of infections. Intravenous immunoglobulin may be appropriate if the patient shows features of a significant infection. Similarly, significant progressive marrow failure, demonstrated by symptomatic anaemia or thrombocytopaenia may require replacement. In this case, the patient fits criteria for immediate treatment based on his lymphocytosis doubling time and splenomegaly.

1. British Committee for Standards in Haematology (BCSH) 2012

2. Chemotherapeutic options in chronic lymphocytic leukaemia: a meta-analysis of the randomised

trials. CLL Trialists' Collaborative Group. J Natl Cancer Inst. 1999;91(10):861

Question 101 of 191

A 77-year-old female is referred to the hospitals ambulatory care clinic by her GP after 2 months of increasing generalised malaise and 'lack of energy' over the past two months. She lives with her husband and until 9 weeks ago, continued to drive and go for walks in the countryside with no limitations to her exercise tolerance. Now, she feels 'tired all the time' but denies any problems with her mood. She has no history of psychiatric disorders. Her past medical history includes hypertension (well controlled on ramipril alone), hypercholesterolaemia (well controlled on simvastatin) and chronic lymphocytic leukaemia, diagnosed 3 years ago and not requiring treatment.

On examination, she has warm peripheries with bilateral conjunctival pallor. She is alert and comfortable at rest. Non-tender lymphadenopathy in bilateral cervical chains. Her cardiovascular, respiratory, abdominal and neurological examinations are otherwise unremarkable. Her blood results are as follows:

Hb	37 g/l
MCV	87 fl
Platelets	17 * 10 /l9
WBC	44.0 * 10 /l9
Blood film	myeloblasts with elongated, needle-like cytoplasmic inclusions

Hb	72 g/l
MCV	101 fl
Platelets	70 * 10 /l9
WBC	67.0 * 10 /l9
Neut	4.0 * 10 /l9
WBC	62.0 * 10 /l9
Reticulocytes	14%
Blood film and direct agglutination test	lymphocytosis, smudge cells, reticulocytes, red cell agglutination at physiological temperature

What is the most likely cause of this patient's anaemia?

A. Cold autoimmune haemolytic anaemia 14%
B. Warm autoimmune haemolytic anaemia 75%
C. B12 deficiency anaemia 4%
D. Iron deficiency anaemia 1%
E. Microangiopathic haemolytic anaemia 6

B. Warm autoimmune haemolytic anaemia 75%

The patient presents with a borderline macrocytic/normocytic anaemia with a positive Coombs test at 37 degree temperature, suggesting an autoimmune haemolytic anaemia. The presence of red cell agglutination at a warm temperature suggests the presence of IgG on red blood cells, which in vivo leads to phagocytosis by a granulocyte: this is warm autoimmune haemolytic anaemia. Conversely, red cell agglutination at cold temperatures, typically between 0 and 4 degrees, suggests the presence of IgM and C3 component of complement, most commonly leading to direct cell lysis by the complement system: this is cold autoimmune haemolytic anaemia. A mildly raised or borderline MCV does not necessarily guarantee a macrocytic cause in this context: the high proportion of reticulocytes in the blood demonstrates increased red cell production from marrow, increasing the release of immature cells with higher corpuscular volume than mature red cells, hence the increased MCV in blood assays. Iron deficiency anaemias typically produce microcytic anaemias with target cells. Microangiopathic haemolytic anaemia (MAHA) is caused by the mechanical destruction of red cells in conditions such as thrombotic thrombocytopenic purpura, leading to fragmented red cells (schistocytes) and a typically normocytic picture with associated thrombocytopenia.

Both warm and cold autoimmune haemolytic anaemias can be idiopathic or caused by lymphoproliferative disorders. Warm agglutinins are also more commonly produced by systemic autoimmune conditions such as SLE, rheumatoid arthritis and systemic sclerosis, while cold agglutinins are also classically triggered by mycoplasma and viral infections such as infectious mononucleosis.

Question 102 of 191

A 57-year-old female presents to pre-assessment surgical clinic prior to an elective arthroscopy of her left knee that she injured while playing tennis. She is otherwise asymptomatic, has no other medical history and is a lifelong non-smoker. She drinks 10 units of alcohol per week. Recently, she has experienced hot flushes and irregular periods, which she puts down to undergoing the menopause. Examination of her cardiovascular, respiratory and abdominal systems are unremarkable.

Her blood results are as follows:

Hb	95 g/l
MCV	59 fl
Platelets	389 * 10 /l9
WBC	4.5 * 10 /l9
Red cell distribution width	13% (normal range 11.5-14.5%)
Blood film	anisocytosis, hypochromia, target cells

Which investigation is most likely to reveal the diagnosis?

A. Serum ferritin
B. Total iron binding capacity
C. Serum iron
D. Haemoglobin electrophoresis
E. Bone marrow biopsy

D. Haemoglobin electrophoresis

The patient is asymptomatic with a microcytic anaemia. Note the disproportionately lower MCV compared to the level of haemoglobin and the normal red cell distribution width: the first is a distinctive feature of thalassaemia beta minor (trait) while the second suggests that all red cells made by the marrow of similar haemoglobin quality, such as in an underlying genetic trait such as thalassaemia beta minor. In contrast, iron deficiency normally demonstrates a significant haemoglobin drop by the time MCV is at such a low value while increasing the RDW during early to mid stages of iron deficiency, as some red cells are produced normally while some are profoundly microcytic.

Diagnosis of thalassaemia beta minor is by haemoglobin electrophoresis. However, diagnosis of iron deficiency is reliant on a combination of indicators: serum iron alone is not necessarily diagnostic as it also appears in anaemia of chronic disease. Serum ferritin is perhaps the most reliable indicator of plasma and marrow iron stores but be wary that it may be increased in inflammatory states, hence mask an underlying iron deficiency anaemia. Total iron binding capacity (TIBC) is a measure of transferrin, to which iron is bound to in plasma. Again, it is a useful indicator of iron stores but can be altered by pregnancy or the oral contraceptive pill. An iron deficiency anaemia picture is generally diagnosed by a combination of all three: low serum iron, high TIBC, low ferritin.

Question 1 of 89

A 57-year-old presents with recurrent episodes of bleeding gums, nosebleeds and intermittent haematuria over the past 6 weeks. He works as an accountant, does not have any past medical history but is an active smoker of 20 pack years. He drinks occasional alcohol.

On examination, scabs and dried blood are noted on mucous membranes. No arthritis or cutaneous abnormalities are noted. The nasal bridge is unremarkable. His conjunctiva appeared pale, respiratory, abdominal and cardiovascular examination was unremarkable. His blood tests are as follows:

Na +	147 mmol/l
K +	3.2 mmol/l
Urea	7.8 mmol/l
Creatinine	70 µmol/l

What is the most likely underlying diagnosis?

A. Acute myeloid leukaemia
B. Acute lymphocytic leukaemia
C. Chronic myeloid leukaemia
D. Chronic lymphoid leukaemia
E. Myelofibrosis

A. Acute myeloid leukaemia

The diagnosis is made on blood film description of needle-like elongated cytoplasmic inclusions, known as Auer rods that are pathognomonic of acute myeloid leukaemia, with myeloblasts typical of myeloid leukaemias. Clinical features are frequently typical of cell line abnormalities secondary to marrow infiltration (shortness of breath on exertion, pallor caused by anaemia; bruising or bleeding caused by thrombocytopaenia) and infections secondary to dysfunctional white cells. Diagnosis is confirmed by bone marrow biopsy, with blast cells accounting for greater than 20% of marrow cellularity. Immunophenotyping, cytogenetic and morphological analysis guides subsequent treatment options.

Question 2 of 89

A 60-year-old female with known chronic lymphocytic leukaemia (CLL) presents with coryzal symptoms. Examination findings are unremarkable. Her blood tests are as follows:

8 months previously	Two months previously	Today	
Haemoglobin	113 g/l	108 g/l	106 g/l
White cell count	32.0 *10^9/l	50.0 *10^9/l	58.0 *10^9/l
Neutrophils	7.0 *10^9/l	4.8 *10^9/l	4.0 *10^9/l
Lymphocytes	25.0 *10^9/l	45.0 *10^9/l	54.0 *10^9/l
Platelets	358 *10^9/l	280 *10^9/l	268 *10^9/l

What is the most appropriate treatment option?

A. Chlorambucil
B. Fludarabine and chlorambucil
C. Observation
D. Prednisolone
E. Fludarabine

C. Observation

CLL is typically an indolent disease which is often managed conservatively in the first instance. Indications for treatment are multiple but include constitutional symptoms, bone marrow failure and massive lymphadenopathy. Additionally, a lymphocyte doubling time of less than 6 months is an indication for treatment, but this is not met here. Chlorambucil, fludarabine and high dose corticosteroids are all possible therapeutic options in CLL.

Question 3 of 89

A 21-year-old male is admitted to hospital after his GP identified a pancytopenia following a workup for recent fatigue and weight loss. An hour after arrival he develops a sustained nosebleed. On review, you notice oozing from his cannula sites and non-blanching purpura over his arms and legs.

What is the most likely cause of this patient's presentation?

A. Henoch-Schonlein purpura
B. Aplastic anaemia
C. Acute promyelocytic leukaemia
D. Meningococcal septicaemia
E. Idiopathic thrombocytopenic purpura

C. Acute promyelocytic leukaemia

DIC is a severe complication of acute promyelocytic leukaemia

This patient has developed disseminated intravascular coagulopathy (DIC) secondary to acute promyelocytic leukaemia (APML). This is a potentially life-threatening complication of APML that is important to be aware of in patients presenting with features of leukaemia.

Henoch-Schonlein purpura does not result in a pancytopenia or bleeding. The purpuric rash present is typically on the lower limbs and secondary to a vasculitic process. Aplastic anaemia also presents with a pancytopenia, but the features suggestive of DIC in this patient point against this as the underlying diagnosis. Meningococcal septicaemia is an important differential to consider though would not be expected to result in complete marrow suppression. Finally, idiopathic thrombocytopenic purpura causes an isolated platelet drop.

Question 4 of 89

A 25 year old man is admitted to the acute medical unit and is treated for a left lobar pneumonia. Looking through his past medical history you note he has had 3 previous admissions with similar presentations in the last 5 years. He has no other past medical history of note, apart from what he describes as 'a few' episodes of sinusitis. His blood differential, after treatment of his pneumonia, is normal. His HIV test is also negative.

What is the possible underlying diagnosis?

A. Cystic fibrosis
B. Selective IgA deficiency
C. Wiskott-Aldrich syndrome
D. Acute lymphoblastic leukemia
E. Digeorges syndrome

B. Selective IgA deficiency

Selective immunoglobulin A deficiency:

- The most common primary antibody deficiency
- Affected patients may develop recurrent chest infections, bronchitis, sinusitis or even otitis media.
- Associated with atopic disorders such as asthma and atopic dermatitis.
- Some patients may also be at risk of severe transfusion reactions.

Wiskott-Aldrich syndrome:

- Characterised by a triad of recurrent chest infections/recurrent sinus infections
- Atopic dermatitis
- Thrombocytopenia and platelet dysfunction

- Inherited as an X linked recessive condition.

Question 5 of 89

A 57-year-old man presents to his General Practitioner with persistent headaches and blurred vision. The symptoms have been present over the past six months but have worsened in recent weeks. On close questioning, the patient also reported a feeling of general fatigue and intermittent muscle aches.

One year previously, the patient had been diagnosed with obstructive sleep apnoea secondary to morbid obesity and had been provided with non-invasive ventilation to use at night. However, the patient admitted that he rarely used this equipment due to a dislike for the tight face mask. Despite dietary and lifestyle advice the patient had gained 6 kg over the past year and had a BMI of 41 kg / m².

Neurological examination including fundoscopy was unremarkable. There were no tender or inflamed joints. Blood tests requested by the GP are detailed below.

Haemoglobin	195 g/L
White cell count	7.5 * 10 /l9
Neutrophils	5.7 * 10 /l9
Lymphocytes	0.9 * 10 /l9
Platelets	195 * 10 /l9
Packed cell volume	0.60
Urea	5.9 mmol / L
Creatinine	110 µmol / L
Sodium	135 mmol / L
Potassium	4.1 mmol / L
eGFR	68 ml / min

Review of a full blood count performed 4 months previously was remarkable for previously unnoticed elevated PCV of 0.56. The patient was urgently referred to haematology for further management.

What is the most appropriate treatment for this patient's erythrocytosis?

A. Aspirin
B. Venesection
C. Hydroxyurea
D. Improved compliance with nocturnal non-invasive ventilation
E. Referral to weight management service

B. Venesection

This patient has a secondary erythrocytosis secondary to hypoxia associated with his obstructive sleep apnoea. He is presenting with significant symptoms of hyperviscosity and should be considered to be at significant risk of thrombotic complications.

Evidence from small case series suggests that erythrocytosis secondary to OSA should be treated with venesection in the presence of hyperviscosity symptoms or a PCV > 0.56. A target PCV of 0.50-0.52 has been shown to increase exercise tolerance.

Aspirin is the mainstay of treatment in polycythaemia vera and cytoreductive treatments such as hydroxyurea are used in high-risk cases.

While weight-loss and improved compliance with OSA treatment may improve erythrocytosis these interventions are likely to require significant time prior to yielding any symptomatic benefit.

Question 6 of 89

You are working in haematology. A 72-year-old man has been referred to you by the general surgeons. He recently had a CT scan for weight loss and a two month change in bowel habit. This showed no lesions within the bowel but did demonstrate some mesenteric lymphadenopathy. The largest lymph node was 4 cm in diameter. He is otherwise well and has a background of hypertension and diet controlled diabetes. He subsequently underwent a CT guided biopsy (histology report below).

The lymph node biopsied lacks a mantle zone and is made up of a predominant population of centrocytes with few tangible body macrophages. Immunohistochemistry confirms strong positivity for CD20 as well as CD70a, CD10, BCL2 and BCL6. The proliferation index (Ki-67) is low, no more than 20%.

What is the most likely diagnosis?

A. Nodular sclerosing lymphoma
B. Lymphoplasmacytic lymphoma
C. Follicular lymphoma
D. Adenocarcinoma of the large bowel
E. Diffuse large B cell lymphoma

C. Follicular lymphoma

The correct answer here can be worked out based on the Ki-67 index. This is the proliferation index and is a marker (antigen) of the cancer cells metabolic rate. In high grade lymphomas such as diffuse large B cell lymphoma the Ki-67 will be high (>45%) therefore answer 5 is wrong. In low grade lymphomas such as follicular lymphoma the Ki-67 is low (<40%).

Follicular lymphoma (a form of non Hodgkin's lymphoma) often presents as incidentally found enlarged lymph nodes and may present without the B symptoms often seen in Hodgkin's lymphoma. It can undergo a transformation at any stage into a high grade lymphoma.

Answer 1 is wrong because as it is a form of Hodgkin's lymphoma the histology report would have mentioned the presence of reed-sternberg cells. Answer 2 is Waldenstrom's macroglobulinemia and presents with an IgM gammopathy. Answer 4 is wrong because an adenocarcinoma of the large bowel would have most likely been seen on a CT scan.

Question 7 of 89

A 72-year-old woman presents to the emergency department following a fall. On examination, her right leg is shortened and externally rotated and she is unable to weight bear. A hip X-ray demonstrates a fractured neck of femur which appears pathological. She has no history of cancer. Following a dynamic hip screw insertion, she recovers well. She has blood tests sent for FBC, U&E, LDH, calcium, albumin, uric acid, serum electrophoresis, immunoglobulins and ESR. She has had a chest X-ray which was normal.

What additional tests should be requested to complete the initial investigations of the pathological nature of the fracture?

A. MRI whole spine
B. MRI hip
C. Urinary electrophoresis

D. Trephine biopsy
E. Bone marrow biopsy

C. Urinary electrophoresis

The correct answer answer is urinary eletrophoresis. This is a patient with a pathological fracture and at high risk of myeloma and needs to be fully investigated.

The following tests are needed to complete a myeloma screen:

FBC, ESR, U&E, calcium, albumin, uric acid

Serum protein electrophoresis Urine protein electrophoresis Immunoglobulin levels

Plain X-ray of symptomatic areas

If initial investigations are suggestive of myeloma then bone marrow aspirate and trephine biopsies are indicated, as well as immunofixation of the serum and urine to demonstrate the nature of the paraprotein.

MRI would be contra-indicated due to the recent operation

Question 8 of 89

A 30-year-old gentleman presents with acute lethargy and shortness of breath. He reports cutting his leg on a wooden splinter in a bench with a red area that arose in the leg and spread rapidly. Two days later his leg remained painful and he started to develop chills and was brought into the hospital by concerned family.

On examination, he is pale and clammy with a capillary refill time of 4 seconds. His chest is clear but his breathing is shallow and rapid. His heart rate is 123 beats/min and is regular while his blood pressure is 85/65 mmHg. His leg shows the cut which is now raised and red-purple with a collection of pus under the skin. His cannula site is oozing blood. He receives three litres of intravenous fluid and is started on vancomycin and gentamicin intravenously.

Hb	130 g/l
Platelets	110 * 10 /l9
WBC	34.0 * 10 /l9
CRP	459 ng/ml
PT	18 seconds
APTT	45 seconds
Fibrinogen	0.1
Chest x-ray	patchy bilateral infiltrates
Wound swab	Streptococcus pyogenes

What is the explanation of the coagulation?

A. Disseminated intravascular coagulopathy (DIC)
B. Activation of thrombin by insect venom
C. Haemodilution by intravenous fluids
D. Haemophilia A
E. Von Willebrand disease

A. Disseminated intravascular coagulopathy (DIC)

Deranged coagulation in sepsis -> DIC

This patient is acutely septic and has deranged coagulation. Haemodilution would not deplete fibrinogen severely. Haemophilia A and Von Willebrand disease have a mildly raised APTT only but normal fibrinogen level. There is no history of an insect bite making it unlikely.

DIC is a consequence of severe sepsis where the clotting cascade is activated throughout the body forming small thrombus throughout the body but depleting the clotting factors. Specifically, there is a low fibrinogen. There are rare cases of snake venom activating the clotting cascade in a manner similar to DIC but there is no recall of a snake and is rare in the UK.

Question 9 of 89

A patient has been admitted with left lower limb deep vein thrombosis. He was diagnosed by the FY1 who has efficiently started him on warfarin.

Two days after initiation you are asked to see this gentleman who has developed skin necrosis over his right thigh.

What is the most likely cause of his skin necrosis?

A. Antiphospholipid syndrome
B. Heparin induced thrombocytopenia (HIT) type II
C. Excessive serum Antithrombin III
D. Acquired haemophilia
E. Protein C deficiency

A. Protein C deficiency

Warfarin induced skin necrosis is rare but very severe. Be reminded that warfarin inhibits production of the vitamin K dependent coagulation factors including factors II, VII, IX and X but also the natural anticoagulants, proteins C and S. The first factors affected by warfarin are the anticoagulants, making warfarin temporarily pro-thrombotic during induction, in its initial few days of use and that is why it is advised to start heparin concurrently with Warfarin. Various theories have been postulated as to the cause of this problem one of which is a background of congenital or acquired protein C, S or Antithrombin III deficiency.

Question 10 of 89

A 38-year-old female presents to the emergency department with pain in her right leg, which she attributes to tripping up and landing on the floor when she went hiking with her boyfriend approximately 1 week ago. She does not recall any insect bites but has become increasingly concerned as her leg has become more swollen and tender in the calf region.

She has no significant medical history but has been recovering from an episode of pneumonia for which her GP prescribed her clarithromycin. Her only other medication is the oral contraceptive pill which she started about 1 month ago. She consumes alcohol socially at the weekends and smokes approximately 10-15 cigarettes a day. On physical exam she is afebrile and her other vital signs are within normal limits. She is able to ambulate in the emergency department without significant issues, and there are no obvious skin breakages or significant bony deformities. You note that her left leg is significantly swollen compared to the right leg and there is evidence of pitting oedema and erythema. Passive dorsiflexion of her left foot leads to significant pain.

What is the next best step in the management of this patient?

A. Obtain a doppler ultrasound scan of her left lower limb
B. D-dimer test
C. Start her empirically on oral amoxicillin for probable lower limb cellulitis
D. X-ray her left tibial and fibula
E. Reassure her and advise her to take regular paracetamol

A. Obtain a doppler ultrasound scan of her left lower limb

If a 2-level DVT Wells score is ≥ 2 points then arrange a proximal leg vein ultrasound scan within 4 hours

This patient most likely has a left lower limb deep vein thrombosis. Her important risk factors include the fact that she is taking the oral contraceptive pill and is a smoker, which combined leads to a significantly increased risk for venous thromboembolic complications. In fact, smoking is a contraindication to starting the oral contraceptive pill in females greater than the age of 35 years. In addition, physical exam findings are also concerning for a deep vein thrombosis. Although we could start investigating her by doing a D-dimer test, if this is normal she still has a high pretest probability of deep vein thrombosis and we could therefore not confidently exclude this diagnosis. Consequently, the best way to confirm or refute a diagnosis of deep vein thrombosis, in this case, would be obtaining a Doppler ultrasound scan of her leg. A D-dimer would not necessarily be wrong, but even if this returned as normal she is at considerable risk of deep vein thrombosis and should have a doppler ultrasound scan done anyway. In addition, she is being treated for pneumonia which is likely to confound the results of the D-dimer test anyway.

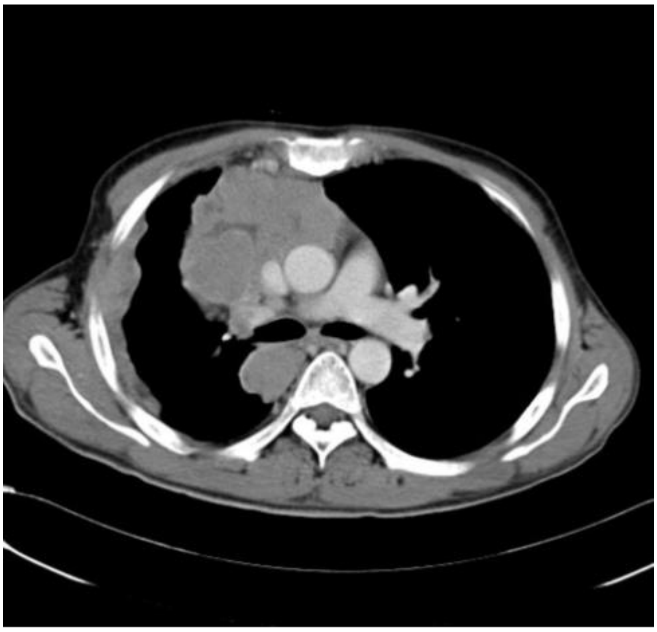
Although she does have swelling and erythema of her lower limb, she is afebrile and her clinical picture does not fit that of cellulitis.

She is ambulant and is unlikely to have sustained any significant bony injuries to her tibia and fibula, particularly as the mechanism of her injury was not very severe. Fractures of the tibia/fibula typically require a more significant mechanism of injury such as motor vehicle accidents.

It would be inappropriate to reassure her and advised her to take regular analgesia, as she is at significant risk of deep vein thrombosis and this needs to be excluded first.

Question 11 of 89

A 51-year-old man is investigated for a chronic cough, chest pain and dyspnoea. He also reports some difficult swallowing bread and meat for the past two weeks. He has no past medical history of note although has smoked for the past 30 years. A CT scan is requested:



© Image used on license from Radiopaedia

What is the most likely diagnosis? Sarcoidosis

A. Lung cancer
B. Cardiac myxoma
C. Oesophageal cancer
D. Thymoma

A. Thymoma

The CT slice at the bifurcation of the main bronchus shows an invasive thymoma presenting as an anterior mediastinal mass.

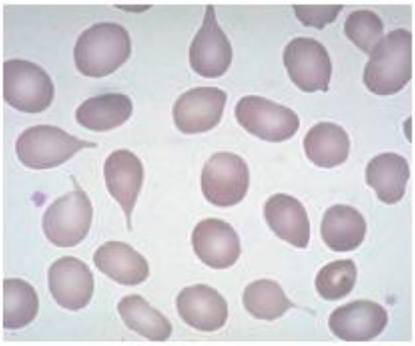
The differential diagnosis of an anterior mediastinal mass includes:

- thymoma
- lymphoma
- thyroid and parathyroid malignancies
- germ cell tumours e.g. teratomas
- thoracic aortic aneurysm

Question 12 of 89

A 77-year-old man is referred to haematology for investigation of anaemia. For several months he has been complaining of fatigue and weight loss. His GP has already arranged upper and lower gastrointestinal (GI) endoscopy which has been reported as normal.

His blood film is shown below:



What is the most likely diagnosis?

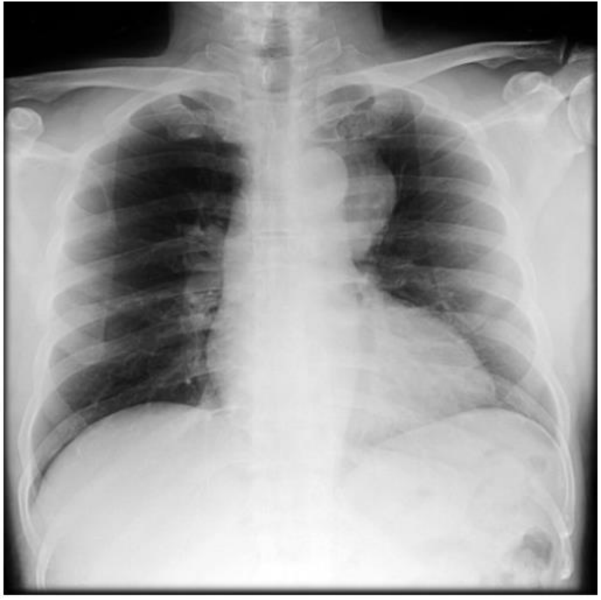
A. Chronic lymphocytic leukaemia
B. Myelofibrosis
C. Iron deficiency anaemia (bleeding from non-GI source)
D. Hyposplenism
E. Autoimmune hemolytic anaemia

B. Myelofibrosis

The blood film shows the typical 'tear-drop' poikilocytes of myelofibrosis.

Question 13 of 89

A 47-year-old man is referred to the respiratory clinic with a 3 month history of cough associated with retrosternal chest pain. A chest x-ray requested by his GP has been reported as abnormal. The chest x-ray is shown below



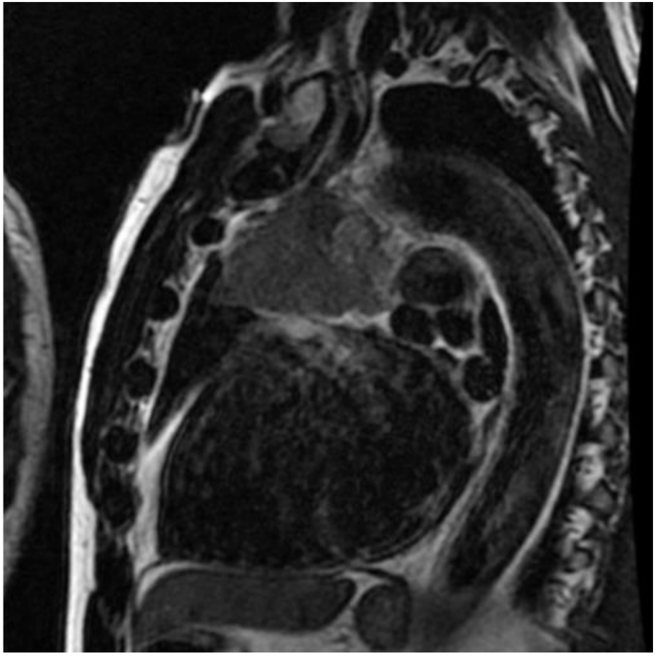
What is the most likely diagnosis?

A. Oesophageal cancer
B. Cardiac myxoma
C. Thymoma
D. Lung cancer
E. Sarcoidosis

C. Thymoma

The chest x-ray demonstrates a soft tissue density projecting to the left of the mediastinum. The distal part of the arch and proximal descending aorta can be seen as separate suggesting it is located anterior to these structures.

A MRI scan from the same patient is shown below:



MRI confirms the presence of an anterior mediastinal mass without convincing macroscopic invasion

Question 14 of 89

A 62-year-old woman presents to the haematology clinic. She has had lower back pain, which has been progressive in nature. She has also been noted to develop unexplained anaemia. Her initial protein electrophoresis and serum-free light chain assays raised suspicion of multiple myeloma. She has a past medical history of transient ischaemic attacks and hypertension. She takes clopidogrel, amlodipine and ramipril.

What imaging should be offered to further assess her?

A. Lumbosacral X-rays
B. Skeletal survey
C. Bone marrow ultrasound
D. Whole body MRI
E. PET scan

D. Whole body MRI

The correct answer is whole body MRI. NICE advises that all patients suspected to have a diagnosis of myeloma should be offered whole body MRI as first-line imaging, and only consider whole body CT if the patient declines MRI or is unable to have it. Skeletal survey should only be considered if CT and MRI are both not possible. Fluorodeoxyglucose positron emission tomography CT (FDG PET CT) can be considered once a diagnosis is confirmed

Question 15 of 89

A 69-year-old gentleman presented for routine follow-up in the oncology clinic. He has metastatic poorly differentiated adenocarcinoma of unknown primary. He commenced palliative chemotherapy with oxaliplatin and fluorouracil two months ago. The most recent CT scan demonstrated stable disease.

Ten days ago he was admitted to the local emergency department with fever and diagnosed with neutropenic sepsis, of which the cause was not clear. He was admitted for IV Tazocin for five days then discharged with co-amoxiclav and filgrastim (G-CSF). He currently feels well. On examination, there are no abnormalities.

Observations:

Saturations	95%
Respiratory rate	14/min
Blood pressure	152/83mmHg
Heart rate	69/min
Temperature	37.3°C

Blood tests:

14 days ago	Today	
Hb	135g/l	124g/l
Platelets	322* 10 /l 9	285* 10 /l9
WBC	0.2* 10 /l 9	23.6* 10 /l9

What is the most appropriate course of action?

A. Restart oral co-amoxiclav
B. Arrange admission for IV tazocin
C. Arrange admission for IV meropenem
D. Start prednisolone
E. Stop filgrastim (G-CSF)

A. Stop filgrastim (G-CSF)

The correct answer is to stop filgrastim. Filgrastim stimulates a white cell count which can increase far above the normal range, and the white cell count will return to normal once it is stopped. The key here is that the patient is clinically well, and further antibiotics are unnecessary

Question 16 of 89

A 67-year-old female presents with 4-month history of increasing lethargy and malaise. She has no past medical history and travels widely, last visiting the Middle East one week prior to this admission, returning with a respiratory tract infection that appears to be resolving. She is a lifelong non-smoker and does not drink alcohol to excess. Over the past two weeks, she reports increasing bilateral persistent headache associated with binocular visual blurring. In addition, she describes a non-specific abdominal discomfort without any changes in bowel habit.

On examination, you note bilateral axillary lymphadenopathy and conjunctival pallor. Cardiovascular and respiratory system examinations were unremarkable. Neurological examination is unremarkable. Fundoscopy reveals dilated tortuous retinal veins. Abdominal examination reveals hepatosplenomegaly. Lastly, you note areas of purpura around her left anterior shin and her right upper arm. A chest radiograph is unremarkable.

Her blood results are as follows:

Hb	87 g/l
MCV	79 fl
Platelets	190 * 10 /l9
WBC	3.4 * 10 /l9
Na +	142 mmol/l
K +	4.5 mmol/l
Urea	7.6 mmol/l
Creatinine	89 µmol/l
Adj Calcium	2.47 mmol/l
Phosphate	1.34 mmol/l
LDH	1890 (normal range 140-280 units/L)
Serum electrophoresis	IgM paraprotein band at 5.4 g/L

A bone marrow biopsy demonstrates 14% infiltration of lymphoplasmacytic cells

What is the most likely diagnosis?

A. Waldenstrom's macroglobulinaemia
B. Multiple myeloma
C. Monoclonal gammopathy of unknown significance (MGUS)
D. Chronic lymphocytic leukaemia (CLL)
E. Upper respiratory tract infection (URTI)

A. Waldenstrom's macroglobulinaemia

There is an enormous IgM paraprotein band on serum electrophoresis, immediately suggesting the differentials to narrow to Waldenstrom's macroglobulinaemia, multiple myeloma and MGUS. The patient is symptomatic, has bone marrow involvement of greater than 10% with IgM band greater than 3g/L, ruling out MGUS. The key to this diagnosis is differentiating between myeloma and Waldenstrom's: it is particularly rare (but not impossible) for an IgM-secreting plasma cell clone in myeloma but this accounts for only 0.5% of all multiple myelomas. Secondly, clinically, the patient demonstrates signs of hyperviscosity syndrome and splenomegaly, both of which are much more common in Waldenstrom's than myeloma. Thirdly, there is a lack of bone symptoms and renal involvement with normal serum calcium: bone lesions are significantly more common in multiple myeloma. Fourthly, fundoscopic tortuous and dilated veins are classical in hyperviscous patient with Waldenstrom's macroglobulinaemia. The diagnosis is clinched on bone marrow biopsy, demonstrating lymphoplasmacytic cells instead of plasma cells, confirmed by cell immunophenotyping.

CLL should not result in a paraprotein band, URTI may result in a rise in IgA but should not result in bone marrow involvement.

Question 17 of 89

A 34-year-old male presents with a 4 day history of bloody diarrhoea and vomiting, fevers and associated with occasional abdominal cramps. He reports no other symptoms. He reports no previous history of gastrointestinal disease; there is no family history of inflammatory bowel disease. He has no past medical history except for a left knee arthroscopy following an injury playing football 7 months ago. He is a lifelong non-smoker, drinks 14 units of alcohol a month, has not travelled abroad in the past year and last ate outside of his home a week ago during a barbecue at his brother's house.

On examination, he appears dehydrated. There is mild generalised abdominal tenderness with increased bowel sounds. Respiratory and cardiovascular examinations were unremarkable. His blood tests are as follows:

Hb	92 g/l
MCV	90fl
Platelets	49 * 10 /l9
WBC	14.2 * 10 /l9
Neutrophils	12.8 * 10 /l9
Blood film	schistocytes, reticulocytosis

Direct antiglobulin test	Negative
Urea	14.9 mmol/l
Creatinine	159 µmol/l
CRP	82 mg/l

What is the cause of this patient's blood abnormalities?

A. Microangiopathic haemolytic anaemia
B. Cold autoimmune haemolytic anaemia
C. Warm autoimmune haemolytic anaemia
D. Iron deficiency anaemia
E. Acute myeloid leukaemia

A. Microangiopathic haemolytic anaemia

The first recognition in this patient is the underlying syndrome: blood film with fragment red cells (schistocytes), thrombocytopaenia acute kidney injury, pyrexia and bloody diarrhoea, should strongly suggest haemolytic uraemia syndrome-thrombotic thrombocytopaenia purpura spectrum (HUS-TTP) in the absence of alternative unifying causes. In this case, gastrointestinal infection by Campylobacter from the recent barbecue, producing Shiga toxins and resulting in endothelial damage, is a strong possible culprit. The patient has a normocytic anaemia with red cell fragmentation and increased reticulocyte production, suggestive of rapid mechanical destruction and the bone marrow releasing immature red cells in (unsuccessful) compensation. This represents microangiopathic haemolytic anaemia (MAHA) in the context of HUS-TTP.

Both cold and warm autoimmune haemolytic anaemias should produce a positive direct antiglobulin test (Coombs): addition of a Coombs reagent containing antihuman globulin should agglutinate red cells IgM and IgG antibodies bound to in cold and warm autoimmune haemolytic anaemias respectively. Iron deficiency anaemia typically produces microcytic anaemias with target cells; there are no blast cells suggestive of leukaemia.

Question 18 of 89

A 23-year-old medical student went to Uganda on his elective but has had to return to the UK early due to illness. He had been careful to take malaria prophylaxis and slept under a mosquito net. He was using primaquine due to previous intolerable side effects with doxycycline. He was complaining of central abdominal pain and had noticed jaundiced sclera in the few days prior to returning to the UK. There is no relevant past medical history and he takes no regular medication. He is a non-smoker and drinks 2-4 units of alcohol weekly.

Observations show a blood pressure of 110/73 mmHg and heart rate of 98 beats per minute. He is apyrexial, has a respiratory rate of 16 per minute and oxygen saturations of 94% on room air.

On examination, he is pale and jaundiced with yellow sclera. There is no cyanosis. His chest sounds clear and heart sounds are normal with nil added. The abdomen is soft, generally tender but with no guarding or peritonism. Bowel sounds are normal.

Bloods show the following:

Haemoglobin	86 g/L	Sodium	139 mmol/L
Platelets	188 x10^9/L	Potassium	3.6 mmol/L
White cell count	11.0 x10^9/L	Urea	3.0 mmol/L
Neutrophils	8.5 x10^9/L	Creatinine	62 micromol/L
Reticulocytes	11%	Albumin	34 g/L
CRP	7 mg/L	Bilirubin	67 micromol/L
ALT	21 iu/L		
Alkaline Phosphatase	40 iu/L		

Peripheral blood film:

Heinz bodies seen with methyl violet staining.

Bite and blister cells also present.

What is the most likely diagnosis?

A. G6PD deficiency
B. Plasmodium falciparum infection
C. Mycoplasma pneumoniae
D. Hereditary spherocytosis
E. Lead poisoning

A. G6PD deficiency

This student has acute haemolytic anaemia (anaemia, reticulocytosis and raised bilirubin with normal ALT). Answers A, C, D and E are all causes of haemolytic anaemia.

The blood film is the main diagnostic tool to differentiate between these answers. Heinz bodies, bite and blister cells are all seen in acute haemolysis associated with G6PD deficiency. The acute haemolysis has been triggered by antimalarial treatment (usually primaquine).

A blood film of hereditary spherocytosis shows spherocytes and reticulocytes. In lead poisoning, there should be dimorphic cells with ring granules on Perl's staining.

Plasmodium falciparum is a common form of malaria that multiplies in the liver. Infection with this can cause anaemia with abnormal liver function tests (LFTs). Persons with G6PD deficiency are somewhat protected from infection with *Plasmodium falciparum* and *Plasmodium vivax* malaria.

G6PD deficiency is X-linked and is more prevalent in Mediterranean populations.

Question 19 of 89

A 51-year-old man presents with dysuria and a low grade fever. He is prescribed a course of Nitrofurantoin for a suspected urinary tract infection. He has a history of ischaemic heart disease for which he takes aspirin and atorvastatin. The following day, he notices that his urine has become very dark and he feels breathless and more unwell.

Bloods show:

Hb	78 g/L
WCC	14.1 x 10^9/L
Neutrophils	13 x 10^9/L
Platelets	280 x 10^9/L
Bilirubin	87 mg/dL
ALT	45 IU/L
Alkaline phosphatase	73 IU/L
Urea	5 mmol/L
Creatinine	80 µmol/L

Blood film microscopy comments on the presence of Heinz bodies.

What is the underlying diagnosis?

A. Hereditary spherocytosis
B. Paroxysmal nocturnal haemoglobinuria
C. Haemolytic uraemic syndrome
D. Urinary sepsis secondary to E. coli
E. Glucose-6-phosphate dehydrogenase deficiency (G6PD)

A. Glucose-6-phosphate dehydrogenase deficiency (G6PD)

The blood tests reveal anaemia with a bilirubin rise, which indicates haemotlyic anaemia. Heinz bodies are red cell inclusions consisting of denatured Hb; they are a feature of oxidative stress. Nitrofurantoin is one of many drugs that can cause haemolytic crisis in G6PD deficiency. Heinz bodies would not usually be seen on the blood films of the other conditions.

Question 20 of 89

A 26 year old female who is 14 days post-partum (spontaneous vaginal delivery) presents to your medical admissions unit with her partner who is worried that she is confused. She is unable to provide any history but her partner tells you that she has gradually gotten worse over the past few days. Her observations are as follows: temperature 38ºC, pulse 90/min, blood pressure 154/88 mmHg, respiratory rate 16/min, sats 99% on room air.

On examination, she looks pale. Her chest is clear and abdomen is soft, non-tender. She has multiple bruises on her arms. Her blood results are pending.

What is the most likely diagnosis?

A. Haemolytic uraemic syndrome
B. Thrombotic thrombocytopenic purpura
C. Idiopathic thrombocytopenic purpura
D. Retained products of placenta
E. Disseminated intravascular coagulation (DIC)

B. Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura is associated with fever, anaemia, thrombocytopenia, renal failure and confusion. Pregnancy and the post-partum state account for about 20% of cases seen.

Haemolytic uraemic syndrome is not associated with fever and confusion. Retained products of placental is more unlikely as her abdomen is soft, non-tender. DIC would be a differential diagnosis but is not the most likely diagnosis here. Idiopathic thrombocytopenic purpura would not cause confusion.

Question 21 of 89

A 52-year-old female with acute lymphoblastic leukaemia in on her third cycle of chemotherapy. She is admitted to the ward after developing a temperature of 38.7ºC before her fourth cycle. She feels well in herself but has ongoing trouble with diarrhoea and mucositis. At present, her stools are type four on the Bristol stool chart and her mouth ulcers are being treated with a lidocaine/nystatin topical solution. She denies any cough, sore throat or urinary symptoms.

On examination, her abdomen is soft and non-tender with normal bowel sounds. Her chest is clear with air entry heard throughout. She has no murmurs, joint effusions or areas of cellulitis. Her mouth contains multiple ulcers with areas of straw colored exudate overlying them.

Hb	110 g/l
Platelets	60 * 10 /l9
WBC	1.1 * 10 /l9
Neuts	0.5 * 10 /l9
Blood culture (1st)	Staphylococcus epidermidis
Blood culture (2nd)	no growth
Chest X-ray	clear lung fields, normal cardiac contour
Nasopharyngeal PCR	negative
Urine dip	negative for leucocytes and nitrites

Which investigation is most likely to elicit the cause of the fever?

A. Sputum culture
B. Urine culture
C. Blood culture
D. Stool sample
E. Swab mouth ulcer

A. Swab mouth ulcer

Mucositis can be a source of neutropenic sepsis

This patient has neutropenic sepsis of unknown source. In neutropenic patients, almost any site

can be the source. From the history there is diarrhoea but her stools are currently normal. There

are no urinary symptoms and the dipstick is normal making the urine unlikely to culture an

organism. Ideally, three blood cultures should be completed in pyrexia of unknown origin so this is

a useful suggestion. Sputum culture is impossible if there is no productive cough and would need

to be induced by bronchoscopy.

Importantly, we are told there are mouth ulcers and this represents a break in the protective lining

through which oral commensal bacteria can enter the blood stream and trigger sepsis. Therefore,

a swab should be taken for bacterial culture and for viral PCR from the ulcer site.

Question 22 of 89

A 45-year-old lady presents to the Emergency Department progressive shortness of breath for the last three days. It is worse on activity but is not associated with any cough or wheeze. She has a past medical history of asthma and HIV, for which takes antiretroviral medication regularly. At her last clinic appointment two weeks ago, she was found to have oral candida and so was given a 2 week course of nystatin and started on dapsone for prophylaxis of pneumocystis jirovecci pneumonia. She is a non-smoker.

On examination, her lips and nail beds have a bluish tinge and she is visibly breathless. Her respiratory rate is 26 per minute and on pulse oximetry her saturations are 91% on air both at rest and on exercise. Her temperature is 36.5ºC and she has not felt feverish. On auscultation she has vesicular breath sounds with minimal wheeze and normal heart sounds with no murmurs. She has no ankle oedema and JVP is not raised. There is no evidence of oral candidiasis and no lymphadenopathy. Her calves are soft and non-tender.

A chest x-ray shows clear lung fields with no focal consolidation or lymphadenopathy. ECG is sinus rhythm at 90 beats per minute with normal complexes throughout.

Arterial blood gas on air:

pH	7.51
PaO2	13.7 kPa
PaCO2	3.34 kPa
HCO3-	22.1 mmol/l
BE	-3.3 mmol/l
sO2	97%
Hb	113 g/l
Na+	143 mmol/l
K+	3.7 mmol/l
Glu	5.2 mmol/l
Lac	1.9 mmol/l

What is the most likely diagnosis?

A. Acute asthma
B. Carbon monoxide poisoning
C. Methemoglobinemia
D. Pneumocystis jirovecii pneumonia
E. Pulmonary embolus

C. Methemoglobinemia

This lady has shortness of breath with low saturations on pulse oximetry but normal PaO2 and saturations on arterial blood gas. This combined with a bluish discolouration and normal chest examination point towards a diagnosis of methemoglobinaemia, a known side effect of the dapsone on which she has been started.

In exacerbation of asthma, one would expect wheeze and a low PaO2. Carbon monoxide poisoning typically results in cherry red appearance. This lady does not have any history of suggest pulmonary embolus and one would again expect a low PaO2, associated with a tachycardia. Pneumocystis pneumonia would be unlikely on prophylaxis, and there may be x-ray changes and drop in saturations on exercise.

Question 23 of 89

A 44 year old female patient is admitted to the oncology ward to undergo chemotherapy for Diffuse Large B-Cell lymphoma stage IVb. She had originlly presented to her GP with intermittent abdominal bloating and constipation and occasional shortness of breath. She also reported having to often get up in the middle of the night to change the bed clothes due to drenching sweats. Her GP had been concerned by these symptoms and had organised an immediate chest X-ray to be undertaken at the nearby hospital.

Chest X-ray

large mediastinal mass with clear lung fields.

On receiving this report the GP arranged an urgent appointment with a local haematologist as he suspected that the patient was suffering from lymphoma. She was seen only 4 days later. Given the clinical history the team at the hospital arranged some urgent investigations.

Hb	9.5 g/dl
Platelets	140 * 10 /l9
WBC	36.5 * 10 /l9
Lactate Dehydrogenase	2540IU/l

CT-guided Lymph node biopsy

cells are large, with prominent nucleoli and abundant cytoplasm and many mitoses expressing

CD19 and CD20 markers

PET scan

large extra-nodal disease bulks most notable in the ileo-caecal area and in the mediastinum. Overall bulky disease in keeping with the diagnosis of advanced stage lymphoma.

The patient is admitted to receive cycle one of R-CHOP chemotherapy under close monitoring.

What electrolyte abnormalities would suggest tumour lysis syndrome?

A. High Potassium, high Calcium, low Phosphate
B. Low Potassium, high Calcium, low Phosphate
C. High Potassium, low Calcium, high Phosphate
D. Low Potassium, low Calcium, high Phosphate
E. Low Potassium, low Calcium, low Phosphate

C. High Potassium, low Calcium, high Phosphate

Question 24 of 89

A previously healthy 68-year-old male patient is referred by his GP to the general medical clinic. He has mixed symptoms of pain in multiple areas, including his upper arm, neck and legs. This has worsened over a period of months and seems not to have been helped with multiple analgesics, including paracetamol, codeine phosphate and ibuprofen. In this time the patient has also become increasingly short of breath.

A full work up is undertaken and the results are shown -

Hb	9.4 g/dl
Platelets	174 * 10 /l9
WBC	8.4 * 10 /l9
Na +	136 mmol/l
K +	4.7 mmol/l
Urea	8.4 mmol/l
Creatinine	125 µmol/l
Corrected calcium	2.9mmol/l
Albumin	34g/L

Kappa light chains detected Lambda light chains absent

IgG elevated IgA normal IgM normal

Urine Bence Jones proteins detected

Skeletal survey multiple osteolytic lesions seen throughtout axial skeleton including on the right humerus, thoracic spine and both femurs.

Given the presumed diagnosis, what tests are most relevant for staging of the condition?

A. Calcium, x-rays and creatinine
B. Free light chain level
C. Renal function
D. B2-microglobulin and albumin
E. Haemaglobin and albumin

D. B2-microglobulin and albumin

The diagnosis here is multiple myeloma. Myeloma is a plasma cell dyscrasia that is more common in men than women. It is most common in elderly populations. The affects of myeloma can easily be remembered by the tetrad of high calcium (c), renal disease (r), anaemia (a) and bone pain (b) (crab). The original staging system was known as the Durie-Salmon Staging system which was developed in 1975. It is still commonly used as a supplementary measure but it's role in staging has been replaced by the International Staging System (ISS) that was implemented by the International Myeloma Working Group in 2005.

Question 25 of 89

A 70 year-old woman presents with severe back pain which has been worsening over the last month. Prior to this she has never suffered from back pain. She has been lethargic, and her husband notes some intermittent confusion. A systemic enquiry reveals long standing exertional breathlessness, and constipation. She has no other bowel or bladder disturbance.

Her background includes chronic obstructive pulmonary disease, which is managed by her GP. She gave up smoking two years ago. Her well woman check up 12 months ago was entirely normal, aside from a slightly raised cholesterol which is being management with diet.

On examination, she has a normal gait. There is some mild tenderness over L3/L4 vertebra with no lower limb neurological deficit. Cardiorespiratory examination reveals an ejection systolic murmur, with a normal second heart sound.

Hb	90 g/l	Na +	135 mmol/l	Bilirubin	5 µmol/l
Platelets	200* 10 /l 9	K +	5.5 mmol/l	ALP	101 u/l
WBC	10 * 10 /l 9	Urea	15 mmol/l	ALT	40 u/l
Neuts	8 * 10 /l 9	Creatinine	230 µmol/l	corrected calcium	2.7 u/l
ESR	40 mm/hr				

What is the most likely diagnosis?

A. Multiple myeloma
B. Monoclonal gammopathy of undetermined significance
C. Non-Hodgkin's, lymphoma
D. Paget's disease
E. Renal cell carcinoma with spinal metastases

A. Multiple myeloma

Multiple myeloma is malignant proliferation of plasma cells, producing a monoclonal protein detected in blood and/or urine; this causes organ or tissue damage. The median age of presentation is 70 years old.

Presenting clinical features include symptoms of:

Impaired renal function- from light chain deposition from plasma cells, other causes include amyloid deposition, dehydration, hypercalcaemia, hyperviscosity, and nephrotoxic drugs Anaemia

Hypercalcaemia- myeloma cells cause an increased production of osteoclast activating factors and cytokines that inhibit osteoblast differentiation

Recurrent infections- decreased humoral immunity

Hyperviscosity symptoms (headaches, epistaxis, blurred vision, and confusion)- high paraprotein levels

Bone pain

Monoclonal gammopathy of undetermined significance (MGUS) is an asymptomatic condition thought to precede multiple myeloma.

Question 26 of 89

Matthew is an 18-year-old man presenting with diarrhoea. The diarrhoea has been ongoing for the past 7 days and his stool is described as a type 6-7 stool on the Bristol stool charts. He did not note any blood or mucous accompanying his diarrhoea. There is accompanying crampy abdominal pains and he noted a fever of 38.2ºC yesterday. He did not note any accompanying weight loss but has been feeling tired over this period.

The abdominal examination was unremarkable. He is not sexually active at present.

He has been hospitalized approximately 5-6 times in the last 3 years with recurrent infections. From his previous medical notes, his last admission related to a chest infection. He had a dry cough and shortness of breath during this time. Oxygen saturation measured on admission was 96% but quickly decreased to 89% on exertion with bilateral opacification noted on chest X-rays.

Stool cultures had been taken and on Ziehl-Neelsen staining, red oocysts are visible within the stool culture. Blood tests taken reveals:

Hb	150 g/L	Male: (135-180)Female: (115 - 160)
Platelets	250 * 10 /L 9	(150 - 400)
WBC	4.5 * 10 /L 9	(4.0 - 11.0)
Neuts	1.1 * 10 /L 9	(2.0 - 7.0)
Lymphs	2.5 * 10 /L 9	(1.0 - 3.5)
Mono	0.6 * 10 /L 9	(0.2 - 0.8)
Eosin	0.3 * 10 /L 9	(0.0 - 0.4)

Immunoglobulin studies were carried out and this revealed reduced levels of IgG and IgA but IgM levels were normal.

What is the most likely unifying diagnosis for his symptoms?

A. Brunton's agammaglobulinemia
B. Chediak-Higashi syndrome
C. Selective IgA deficiency
D. Hyper IgM syndrome
E. Wiskott-Aldrich syndrome

D. Hyper IgM syndrome

Hyper IgM syndrome characteristically presents with infections e.g. *Pneumocystis* pneumonia, hepatitis, diarrhoea

Hyper IgM syndrome is a rare X-linked inherited immunodeficiency that presents with multiple infections throughout their life and typically presents in infancy. It is common to see opportunistic infections as described above as cryptosporidiosis and *Pneumocystis jirovecii* pneumonia. Definitive testing requires flow cytometry to identify the lack of expression of CD40 on T-cells or molecular genetic testing to identify a pathogenic variant on the CD40LG gene. However, findings of neutropenia and reduced IgG and IgA with normal or elevated IgM levels in patients presenting with recurrent, chronic infection highly suggests this diagnosis.

Chediak-Higashi syndrome presents with recurrent infections but this tends to be caused by more common pathogens with recurrent *Staph aureus* being the most common. It is also accompanied by other findings including albinism, photophobia and peripheral neuropathy during teenage years.

Selective IgA deficiency patients tend to be asymptomatic. However, patients can present with recurrent sinopulmonary infections and gastrointestinal infections. It is unlikely in this case due to low IgG levels as selective IgA deficiency will typically have normal IgG levels.

Brunton's agammaglobulinemia will also present with recurrent bacterial infections but investigations will reveal a generalized reduction in all immunoglobulin levels. Definitive tests include genetic testing for mutations within the BTK gene.

Wiskott-Aldrich syndrome typically presents with symptoms bruising and petechiae with eczema during the 1st month of life. Investigations will show thrombocytopenia and immunoglobulin tests will show reduced IgM but elevated IgA and IgE with normal IgG levels. Note that these patients are at increased risk of autoimmune conditions and haematology malignancy.

Question 27 of 89

A 54-year-old woman presents to the emergency department. She has noticed a sore throat over the last 24 hours and checked her temperature and found it to be 38.2ºC. Her other observations are all normal. She has had no other symptoms and specifically denies coughing, chest pain, dysuria and diarrhoea. She is currently undergoing chemotherapy for breast cancer having last had treatment six days ago.

What is the most appropriate treatment?

A. Confirm neutropenia before treatment
B. IV co-amoxiclav and oral clarithromycin
C. Oral metronidazole
D. IV piperacillin with tazobactam
E. IV gentamicin

D. IV piperacillin with tazobactam

Piperacillin with tazobactam (Tazocin) is the empirical antibiotic of choice for neutropenic sepsis

The correct answer is IV piperacillin with tazobactam. This is a patient who is likely to have a low neutrophil count as she has recently had chemotherapy. Such patients should be treated as neutropenic sepsis if there is a temperature above 38ºC or any other sign of sepsis, and need immediate IV piperacillin with tazobactam. Some units use vancomycin as well at this point. This should be given before confirming the neutropenia as that would cause an unnecessary delay. IV gentamicin would be generally used for pyelonephritis, whilst IV co-amoxiclav and oral clarithromycin would be used for a severe community acquired pneumonia.

Question 28 of 89

A 62-year-old man had a routine set of blood tests performed by his General Practitioner. These demonstrated an erythrocytosis (Packed Cell Volume 0.56) but no other abnormality. Further questioning by the GP found that the patient had no symptoms of hyperviscosity, was a nonsmoker with no symptoms of daytime somnolence and took no regular medications. Past medical history included only a left knee hemiarthroplasty performed due to osteoarthritis.

Two weeks after the initial blood test, the patient's bloods were repeated and showed the persistence of the erythrocytosis. A referral to haematology clinic was made for further investigation. Details of further investigations arranged through haematology clinic are listed below.

Haemoglobin	188 g / L
White cell count	6.7 * 10 /l
Neutrophils	3.2 * 10 /l
Lymphocytes	2.1 * 10 /l
Monocytes	0.8 * 10 /l
Eosinophils	0.3 * 10 /l
Basophils	0.3 * 10 /l
Platelets	202 * 10 /l
Packed cell volume	0.59
Urea	4.5 mmol / L
Creatinine	97 micromol / L
Sodium	140 mmol / L
Potassium	3.9 mmol / L
eGFR	85 ml / min
Ferritin	80 ng / ml
Albumin	38 g / L
Alkaline phosphatase	89 U / L
ALT	25 U / L
Bilirubin	20 micromol / L
JAK 2 V617F mutation	Negative
Serum erythropoietin	0 U / L (reference 0-19)

Blood film: no abnormality detected; no features of myeloproliferative disease Abdominal ultrasound: liver, hepatic duct system and gallbladder unremarkable; mild-moderate splenomegaly; kidneys and renal tract unremarkable

What is the most appropriate next investigation?

A. JAK2 exon 12 mutation testing
B. Bone marrow aspiration and trephine biopsy
C. Measurement of red cell mass
D. CT brain
E. Erythropoietin receptor gene analysis

A. JAK2 exon 12 mutation testing

Erythrocytosis is defined as a haemoglobin > 18.5 g / dL or PCV > 0.52 (male) / 0.48 (female). Patients with a persistent erythrocytosis without a clear cause (i.e. chronic hypoxia or drug causes) should be referred to haematology for further investigation. An urgent referral should be made if symptoms of hyperviscosity or polycythaemia (raised PCV, white cells and platelets) are present.

More than 95 % of individuals with polycythaemia vera test positive for the JAK 2 V617F mutation. Other baseline investigations include a blood film to exclude myeloproliferative disease, renal and liver profiles and serum ferritin (as iron deficiency can mask the degree of erythrocytosis). Abdominal ultrasound is performed in patients with high suspicion for polycythaemia vera as this condition is associated with radiographical splenomegaly in two-thirds of cases.

A low serum erythropoietin is suggestive of primary bone marrow disease even in the absence of JAK 2 mutation and should prompt testing for the rarer exon 12 mutation of JAK 2. This test should be performed before the more invasive bone marrow biopsy.

Raised serum erythropoietin should prompt investigation for an exogenous source, for example, CT brain to look for a cerebellar haemangioma or meningioma.

Question 29 of 89

A 78-year-old man presents to the acute medical unit with a 3-day history of lower limb weakness. He has a 6-month history of progressive back pain. He denies any bowel or bladder dysfunction, and saddle anaesthesia.

Blood results are as follows:

Hb	110 g/L	Male: (135-180) Female: (115 - 160)
Platelets	182 * 10 /L 9	(150 - 400)
WBC	6.8 * 10 /L 9	(4.0 - 11.0)
Na +	134 mmol/L	(135 - 145)
K +	5.1 mmol/L	(3.5 - 5.0)
Urea	16.2 mmol/L	(2.0 - 7.0)
Creatinine	288 µmol/L	(55 - 120)
Paraprotein	No paraprotein detected	
Kappa free light chains	12,450 mg/L	(3.3 - 19.4)
Lambda free light chains	125 mg/L	(5.7 - 26.3)
Kappa to Lambda ratio	99.6	(0.26 - 1.65)

An MRI spine confirms cauda equina syndrome due to a large paravertebral soft tissue mass. In addition, there is widespread abnormal marrow involvement throughout the spine.

What is the most likely diagnosis?

A. High grade B cell lymphoma
B. Multiple myeloma
C. Prostate carcinoma
D. Solitary bone plasmacytoma
E. Solitary extra medullary plasmacytoma

B. Multiple myeloma

In approximately 1-2% of myeloma cases, the myeloma cells produce very low amounts of paraprotein, which can only be detected using the serum free light chain test. This is called oligosecretory myeloma

The diagnosis is most certainly **multiple myeloma** due to evidence of a monoclonal plasma cell population (markedly raised kappa to lambda ratio) and myelomatous end-organ dysfunction (e.g. anaemia, renal dysfunction and diffuse bone involvement). Although the paraprotein is negative, in approximately 1-2% of myeloma cases, the myeloma cells produce very low amounts of paraprotein, which can only be detected using the highly sensitive serum free light chain test.

Light chains are secreted by B-cells and plasma cells. Individual B- or plasma cells possess either kappa or lambda light chains, but never both together. Interpretation of serum free light chains (sFLC) can be confusing. It is important to remember that it is the ratio that is the most important aspect of the analysis. Several diseases can give rise to increased absolute levels of sFLC. For example due to decreased excretion as seen in renal failure, or due to increased production (e.g. infections, or inflammatory conditions). These 'reactive' causes will result in a broadly similar increase in both kappa and lambda light chains thereby maintaining a normal ratio. However, in monoclonal conditions, the B-cell or plasma cell clone will be either lambda or kappa light chain restricted subsequently resulting in an abnormal ratio.

The large soft tissue mass likely represents an extramedullary plasmacytoma. However, the diagnosis of a **solitary extramedullary plasmacytoma** is excluded given that the patient has myelomatous end-organ dysfunction and involvement of the axial skeleton.

Similarly, a **solitary bone plasmacytoma** is excluded due to the absence of a bone plasmacytoma and the presence of myelomatous end-organ dysfunction.

Although lymphomas can present with soft tissue masses and produce light chains, the clinical features (e.g. anaemia and renal impairment) are more in keeping with myeloma, making a **highgrade B cell lymphoma** less likely.

Prostate carcinoma classically presents with sclerotic bone metastases, and would not cause an abnormal serum free light chain ratio.

Question 30 of 89

A 72-year-old man attends the emergency department with a headache and blurred vision which has progressively worsened over the past 2 weeks. On examination, his observations are within normal limits, and he has no focal neurology. On fundoscopy, there is bilateral retinal vein dilation and tortuosity with visible retinal haemorrhages.

Blood results are as follows:

Hb	90 g/L	Male: (135-180)Female: (115 - 160)
Platelets	110 * 10 /L 9	(150 - 400)
WBC	4.8 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	10.8 mmol/L	(2.0 - 7.0)
Creatinine	184 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)

Plasma viscosity	4.2mPas	(1.50 -1.72)
IgG	1.2 g/L	(6-16)
IgM	42 g/L	(0.4 - 2.5)
IgA	0.2 g/L	(0.8 - 3.0)

Given the likely diagnosis, what treatment is urgently indicated?

A. Chemotherapy
B. Ibrutinib
C. Plasma exchange
D. Red cell transfusion
E. Steroids

C. Plasma exchange

Patients with Waldenstrom's macroglobulinaemia often present with issues secondary to hyperviscosity

The patient has clinical features of hyperviscosity (e.g. headache, blurred vision, and renal impairment). This is confirmed biochemically with the raised plasma viscosity. The fundoscopic appearances (bilateral retinal vein dilation and tortuosity with retinal haemorrhages) are also classic for hyperviscosity within the retinal vasculature.

The markedly raised IgM level is suggestive of Waldenstrom's macroglobulinaemia.

The presence of anaemia and thrombocytopenia are most likely due to bone marrow infiltration. However alternative causes should also be considered (e.g. autoimmune haemolytic anaemia, and immune thrombocytopenia).

Plasma exchange is correct. Hyperviscosity is a haematological emergency and the patient thus needs emergency plasma exchange. Plasma exchange is an extra-corporeal technique able to remove macromolecules (e.g. IgM) from blood.

Chemotherapy is incorrect. Although the patient will most certainly need chemotherapy to treat their underlying disorder, the first priority is to treat the hyperviscosity by reducing the IgM level with plasma exchange.

Ibrutinib is incorrect. Ibrutinib is a type of tyrosine kinase inhibitor (TKI) that is highly efficacious in a variety of haematological malignancies. It is less toxic compared to traditional chemotherapies and is therefore often used as a first-line agent in frail elderly patients. It can also be used in Waldenstrom's macroglobulinaemia however at the current time the priority is for plasma exchange.

Red cell transfusion is incorrect. Although the patient is anaemic, they most certainly should not receive a red cell transfusion at the current time as this could worsen the hyperviscosity.

Steroids is incorrect. Steroids are often used as chemotherapy adjuncts to treat Waldenstrom's macroglobulinaemia, however at the current time the priority is for plasma exchange.

Question 31 of 89

A 35-year-old woman who was diagnosed with hereditary angioedema is about to undergo an elective meniscal repair for her left knee. She has been well otherwise with no recent changes to her health or medications.

Which is the drug of choice for prophylaxis for her hereditary angioedema prior to her procedure?

A. Prednisolone
B. Hydrocortisone
C. Conestat alfa
D. Tranexamic acid
E. Icatibant

D. Tranexamic acid

The best answer here is tranexamic acid.

In hereditary angioedema, the relevant medications can be used as follows:

A C1-esterase inhibitor can be used for short-term prophylaxis before procedures or to terminate acute attacks of hereditary angioedema. Conestat alfa and icatibant are licensed for the treatment of acute attacks of hereditary angioedema in adults with C1-esterase inhibitor deficiency. Tranexamic acid and danazol are used for short-term and long-term prophylaxis.

There is no role of glucocorticoids in this case

Question 32 of 89

A 65-year-old woman presents to the emergency department with a painful leg. She had noticed that her calf started to become tender when she was getting dressed in the morning and found it to be swollen. She was concerned and called her GP surgery who gave her an emergency appointment. She was seen by her GP earlier in the day who suspected a deep vein thrombosis and advise her to attend her local emergency department.

She has a past medical history of breast cancer which was operated on three months ago with a wide local excision, and she has been told that the operation was successful in removing the cancer. Her observations are stable. On examination, she has a swollen left calf which is mildly tender without erythema. A D-dimer sent by the emergency department team was positive but all other blood tests are normal. She undergoes a doppler ultrasound scan which shows no thrombus.

How should she be further managed?

A. Start warfarin
B. Repeat ultrasound scan within 6-8 days
C. CT pulmonary angiogram
D. Start treatment dose low-molecular weight heparin
E. Repeat D-dimer

B. Repeat ultrasound scan within 6-8 days

The correct answer is to repeat the ultrasound scan within 6-8 days. This is a patient with a major risk factor for deep vein thrombosis (DVT) and pulmonary embolus (PE) who presents with typical features of a DVT; unilateral tender and swollen calf. She would likely have a Well's score at 2 and be considered at high risk.

Since the ultrasound is negative, a repeat ultrasound is advised, and there as of yet no indications to start treatment with either warfarin or heparin. In patients with cancer warfarin is not recommended as treatment for DVT or PE. A CT pulmonary angiogram is not indicated as there are no symptoms or signs suggestive of a pulmonary embolus. Repeating the D-dimer is unlikely to give any additional information.

'Venous thromboembolic diseases: diagnosis, management and thrombophilia testing' Clinical guideline [CG144]. The National Institute for Health and Care Excellence, June 2012.

Question 33 of 89

A 44-year-old female is referred to haematology outpatients with fatigue, shortness of breath and abnormal blood results organized by her general practitioner. She has no past medical history and is on no medications. She does not smoke or drink alcohol. She works in a bakery.

Clinical examination is unremarkable. Blood tests:

Hb	101 g/L	Male: (135-180)Female: (115 - 160)
Platelets	111 * 10 /L 9	(150 - 400)
WBC	14.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)

A blood film is organized, which demonstrates Auer rods. What is the most likely diagnosis?

A. Acute lymphocytic leukaemia
B. Acute promyelocytic leukaemia
C. Chronic lymphocytic leukaemia
D. Chronic myeloid leukaemia
E. Thrombotic thrombocytopenic purpura

B. Acute promyelocytic leukaemia

Auer rods on blood film strongly suggests acute promyelocytic leukaemia

Acute lymphocytic leukaemia is incorrect. Auer rods are not typical of the peripheral blood film in this condition. It may show blast cells in this case or it may be normal if the cells are confined to the bone marrow.

Chronic myeloid leukaemia is incorrect. The blood film in this case would not demonstrate Auer rods but rather a significant leucocytosis consisting of the whole spectrum of mature granulocytes. Organomegaly and lymphadenopathy are common.

Chronic lymphocytic leukaemia is incorrect. This typically affects an older age range with a significant lymphocytosis. The blood film may show 'smear' cells.

Thrombotic thrombocytopenic purpura is incorrect. Clinically this is often characterized by confusion, headache, fever and bruising. It is a medical emergency. The blood film will show schistocytes.

Question 34 of 89

A 58-year-old male is referred to the haematology outpatient department with reports of widespread bruising. He does not have any significant past medical history and does not take any regular medications. He does not smoke or drink alcohol.

On examination, there are widespread ecchymoses affecting all of his limbs, abdomen and thorax. Blood tests:

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	167 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Activated partial thromboplastin time (APTT)	61 seconds	(30-40)
Prothrombin time	11 seconds	(11 - 12.5)
Factor VIII	8 IU/dl	(50-150)
Bleeding time	5 minutes	(3-10)
Lupus anticoagulant	absent	(present)

A mixing study is abnormal and further testing demonstrates the presence of factor VIII inhibitor.

What is the most likely diagnosis?

A. Acquired haemophilia A
B. Haemophilia B
C. Hereditary haemophilia A
D. Vitamin K deficiency
E. Von Willebrand's disease

A. Acquired haemophilia A

Acquired haemophilia A is diagnosed in patients without previous or familial histories of bleeding who have isolated prolongation of the activated partial thromboplastin time (aPTT), reduced FVIII levels as well as evidence of FVIII inhibitor activity

Acquired haemophilia A is the correct answer. This acquired haemophilia presents in later life without a preceding history of coagulopathy or family history. It is characterised by an isolated prolongation of the activated partial thromboplastin time (aPTT), reduced FVIII levels as well as evidence of FVIII inhibitor activity. It typically presents with bleeding into the skin or muscles and occasionally haematuria or melena. Haemarthrosis is less likely than with an inherited haemophilia. It is autoimmune disorder with the formation of antibodies that attack clotting factors. A mixing study is crucial in differentiating inherited factor deficiencies from acquired factor deficiencies. In inherited disorders that are characterized by a factor deficiency, the addition of normal plasma to blood restores the clotting parameters. In individuals with a factor inhibitor, the coagulation test remains abnormal.

Haemophilia B is incorrect. This is inherited bleeding disorder characterised by deficiency of factor IX.

Hereditary haemophilia A is incorrect. The absence of a family history, bleeding from a young age and normal mixing study, make this an unlikely diagnosis.

Vitamin K deficiency is incorrect. This will cause an abnormal PT and APTT.

Von Willebrand's disease is incorrect. This will cause an abnormal bleeding time.

Question 35 of 89

A 55-year-old woman is referred to the haematology outpatient department with unexplained eosinophilia. She has a past medical history of systemic lupus erythematosus and recurrent urinary tract infections. Her regular medications include azathioprine and nitrofurantoin.

On examination, there is a rash across the malar region that spares the nasolabial folds but is otherwise unremarkable.

Plain radiography of the chest is unremarkable.

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Neuts	5.2 * 10 /L 9	(2.0 - 7.0)
Lymphs	2.0 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.8 * 10 /L 9	(0.0 - 0.4)

What is the most likely explanation for her eosinophilia?

A. Azathioprine
B. Eosinophilic granulomatosis with polyangiitis
C. Hypereosinophilic syndrome
D. Nitrofurantoin
E. Systemic lupus erythematosus

D. Nitrofurantoin

Nitrofurantoin can cause eosinophilia

Nitrofurantoin is correct. This is an antibiotic used for urinary-tract infections, sometimes given as a prophylactic long-term dose to prevent recurrent infections. It is associated with eosinophilia as a recognised side effect and is the most likely explanation in this case.

Azathioprine is incorrect. Eosinophilia is not a common side effect of this medication. Indeed, it may be used as a steroid-sparing agent in some hyper-eosinophilic syndromes. It is more likely to cause cytopaenias as a side effect.

Eosinophilic granulomatosis with polyangiitis (EGPA) is incorrect. A malar rash is not typical of EGPA but rather of lupus. EGPA typically causes a vasculitic rash, which would be non-blanching and not likely to be located in the malar region. Additionally, there is no history of asthma or sinus problems, making the diagnosis unlikely. Furthermore, the eosinophil count in this disorder tends to be >1.5 * 10 /L.

Hypereosinophilic syndrome is incorrect. This is a myeloproliferative disorder associated with persistent eosinophilia and organ damage. The eosinophil count must be at least 1.5 * 10 /L for this diagnosis to be considered.

Systemic lupus erythematosus (SLE) is incorrect. This disorder is associated with haematological abnormalities. However, active SLE is typically associated with cytopaenias (anaemia, thrombocytopaenia, leucopaenia) rather than the converse. Eosinophilia is not typical

Question 36 of 89

A 74-year-old patient is referred to the haematology outpatient clinic with a lump in her neck. She has no past medical history.

On examination, widespread lymphadenopathy is detectable in the cervical, inguinal and axillary regions.

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	95 * 10 /L 9	(4.0 - 11.0)
Neuts	2.0 * 10 /L 9	(2.0 - 7.0)
Lymphs	92.7 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.1 * 10 /L 9	(0.0 - 0.4)

Given the presentation, what is the most important investigation to confirm the diagnosis?

A. Bone marrow aspiration
B. Bone marrow trephine biopsy
C. Cytogenetics
D. Immunophenotyping
E. Labelled white blood cell scan

D. Immunophenotyping

CLL - immunophenotyping is investigation of choice

Immunophenotyping is incorrect. Immunophenotyping by flow cytometry is a method used to detect the presence or absence of white blood cell antigens. These antigens are protein structures associated with white blood cells. Specific groupings of these antigens are normally present on or within white blood cells (WBCs) and are unique to specific cell types and stages of cell maturation. Specific patterns of antigens are present on abnormal cells seen in specific lymphomas like chronic lymphocytic leukaemia (CLL). On flow cytometry, CLL cells classically demonstrate CD5, CD19, CD23, weak monotypic surface immunoglobulin and weak or absent CD79B, CD22 and FMC7.

Bone marrow aspiration is incorrect. A bone marrow aspirate contains a liquid sample from the bone marrow for analysis. Bone marrow (BM) aspirate and trephine biopsy is not typically necessary at diagnosis but is used in cases with atypical features or to rule out differential diagnoses in the case of anaemia/thrombocytopenia.

Bone marrow trephine biopsy is incorrect. A trephine biopsy removes a small piece of bone with the marrow inside. Again, this is not required at diagnosis. Bone marrow trephine biopsies may show interstitial, nodular or diffuse infiltration if carried out.

Cytogenetics is incorrect. This may be used to inform prognosis (as a complex karyotype is associated with poor survival). However, it is not typically required at diagnosis.

Labelled white blood cell scan is incorrect. This scan is typically used to localise a site of unknown infection rather than diagnose CLL

Question 37 of 89

A 44-year-old male presents with a 2-month history of increasing lethargy. His wife reports him to be not quite himself for the past 2 months now, with poor oral intake and poor appetite. He is a self-employed software engineer but currently is unable to work due to his lethargy. He was previously treated for Hodgkin's lymphoma 5 years ago and has since been in remission.

On examination, he has no conjunctival pallor, is dry on his mucous membranes and extremely lethargic. Firm, rubbery lymph nodes are noted in the right axilla. Cardiovascular examination reveals a soft systolic murmur, respiratory and abdominal examinations are unremarkable. He is a non-smoker and drinks alcohol only occasionally. His blood tests are as follows:

Hb	88 g/l
MCV	104 fl
Platelets	94 * 10 /l9
WBC	12.8 * 10 /l9
Red cell distribution	9% (normal 11.5-14.5%)
Blood film	leucoerythroblastic with myeloblasts

What is the most likely cause of this patient's anaemia?

A. B12 and folate deficiency
B. Iron deficiency
C. Anaemia of chronic disease
D. Myelodysplasia post-chemotherapy
E. Marrow infiltration

A. Marrow infiltration

This patient has a symptomatic macrocytic anaemia, of which B12 and folate deficiency, myelodysplasia post-chemotherapy and marrow infiltration could all be causes. Iron deficiency results in a microcytic anaemia while anaemia of chronic disease typically causes a microcytic or normocytic anaemia. Blood cells in B12 and folate deficiency are typically megaloblastic, large immature red cells caused by impaired DNA synthesis. Myelodysplasia typically results in red cells of abnormal shapes (poikilocytosis) and sizes (anisocytosis) with Pappenheimer bodies (abnormal granules of iron). Chemotherapy is a possible cause of myelodysplasia but typically after recent treatment only. Sadly, in this case, the blood film of myeloblasts and erythroblasts suggests the transformation of Hodgkin's lymphoma into acute myeloid leukaemia, a well-recognised complication of Hodgkin's lymphoma chemotherapy with older alkylating agents, typically 5 to 10 years after treatment. Blast cells have now subsequently infiltrated the bone marrow, resulting in macrocytic anaemia.

Question 38 of 89

A 78-year-old gentleman with chronic lymphocytic leukaemia (CLL) presents with spontaneous bruising. He recalls no trauma and is otherwise well although he takes aspirin, simvastatin and ramipril for a previous myocardial infarction.

On examination, he looks well. His conjunctiva are pale but his chest is clear and he is warm and well perfused. A number of purpura are noted across the arms, back and chest. Palpable lymph nodes are felt in the left inguinal region. There is no hepatosplenomegaly.

Hb	104 g/l	Na +	135 mmol/l
Platelets	54 * 10 /l 9	K +	4.0 mmol/l
WBC	10.3 * 10 /l 9	Urea	3.4 mmol/l
Neuts	6.7 * 10 /l 9	Creatinine	87 µmol/l
Lymphs	3.4 * 10 /l 9	CRP	14 mg/l
Eosin	0.1 * 10 /l9		

What is the most appropriate management option?

A. Suspend aspirin
B. Start chlorambucil
C. Start dexamethasone
D. Platelet transfusion
E. Splenectomy

B. Start chlorambucil

Thrombocytopenia -> indication to start treatment in CLL

This gentleman has developed thrombocytopenia on a background of CLL. This is an indication to start chemotherapy. In some cases, these may also respond to steroids but typically chemotherapy would be started and chlorambucil is a commonly used agent. Suspending aspirin will not fix thrombocytopenia but may be advised. There are no signs of hypersplenism as the cause of the thrombocytopenia. Platelet transfusion will not fix the underlying problem and is not urgent given there is no acute bleeding.

Question 39 of 89

A 30-year-old previously fit and well gentleman is injured following a road traffic accident after being thrown off his motorcycle. He was blue-lighted to the emergency department, where he was found to have multiple, profusely bleeding, lacerations of his extremities.

He was transfused 2 units of cross-matched blood, with no reactions detected in blood bank. Ten minutes after the transfusion, the patient developed severe urticaria.

Which of the following syndromes would contribute to the patient's picture?

A. Adenosine deaminase deficiency
B. Ataxia telangiectasia
C. DiGeorge syndrome
D. Selective IgA deficiency
E. Wiskott-Aldrich syndrome

D. Selective IgA deficiency

IgA deficiency is associated with anaphylactic reaction to blood products

The majority of selective IgA deficiency patients are asymptomatic; with about 5% suffering from recurrent respiratory tract infections. The condition becomes clinically significant when blood transfusion is required, as there is the potential for anaphylaxis to occur on exposure to IgA containing blood products.

Although rare, anaphylaxis can happen from the first transfusion if the patient has been previously exposed to IgA i.e. in consumed animal meat products. If ever the patient needs a future blood transfusion, the transfused blood must be IgA free.

Question 40 of 89

A 16-year-old female was admitted with new onset facial swelling. The facial swelling started 45 minutes ago and initially involved her lips. She complained of a sensation of choking and a feeling of being unable to speak with hoarseness of her voice. She had been investigated on multiple occasions for abdominal pain and was diagnosed with non-specific abdominal pain. She was not taking any medication and was otherwise healthy prior to the admission.

She was given prednisolone 40mg PO and chlorpheniramine 10mg PO and admitted for observation. Whilst in the department she developed profound shortness of breath with associated stridor. Her swelling around her lips worsened and involved the whole of her face. On examination, she was in respiratory distress with severe biphasic stridor. Her respiratory rate was 32/min with an oxygen saturation of 88% on air. Auscultation of her chest also revealed the presence of a widespread polyphonic wheeze. Examination of her cardiovascular system revealed the presence of flushed peripheries with a bounding peripheral pulse. Her pulse was 102bpm and her blood pressure was 92/68 mmHg. Her GCS was 15 and neurological and abdominal examinations were unremarkable. She was cannulated and commenced on stat intravenous colloid solution. She was given adrenaline 0.5mg IM on three separate occasions within 10 minutes with no improvement. She was transferred immediately to the Intensive Care Unit and an anaesthetist fast bleeped to secure her airway.

What is the best immediate management step pending definitive airway management?

A. Commence IV adrenaline infusion
B. Commence danazol
C. Commence IV dopamine
D. Commence fresh frozen plasma infusion
E. Commence C1 esterase inhibitor concentrate infusion

E. Commence C1 esterase inhibitor concentrate infusion

Hereditary angioedema: the acute management is IV C1-inhibitor concentrate or fresh frozen plasma if this is not available

This patient has hereditary angioedema. This condition is characterised by a lack of C1 esterase inhibitor and may present with laryngeal oedema, recurrent abdominal pain and localized subcutaneous swelling. Laryngeal oedema may be fatal, does not respond to glucocorticoids or antihistamines, and has an only modest response to adrenaline. The immediate management is to commence C1 esterase inhibitor concentrate infusion. Fresh frozen plasma infusion may be administered if the concentrate is not available. Danazol is more suitable for subcutaneous oedema or as prophylaxis in certain situations eg prior to surgery.

Question 41 of 89

An 18-year-old woman presents to the emergency department with two weeks of right upper quadrant pain. She also reported longstanding pain in her right femur. She has recently returned from a holiday in Tanzania.

On examination, there was mild tenderness in the right upper quadrant of the abdomen. There was hepatomegaly and splenomegaly detectable along with conjunctival pallor. She is afebrile. There is tenderness over the right femur.

Hb	91 g/L	Male: (135-180)Female: (115 - 160)
Platelets	112 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.3 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
LDH	512 U/L	(200-400)
Recticulocytes	43 * 10 /L 3	(5-15)
Direct antiglobulin test	negative	(negative)
Haptoglobin	101 mg/dl	(50-220)

An ultrasound abdomen demonstrates massive splenomegaly (24 x 8 cm) and hepatomegaly. An x-ray of the right femur demonstrates an Erlenmeyer flask deformity.

What is the likely diagnosis?

A. Autoimmune haemolytic anaemia
B. Chronic myeloid leukaemia
C. Gaucher's disease
D. Malaria
E. Myelofibrosis

C. Gaucher's disease

Gaucher disease causes splenomegaly

Gaucher's disease is the correct answer. The patient has hepatomegaly and massive splenomegaly along with anaemia and thrombocytopenia. While all of the options listed can cause splenomegaly, only Gaucher's disease is associated with constriction of the diaphysis and flaring of the metaphysis of the femur, resulting in a deformity known as the Erlenmeyer flask deformity (named because it resembles the conical flask used by chemists).

Autoimmune haemolytic anaemia is incorrect. This is a cause of mild rather than massive splenomegaly. Additionally, the negative direct antiglobulin test and haptoglobin make haemolysis unlikely.

Chronic myeloid leukaemia is incorrect. While this can cause hepatosplenomegaly and cytopenias, it is not associated with characteristic bone abnormalities like Gaucher disease. Additionally, it tends to present in older age rather than childhood/adolescence, like Gaucher's disease.

Malaria is incorrect. While she has travelled recently to Africa, she is afebrile and therefore this diagnosis is very unlikely.

Myelofibrosis is incorrect. This is another cause of massive splenomegaly. However, the characteristic bone abnormality in this condition is osteosclerosis. Additionally, it tends to present after the age of 60.

Question 42 of 89

A 72-year-old lady is on her third cycle of chemotherapy following mastectomy and axillary clearance of her left breast. She has a PICC line in situ through which she receives her chemotherapy. She developed chills and lethargy two days prior which led her to seek her GP who arranged admission to hospital. She has had one episode of diarrhoea and is currently being barrier nursed. Her swallowing is a problem due to odynophagia and she is only managing to take oral fluids.

She is currently taking G-CSF, omeprazole and dexamethasone. She has not travelled abroad and reports that she is excluding soft cheeses and pates from her diet.

On exam, she has a clear chest with no murmurs. There is *Candida* in the mouth and a temperature of 38.5ºC recorded on admission. There are no wounds or rashes to be seen. She was started on broad-spectrum intravenous antibiotics and oral nystatin and admitted. You are asked to review her as she has spiked a fever of 39.8ºC on her third day after admission and she is struggling to swallow fluids due to retrosternal pain.

Hb	96 g/l	Na	139 mmol/l
Platelets	123 * 10 /l	K	5.1 mmol/l
WBC	1.6 * 10 /l	Urea	4.5 mmol/l
Neuts	0.5 * 10 /l	Creatinine	56 µmol/l
Lymphs	0.1 * 10 /l	CRP	96 mg/l
Eosin	0.1 * 10 /l		

Chest X-ray	clear lung fields, no effusion, no air under the diaphragm
Bloods cultures (1st peripheral)	no growth
Blood cultures (PICC line)	no growth
Blood cultures (2nd peripheral)	coagulase negative *staphylococcus*
Urine microscopy	no pyuria, no growth
Skin swab (PICC site)	awaited

What of the following is the most appropriate action?

A. Start metronidazole
B. Start fluconazole
C. Take a further set of blood cultures
D. Increase dose of G-CSF
E. Start paracetamol

B. Start fluconazole

Neutropenic sepsis with no response to antibiotics at 48 hrs - > possible fungal infection

This lady has neutropenic sepsis of unknown source and has failed to improve despite broadspectrum antibiotics. This prompts thoughts of what the cause could be. Increasing G-CSF may help her white cells increase but it does not treat the infection present. Paracetamol may reduce fevers but it does not treat the infection. Adding metronidazole is a reasonable thought since it covers anaerobic organisms and she has had a single episode of diarrhoea but the source of the sepsis is not clearly abdominal. Taking two sets of further blood cultures will be part of the workup needed but will not improve the patient's situation. Starting fluconazole is the answer. In any neutropenic sepsis, fungal causes should be considered especially if the patient does not improve on broad spectrum antibiotics. She has oral candida with odynophagia suggests possible oesophageal candidiasis. We should consider this especially given the *Candida* seen.

Question 43 of 89

A 50-year-old woman presents to the emergency department with a 3-day history of headache and blurred vision. Despite taking co-codamol and ibuprofen, her headache has not been relieved and she has since started vomiting. She describes feeling generally unwell for the last 2-3 weeks with general malaise and body aches but denies fever and has no past medical history.

On examination, her visual acuity is reduced with noticeable nystagmus more pronounced on the left side. The remainder of her neurological examination is unremarkable.

Laboratory tests:

Hb	99 g/L	(115 - 160)
Platelets	150 * 10 /L 9	(150 - 400)
WBC	38.3 * 10 /L 9	(4.0 - 11.0)
Lymphs	3.2 * 10 /L 9	(1.0 - 3.5)
Eosin	0.2 * 10 /L 9	(0.0 - 0.4)
Na +	136 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	90 µmol/L	(55 - 120)
Bilirubin	20 µmol/L	(3 - 17)
ALP	87 u/L	(30 - 100)
ALT	39 u/L	(3 - 40)
Albumin	38 g/L	(35 - 50)

What is the most likely diagnosis?

A. Acute myeloid leukaemia
B. Idiopathic intracranial hypertension
C. Meningitis
D. Multiple sclerosis
E. Non-Hodgkin's lymphoma

A. Acute myeloid leukaemia

Acute myeloid leukaemia can present acutely with hyperviscosity syndrome

This patient is presenting with hyperviscosity syndrome. Hyperviscosity syndrome is the increased viscosity of the blood caused by hyperproliferative states (e.g. leukaemia and polycythaemia), increased cell components (e.g. RBCs and WBCs) or increased immunoglobulins (e.g. multiple myeloma). Different bodily systems can be affected, but commonly the central nervous can be affected causing headaches, nystagmus and visual disturbance. This patient's blood results demonstrate a raised WBC count and a normal lymphocyte count, indicating that a large portion of the WBC is made of neutrophils, in keeping with a diagnosis of **acute myeloid leukaemia**. Additional symptoms of acute myeloid leukaemia include lethargy and malaise that are also described by this patient.

Idiopathic intracranial hypertension (IIH) is most common in women and is associated with obesity. It can present with a pressure-type headache with blurred vision. However, eye signs include 6th nerve palsy and papilloedema on fundoscopy. Furthermore, IIH does not explain this patient's raised WBC.

Meningitis can be secondary to a viral or bacterial infection. Presenting features typically include headache, fever and meningism. Vomiting and photophobia may also be seen. Although this patient has a raised WBC that could represent an underlying infection, meningitis does not typically cause nystagmus and the absence of fever and meningism also suggest an alternative diagnosis.

Multiple sclerosis is a demyelinating disease of the central nervous system. Common presenting symptoms include optic neuritis. Although a patient with multiple sclerosis could present with headache and nystagmus, it does not explain this patient's raised WBC.

Non-Hodgkin's lymphoma is a malignant proliferation of lymphocytes. It can present with malaise and hyperviscosity syndrome as described by this patient. However, additional symptoms include painless lymphadenopathy and constitutional symptoms such as night sweats and weight loss which are not described in this question. Furthermore, the presence of a normal lymphocyte count points towards an alternative diagnosis.

Question 44 of 89

A 44-year-old woman visits her general practitioner with a 10-day history of intermittent epistaxis. She has never had nosebleeds before but now says that even after blowing her nose, it will bleed for 2-3 minutes at a time. There is a past medical history of hypothyroidism for which she takes levothyroxine 75 micrograms daily. Other than recovering from influenza 3 weeks ago, she has had no recent illnesses.

On examination, she is afebrile. Her heart rate is 71bpm and regular with a blood pressure of 125/65mmHg. On auscultation, she has a clear chest with normal heart sounds. Her abdomen is soft and non-tender with no palpable organomegaly. There are multiple bruises and petechiae over her lower limbs and trunk.

Investigations:

Hb	116 g/L	Male: (135-180)Female: (115 - 160)
Platelets	16 * 10 /L 9	(150 - 400)
WBC	5.1 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	3.5 mmol/L	(3.5 - 5.0)
Urea	5.0 mmol/L	(2.0 - 7.0)
Creatinine	61 µmol/L	(55 - 120)
Prothrombin time (PT)	12 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	28 secs	(25-35 secs)
Fibrinogen	2.6 g/L	(2 - 4)
D-Dimer	254 ng/mL	(< 400)

What is the most appropriate next step in this patient's management?

A. Desmopressin
B. Eltrombopag
C. IV immunoglobulin
D. Platelet transfusion
E. Prednisolone

A. Prednisolone

First-line treatment for ITP is oral prednisolone

This patient has immune thrombocytopenic purpura (ITP) the immune-mediated destruction of platelets. In ITP, autoantibodies are directed against glycoprotein IIb/IIIa or Ib-V-IX complexes and can be detected in up to 60-70%. The disease can develop acutely in children following a viral infection or vaccination and usually presents with mucocutaneous bleeding. There is also an association with autoimmune disease. ITP in children is often self-limiting compared to adults which tends to be more of a chronic condition with a relapsing-remitting course. This patient has a history of hypothyroidism and is recovering from a recent viral infection making ITP more likely. Features include easy bruising, epistaxis, purpura and menorrhagia. Massive haemorrhage is a rare complication. The treatment of choice is oral prednisolone at a dose of 1-2mg/kg. Approximately 80% respond to initial treatment.

Desmopressin is used in the treatment of Von-Willebrand's disease (VWD). VWD is a common inherited bleeding disorder that may first present as spontaneous mucocutaneous bleeding. It is caused by a deficiency in the von-Willebrand factor, a protein molecule that encourages platelet adhesion and binds to clotting factor VIII to prevent it from being broken down. A deficiency in this factor predisposes patients to increased bleeding. Blood tests in patients with VWD may demonstrate a microcytic anaemia, thrombocytopenia and a prolonged APTT (especially if factor VIII levels are reduced). However, this patient has never encountered issues with bleeding prior to a recent viral illness. This history combined with an isolated thrombocytopenia makes ITP the more likely diagnosis.

Eltrombopag is a thrombopoietin receptor agonist which acts to increase the platelet count. It is used as a 3rd-line treatment of ITP and is typically prescribed for chronic or refractory ITP.

IV immunoglobulin (IVIG) is another potential treatment option for ITP. It is commonly used in patients who fail to respond to corticosteroids or in patients for which corticosteroids are contraindicated. Another indication for IVIG is if a rapid rise in platelets is needed, for example prior to surgery.

Platelet transfusions are not the treatment of choice in ITP. They are reserved for extreme haemorrhage including intracranial haemorrhage.

Question 45 of 89

A 39-year-old man is referred to the haematology clinic by his GP due to abnormal blood results.

In the clinic, he reports a 2-week history of fatigue, malaise and intermittent abdominal pain. His past medical history includes anxiety and depression for which he takes citalopram. There is no history of smoking or recreational drug use although he drinks 6 cans of cider most evenings. He returned from a trip to India last month.

On examination, he appears lethargic. Chest auscultation is clear and his abdomen is soft with generalised tenderness.

Repeat blood tests are requested:

Hb	100 g/L	(135-180)
Mean Cell Volume	105 fL	(80 - 100)
Platelets	100 * 10 /L 9	(150 - 400)
WBC	7.1 * 10 /L 9	(4.0 - 11.0)
Bilirubin	80 µmol/L	(3 - 17)
ALP	118 u/L	(30 - 100)
ALT	40 u/L	(0 - 40)
AST	65 u/L	(< 35)

Blood glucose	6.1 mmol/L	(4 - 7)
Total cholesterol	7.3 mmol/L	(< 5)

Further investigations are sent:

Blood film	Schistocytes
Coombs test	Negative

What is the most appropriate management for this patient?

A. Alcohol cessation
B. Artesunate
C. Blood transfusion
D. Intravenous immunoglobulin (IVIg)
E. Prednisolone

A. Alcohol cessation

Zieve syndrome usually resolves with abstinence from alcohol

Alcohol cessation is correct. This patient has a likely diagnosis of Zieve syndrome given the triad of non-autoimmune haemolysis, jaundice and hyperlipidaemia on a background of alcohol excess. The negative Coombs test indicates non-autoimmune haemolytic anaemia. In Zieve syndrome, jaundice can be cholestatic in nature but also secondary to haemolysis. The raised ALP supports a cholestatic picture. Zieve syndrome is a rare syndrome and generally resolves following the cessation of alcohol use.

Artesunate is incorrect. Another differential diagnosis for haemolytic anaemia includes infective causes such as malaria. Although this patient has recently travelled to India, the majority of India is relatively malaria-free in comparison to other parts of the world. It also does not account for the raised triglyceride level and cholestatic jaundice.

Blood transfusion is incorrect. Generally, the threshold for blood transfusion is a Hb < 70g/dL or < 80g/dL if the patient has ischaemic heart disease. It would not treat this patient's underlying diagnosis.

Intravenous immunoglobulin (IVIg) is incorrect. This can be used to treat autoimmune haemolytic anaemia and other haematological conditions such as immune thrombocytopenic purpura. However, the negative Coombs test makes autoimmune haemolytic anaemia highly unlikely.

Prednisolone is incorrect. Like IVIg, prednisolone is used in the treatment of autoimmune haemolytic anaemia. This is unlikely to be the underlying diagnosis since the Coombs test is negative. Therefore, other causes of haemolytic anaemia should be considered and investigated

Question 46 of 89

A 59-year-old man suddenly becomes unwell on the oncology unit. He is receiving an intravenous infusion of a new chemotherapy agent as part of a clinic trial. He says he feels very lightheaded. On examination his blood pressure is 80/50 mmHg, heart rate is 120/min, oxygen saturations are 94% on air and bilateral wheeze is heard on auscultation of the chest. An ECG shows a sinus tachycardia of 120 beats per minute. The infusion is stopped, the patient is lay flat with their legs raised and an arrest call has been put out.

What should you administer immediately?

A. 0.5mL of 1:1000 intramuscular adrenaline
B. 0.5mL of 1:10000 intramuscular adrenaline
C. 0.5mL of 1:1000 intravenous adrenaline
D. 0.5mL of 1:10000 intravenous adrenaline
E. 1mL of 1:10000 intravenous adrenaline

A. 0.5mL of 1:1000 intramuscular adrenaline

Anaphylaxis - adult adrenaline dose = 500 mcg (0.5 ml of 1 in 1,000)

This patient is having an anaphylactic reaction to the infusion. Essential immediate management of anaphylaxis comprises: recognition that the patient is seriously unwell, removal of the trigger (if possible), an early call for help, assessment via the ABCDE (airway, breathing, circulation, disability, exposure) approach and administration of adrenaline.

The correct dose of adrenaline in anaphylaxis via the intramuscular route is 0.5mL of 1:1000 (1mg in 1mL/ 0.5mg in 0.5mL). Adrenaline should usually be administered via the intramuscular route as there is a lower risk of inappropriate administration, the incidence of adverse effects is rare, it is an easy method to learn and IV access is not required. Inappropriate intravenous administration risks precipitating arrhythmias, which may result in cardiac arrest. Specialists such as anaesthetists may use the intravenous route, but for the majority of practitioners the intramuscular route is the best option.

As soon as possible after or concurrently with the administration of adrenaline; high-flow oxygen and a rapid intravenous fluid challenge should be delivered. Subsequent to this, an intravenous or intramuscular antihistamine (e.g. chlorphenamine) and steroid (e.g. hydrocortisone) may be given.

Question 47 of 89

A 24-year-old male is admitted with shortness of breath. On examination his respiratory rate is 34 breaths per minute and heart rate is 125 beats per minute. His blood pressure is 120/85 mmHg. An SpO2 reading is 84%. He looks cyanotic. He has a past medical history of coeliac disease, dermatitis herpetiformis, rheumatoid arthritis and asthma. His regular medicines include dapsone, prednisolone, paracetamol and ibuprofen. He just recently completed a course of amoxicillin for a chest infection.

An arterial blood gas is performed (on 15 litres of O2):

Hb	125 g/l
pH	7.33
PaO2	58.11 kPa
PaCO2	2.48 kPa
SO2	99.7%
HCO3	12 mmol/l

What drugs is most likely implicated?

A. Dapsone
B. Amoxicillin
C. Prednisolone
D. Ibuprofen
E. Paracetamol

A. Dapsone

Dapsone + dyspnoea → methaemoglobinaemia

Several inferences should be made with regards to the blood gas. The PaO2 is appropriately high given the patient is on 15L of O2. A simple way of estimating an appropriate PaO2 is to multiple the % of inspired O2 (FiO2) by 2/3. For example, 15L of O2 driven by a non-rebreather mask delivers approximately 90% of O2. Therefore we would expect the PaO2 to be is approximately 2/3 * 90 = 60 kPa. The patient in this example has a PaO2 of 62.22 kPa. Therefore we can confidently state that gas exchange at the level of the alveoli is not the cause of the cyanosis. It is important toremember that the PaO2 is a measure of dissolved O2 in blood. Oxygen is carried in the blood in two forms: dissolved in plasma (about 2% of the total) and reversibly bound to haemoglobin (about 98% of the total). Therefore alternative causes for the cyanosis should be sought e.g. anaemia, shock, and toxic causes (e.g. methemoglobinemia).

The saturation of Hb on the ABG (SaO2) is 99.7%. This is strange as there is a large discrepancy between this and the peripheral pulse oximeter result (86%). This should alert you to consider two differentials - carbon monoxide poisoning and methemoglobinemia. The SaO2 on the blood gas machine is broken down to several components - O2Hb (the 'true' saturation of Hb with O2), COHb (carboxyhemoglobin), HHb, and MetHb. The sum of all these components produces the total saturation SaO2. In this case, the patient has a significantly high MetHb confirming the diagnosis of methemoglobinemia. The true oxygen saturation is 55.3%. This is the cause of the hypoxia and the resultant lactic acidosis.

Methemoglobinemia describes haemoglobin which has been oxidised from Fe2+ to Fe3+. Fe3+ cannot bind oxygen, and hence the oxidation dissociation curve is moved to the left. This results in tissue hypoxia. Drugs (e.g. sulphonamides, nitrates, dapsone, sodium nitroprusside, primaquine) are common causes. Dapsone is a common cause of methemoglobinemia.

None of the other agents are known to cause methemoglobinemia.

Question 48 of 89

A 64-year-old man presents to the haematology clinic with a history of back pain over the past 6 months. On systematic enquiry and examination, there are no features of spinal cord compression or cauda equina syndrome.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	165 * 10 /L $_9$	(150 - 400)
WBC	6.2 * 10 /L $_9$	(4.0 - 11.0)
Na $^+$	135 mmol/L	(135 - 145)
K $^+$	4.8 mmol/L	(3.5 - 5.0)
Urea	10.8 mmol/L	(2.0 - 7.0)
Creatinine	190 µmol/L	(55 - 120)

Protein electrophoresis	Monoclonal IgG 38g/l

Given the likely diagnosis, what is the imaging modality of choice?

A. CT PET
B. No imaging required
C. Plain film skeletal survey
D. Whole body MRI
E. Whole body low-dose CT

D. Whole body MRI

Whole body MRI 1st line imaging in suspected multiple myeloma

The clinical features (e.g. back pain, anaemia, renal dysfunction), and the presence of a paraprotein make multiple myeloma the most likely diagnosis.

Whole body MRI is recommended as the first-line imaging modality in multiple myeloma. MRI is the most sensitive tool available for detecting marrow infiltration at an early stage, before bone destruction occurs, as well as offering improved detection of lesions, particularly in the axial skeleton.

Skeletal survey is incorrect. The major disadvantage of plain X-rays is the significantly lower sensitivity compared to advanced imaging. Lytic lesions are only demonstrated when at least 30-50% of the trabecular bone has been lost and around 20% of myeloma patients have no abnormal findings by plain X-ray. Plain X-rays cannot distinguish osteopenia or vertebral collapse caused by myeloma from more common causes such as early osteoporosis or corticosteroid use. For these reasons - skeletal surveys with plain X-rays are no longer recommended.

CT skeletal survey is incorrect. From a practical point of view, CT has the advantage of being quick to perform and allows patients to lie on their back, without the need to change position. CT is also helpful for visualising soft tissue involvement, assessing spinal fracture stability, depicting spinal cord and cauda equina compression (although MRI is superior for this), guiding needle biopsies and surgical interventions, and planning radiotherapy. However, MRI remains the gold standard.

FDG PET/CT is incorrect. PET may be considered for patients with newly diagnosed nonsecretory or oligosecretory myeloma and for evaluation of extramedullary disease. Although FDG PET/CT has some prognostic value when used in the initial diagnosis of myeloma, there is currently insufficient evidence to justify the routine use of FDG PET/CT in all cases of newly diagnosed myeloma.

No imaging required is incorrect. The patient most certainly has a new diagnosis of multiple myeloma and thus cross-sectional imaging is required.

Question 49 of 89

A 22-year-old man is seen in the general medical clinic. He has had several episodes of gallstones over the last three months. He is due to see the surgical team for consideration of laparoscopic cholecystectomy but he was also referred to the medical team due to anaemia. He has needed blood transfusions in the past when he has become tired and found to be anaemic. He was referred for an appointment with a haematologist but was unable to attend and therefore discharged from the clinic without seeing the consultant. He takes no regular tablets. He is unaware of any family history of significant medical problems, but does think that his mother used to turn yellow when slightly unwell, but thinks that this has never been a serious medical problem. He also knows that his father, to whom he is estranged, had some medical problem with his blood. His observations are normal as is his examination apart from conjunctival pallor and 2cm of a palpable spleen.

Blood tests:

Hb	110 g/l
MCV	84.1 fl
MCHC (mean corpuscular haemoglobin concentration)	391 g/l
Platelets	389 * 10 /l9
WBC	8.2 * 10 /l9
Na +	138 mmol/l
K +	4.8 mmol/l
Urea	5.2 mmol/l
Creatinine	85 µmol/l
Bilirubin	22 µmol/l
ALP	42 u/l
ALT	15 u/l

What is the most likely underlying diagnosis?

A. Sickle cell disease
B. Pernicious anaemia
C. Glucose-6-phosphate dehydrogenase (G6PD) deficiency
D. Thalassaemia
E. Hereditary spherocytosis

A. Hereditary spherocytosis

Hereditary spherocytosis is an explanation for anaemia in recurrent gallstones

This young man has a history of anaemia with recurrent gallstones. This implies that there has been destruction of red blood cells and the subsequent rise in bilirubin has provoked the formation of gallstones. The presence of normocytic anaemia with elevated MCHC further supports a diagnosis of spherocytosis. The family history of potentially Gilbert's syndrome would raise the possibility of the patient having this diagnosis as well, which would increase the possibility of gallstones in spherocytosis. The presence of splenomegaly supports this diagnosis. Diagnosis would be confirmed with microscopy and osmotic fragility testing. Pernicious anaemia would be macrocytic and would not be associated with haemolysis. Sickle cell disease would clinically have severe haemolytic normocytic anaemia, recurrent infections and vaso-occlusive phenomena. The absence of such episodes and age of presentation makes sickle cell disease unlikely. In addition, it is screened for in the UK and routinely diagnosed in the neonatal setting. G6PD is a X-linked cause of haemolytic anaemia triggered commonly by drugs causing acute episodes of haemolysis. The absence of a neonatal history of jaundice and demographic risk factors, as well as no trigger makes this less likely, as does the presence of splenomegaly. Thalassaemia would not cause splenomegaly or gallstones

Question 50 of 89

A 32-year-old woman is on her second cycle of chemotherapy for breast cancer. She has developed two days of watery diarrhoea and vomiting. She has occasional chills and feels generally weak. She has not travelled abroad and there are no ill contacts. Her husband is a farmer and together they attended a farm foods show which hosted local cheese and meats in the local region.

On examination, she has a soft abdomen that is mildly tender in the right iliac fossa. Her mucosa is dry and she is achy in muscle groups throughout her body.

Hb	110 g/l	Na +	138 mmol/l
Platelets	348 * 10 /l 9	K +	3.9 mmol/l
WBC	2.4 * 10 /l 9	Urea	4.3 mmol/l
Neuts	0.7 * 10 /l 9	Creatinine	76 µmol/l
Lymphs	1.4 * 10 /l 9	CRP	96 mg/l

Stool specimen	gram-positive bacillus

What is the causative organism in this case?

A. Listeriosis
B. Salmonellosis
C. Shigellosis
D. Clostridium perfringens poisoning
E. Staphylococcus aureus poisoning

A. Listeriosis

Neutropenic patients should avoid soft cheese due to risk of listeriosis

This is a case of neutropenic sepsis. Patients are at high risk to many organisms and it is suggested they avoid cold meats and dairy products. She had gastrointestinal symptoms and cultured a gram-positive bacillus. This immediately rules out salmonellosis and shigellosis. The gram-positive is a bacillus so cannot be *staphylococcus*. Of the two remaining, only *listeria* is found in dairy products and therefore is the likely cause of her illness

Question 51 of 89

A 22-year-old woman awaiting stem cell transplant for acute myeloid leukaemia has become unwell over the past three days and arrives with a Glasgow Coma Scale of 3 in the emergency department. Her boyfriend who is present with her reports that she has had severe headaches and been sitting in bed but gradually became more confused. She was struggling to breathe and began to seize causing him to call the ambulance.

On examination, she is intubated and has bilateral coarse crepitations. Her pupils are reactive but she is sedated and does not respond to pain. There is papilloedema bilaterally and haemorrhages are seen in the left eye. She is warm and well perfused but her left arm is cold and pale. She is transferred to the intensive care unit.

Hb	120 g/l
Platelets	350 * 10 /l9
WBC	105 * 10 /l9
Troponin	10,876 (normal range <20)
CRP	56 mg/l
Chest x-ray	bilateral pulmonary infiltrates, small left sided effusion

What medical treatment will correct her underlying pathology should be initiated?

A. Intravenous antibiotics
B. High dose corticosteroids
C. Leukapheresis
D. High dose chemotherapy
E. Venesection

C. Leukapheresis

Leukapheresis can be used to acutely lower the white cell count in AML

This lady presents with pulmonary oedema and neurological dysfunction on a background of hyperleukocytosis. This is leukostasis where the blood is thick in white cells. The treatment is to rapidly remove white cells. This can be done by leukapheresis of the blood and removing the white cells which is called leukapheresis and this is the most appropriate answer. Venesection and high dose chemotherapy are less effective ways of achieving a lower white cell count.

Corticosteroids and antibiotics will not help.

Question 52 of 89

A 64-year-old woman is referred by her GP to the haematology clinic with an incidental lymphocytosis noted first four months prior. On questioning, she reports that she has been feeling more fatigued over the past few months and has begun to experience episodes of early satiety, both of which she attributed to looking after her two grandchildren. She is otherwise well and denies any fevers, night sweats or unusual bruising.

On examination, she is slim with an unremarkable cardiovascular and respiratory exam. There is a fullness in the left upper quadrant which moves with inspiration but no lymphadenopathy.

Her blood tests are shown below:

Hb	140 g/L	Male: (135-180)Female: (115 - 160)
Platelets	200 * 10 /L 9	(150 - 400)
WBC	30.1 * 10 /L 9	(4.0 - 11.0)
Neuts	4.0 * 10 /L 9	(2.0 - 7.0)
Lymphs	25.0 * 10 /L 9	(1.0 - 3.5)
Mono	0.8 * 10 /L 9	(0.2 - 0.8)
Eosin	0.3 * 10 /L 9	(0.0 - 0.4)
Blood Film	lymphocytosis with smudge cells	

Ultrasound abdomen confirms splenomegaly.

Chromosomal analysis is performed to guide further management.

Given the likely diagnosis, which of the following chromosomal findings would suggest a poor prognosis?

A. >2% mutation immunoglobulin heavy chain variable region
B. Deletion of 13q
C. Deletion of 17p
D. < 20% CD38 expression
E. TP53 - wild-type

C. Deletion of 17p

del 17p is associated with a poor prognosis in CLL

This patient has chronic lymphocytic leukaemia (CLL) demonstrated by a history of significant lymphocytosis for > 3 months and splenomegaly with a blood firm showing smudge cells. A bone marrow aspirate is not required in all CLL patients but may be indicated in patients with anaemia and/thrombocytopenia to confirm whether these may be attributed to marrow infiltration or splenic destruction.

The deletion of 17p is associated with a poor prognosis in CLL. All other options are markers of good prognosis. Note that a wild type TP53 refers to an unmutated form, however, a mutated TP53 is, by contrast, a bad prognostic marker.

Question 53 of 89

A 54-year-old alcoholic man with chronic hepatitis C is taken to the emergency department by the police. There it was noted that the man had blisters and crusted lesions on his face and lower arms.

Laboratory tests showed elevated plasma porphyrins and elevated uroporphyrin I in the urine, and isocoproporphyrin in the faeces. Biopsy of the skin lesion showed subepidermal blisters with minimal inflammation, marked solar elastosis, thickening of the vessel wall in the papillary dermis and 'caterpillar bodies' in the roof of the blister.

Which of the following is the most likely diagnosis?

A. Acute intermittent porphyria
B. Delta-aminolevulinic acid dehydrase deficiency
C. Erythropoietic protoporphyria
D. Hereditary coproporphyria
E. Porphyria cutanea tarda

A. Porphyria cutanea tarda

Porphyria cutanea tarda causes chronic blistering and crusting skin lesions on sun-exposed skin. Precipitating factors: iron (even if normal amounts), oestrogen and alcohol use, and chronic hepatitis C infection.

The findings on skin biopsy can help with the diagnosis but are not very specific (the 'caterpillar bodies' are essentially clumps of basement membrane material). The key to the diagnosis is the presentation and porphyrin analysis

Question 54 of 89

A 68-year-old female, presents with lethargy and anorexia. She underwent a partial gastrectomy 3 years ago for bleeding gastric ulcer. Her blood results showed:

Hb	90 g/l
MCV	109 fL
Platelets	60 * 10 /l9
WBC	3.5 * 10 /l9
Blood film	Oval erythrocytes, macrocytic erythrocytes, hypersegmented neutrophils, low platelets and basophilic stippling

What is the underlying diagnosis?

A. Sideroblast anaemia
B. Spur cell haemolysis
C. Vitamin-B12 deficiency
D. Thalassaemia
E. Myelodysplasia

C. Vitamin-B12 deficiency

Gastrectomy is defined as partial when a part of the stomach is removed surgically and as total when the entire stomach is removed. Typical indications are gastric cancer, recurrent gastric ulcers, large duodenal perforations, bleeding gastric ulcers and gastrointestinal stromal tumours. Malnutrition is less common after partial than after total gastrectomy, but the key nutritional deficiencies are iron-deficiency anaemia, calcium deficiency, and vitamin B12 deficiency. However, the hypersegmented neutrophils are strongly suggestive of B12 deficiency.

Hypersegmented neutrophils are hallmarks of B12 deficiency in multiple choice questions

Question 55 of 89

A 19-year-old man is referred to see you as he has been suffering from recurrent epistaxis and he tells you that if he accidentally injures himself the wound bleeds for a long time.

Initial blood tests are as follows:

Hb	101 g/l
MCV	79 fl
Platelets	298 * 10 /l9
WBC	9.2 * 10 /l9
Bleeding time	Prolonged
PT	14 seconds
APTT	28 seconds
LDH	290 u/l (240 - 480 u/L)
Factor VIIIc	low
Ristocetin platelet aggregation test	Impaired aggregation

What is the single most likely diagnosis?

A. Haemophilia A
B. Haemophilia B
C. Haemophilia C
D. Idiopathic Thrombocytopenic Purpura (ITP)
E. von Willebrand's disease

A. von Willebrand's disease

This patient has a coagulopathy and normal platelets, which immediately excludes ITP. Factor VIIIc is low, meaning that the diagnosis must either be haemophilia A or von Willebrand's disease. In this patient two things favour the diagnosis of von Willebrand's over haemophilia A. Firstly, the bleeding time is prolonged and secondly, the platelet aggregation is impaired in response to ristocetin. Both of these would be normal in haemophilia.

question 56 of 89

A 21-year-old girl complains of easy bruising. She has menorrhagia for which she is being investigated by the gynaecology team. She takes no regular medications. Her father had prolonged bleeding after a tooth extraction.

Blood tests show:

Hb	110 g/L
MCV	74 fL
WBC	4.2 x 10^9/L
Platelets	135 x 10^9/L
APTT	45 seconds
INR	1.0

What is the most likely diagnosis?

A. Haemophilia B
B. Anti-thrombin III deficiency
C. Von Willebrand's disease
D. Immune thrombocytopenia
E. Haemophilia A carrier

C. Von Willebrand's disease

Von-Willebrand's disease is an autosomal dominant condition (chromosome 12) that leads to a mild-moderate bleeding tendency. The prevalence of clinically significant cases is 1 in 10,000. Factor VIII is bound to vWF, which protects it from breakdown, so deficiency of vWF can lead to low factor VIII levels and a prolonged APTT. In this case the patient also has a microcytic anaemia, which would be in keeping with iron deficiency anaemia secondary to menorrhagia. Haemophilia B (Factor IX deficiency) is X-linked so does not affect females. Haemophilia A (Factor VIII deficiency) is also X-linked. Most carriers are asymptomatic. The APTT is normal in ITP. Anti thrombin III deficiency is a pro thrombotic condition.

Question 57 of 89

A 72-year-old woman with breast cancer presents with a swollen, painful left calf. She is known to have metastases in the vertebral bodies and is taking denosumab as prophylaxis. A Doppler ultrasound is arranged which shows a proximal deep vein thrombosis on the left side. This is her first episode of venous thromboembolism.

What is the most appropriate management?

A. Warfarin for 3 months
B. Warfarin for 6 months
C. Low-molecular weight heparin for 3-6 months
D. Direct oral anticoagulants (DOACs) for 3-6 months
E. Aspirin 300 mg for 3 months

C. Low-molecular weight heparin for 3-6 months

Cancer patients with VTE - 6 months of a DOAC

Question 58 of 89

A 23-year-old gentleman reviewed by the on-call medical team after having become unwell in the radiology department. He was undergoing a contrast-enhanced MRI of the small bowel to investigate ongoing diarrhoea. He has no other past medical history and takes no regular medications. He is not known to have any allergies.

Ten minutes ago he started feeling his throat closing up and became very anxious. This was shortly after having been given a contrast agent by IV injection. The medical emergency team arrives quickly and note him to be tachycardia at 132/min and hypotensive with a blood pressure of 82/35mmHg. He also has a widespread erythematous rash over his body and feels itchy. He is treated for anaphylactic shock.

Which blood tests could confirm anaphylaxis?

A. Histamine levels

B. Mast cell tryptase immediately and repeat within one to two hours
C. Mast cell tryptase immediately and repeat within 12 hours
D. Mast cell tryptase immediately and repeat within 24 hours
E. Serum immunoglobulins

B. Mast cell tryptase immediately and repeat within one to two hours

Anaphylaxis - serum tryptase levels rise following an acute episode

The correct answer is mast cell tryptase immediately and repeat within one to two hours. Tryptase levels are the most specific marker for an anaphylactic reaction. Tryptase is a marker of mast cell activation. Serum concentration is normally very low and will quickly return to normal, which is why an immediate sample can be useful but should never delay treatment. Tryptase levels increase to maximum levels over 30 minutes from the onset of symptoms, then peaks at one to two hours. The half-life of tryptase is roughly two hours and may return to normal within six to eight hours. This means that a sample at 12 or 24 hours may not confirm anaphylaxis. Histamine levels can be elevated in various conditions, including simple allergic reactions and does not help to distinguish anaphylaxis. Immunoglobulins are elevated in cell-mediated immune responses.

Question 59 of 89

A 43 year old man is brought to the Emergency Department by his wife. She has become worried about him in the past six months as he has become increasingly confused, aggressive and depressed. He has also lost 4kg in weight in this time and has developed severe, intermittent abdominal pain and diarrhoea, and complains of constant headaches.

Examination reveals a normal cardiorespiratory examination but the abdomen is diffusely tender and there is tender fullness in the right upper quadrant. Neurological examination reveals minor hypotonia throughout and there are bilateral radial nerve palsies as well as a left common peroneal nerve palsy. Sensation appears intact. He is alert but confused with an abbreviated mental test score of 7/10.

Blood tests reveal:

Sodium	136mmol/L	ALP 135U/L Haemoglobin 79g/L
Potassium	5.1mmol/L	AST 265U/L MCV 101fL
Urea	7.1mmol/L	ALT 298U/L White cells 9.4x10^9/L
Creatinine	102µmol/L	GGT 197U/L Neutrophils 5.6x10^9/L
CRP	10mg/L	Bilirubin 12µmol/L Lymphocytes 3.1x10^9/L
Calcium (corr)	2.34mmol/L	Eosinophils 0.1x10^9/L
Phosphate	0.56mmol/L	Basophils 0.6x10^9/L
Magnesium	0.76mmol/L	
Glucose	3.8mmol/L	

The blood film shows anaemia with a dimorphic picture, significant reticulocytosis and high basophil numbers with cytoplasmic stippling.

The patients wife tells you all the symptoms coincided with the patient starting a new job as a loading crane driver at a scrap-yard.

What is the most likely diagnosis?

A. Chronic alcoholism
B. Acute promyelocytic leukaemia
C. Porphyria cutanea tarda
D. Chronic lead poisoning
E. Minimata disease

D. Chronic lead poisoning

Abdominal pain, constipation, neuropsychiatric features, basophilic stippling → lead poisoning

The above vignette gives a classical description of chronic lead poisoning, also known as plumbism or Devon colic. The typical signs are gastrointestinal and neuropsychiatric and include severe, colicky abdominal pain with weight loss and diarrhoea and a metallic taste in the mouth. Insidious neurological signs include headache, difficulty concentrating, subtle personality changes including aggression and difficulty sleeping, dyspraxia and cerebellar signs. The pathognomonic hallmark of chronic lead poisoning is a radial nerve palsy, or wrist drop, although many peripheral nerve palsies may be seen. Patients may also have a bluish discolouration to their skin and a blue line on the gums, known as Burtons line, is very rarely seen. Biochemically, a hepatitic picture can be seen and also occasionally renal impairment due to proximal renal tubular failure, particularly with increased excretion of phosphate and glucose and acidification of the urine. However, most notable is the haematological impact of lead poisoning with a pronounced anaemia, often with dimorphic picture and reticulocytosis due to arrest of the haem biosynthetic pathway. Basophilia with stippling is seen and bone marrow trephine may show ring sideroblasts.

Blood lead levels do not correlate well with total lead burden and the diagnosis may be missed due to incorrect assay or test selection. Since lead is concentrated in red cells, whole blood levels of lead rather than plasma must be analysed, however testing for enzymes affected by lead is more reliable than whole lead levels alone, and hence erythrocyte zinc protoporphyrin (ZPP) levels and delta aminolevulinic acid dehydratase (ALAD) are more reliable. These, coupled with skeletal analysis and blood lead levels are used to test for occupational lead poisoning. The term metal fume fever is used to describe many syndromes of heavy metal and metal oxide poisonings, often in gantry crane drivers who deposit scrap metals in furnaces from above. Many scrap metals are coated in lead based paints leading to occupational lead toxicity syndromes.

Lead poisoning is clinically similar to porphyria and pathologically an interruption in haem pathways are seen in both. The classical hallmark of porphyria cutanea tarda is a blistering photosensitive rash that is not present in this case. Chronic alcoholism may cause B12 deficiency and hence a megaloblastic anaemia and confusion but it is unlikely to cause this constellation of neuropathies and does not explain the basophilic stippling. There is no mention of the patients alcohol habits either. An acute promyelocytic leukaemia presents with non specific symptoms and infections. It may present with sudden onset neurological symptoms only if there is a spontaneous intracranial bleed, in which case the outlook is bleak. It is unlikely here. Minimata disease is an acute mercury toxicity and presents with neuropsychiatric symptoms and rapid death. It would not be expected to cause the haematological picture seen here.

Question 60 of 89

A 30-year-old man with acute myeloid leukaemia receives a bone marrow transplant from a matched unrelated donor.

7 days post-transplant, he develops a non-blanching purpuric rash over both legs. The rash is not itchy or scaly.

His heart rate 98/min and his blood pressure is 124/72 mmHg. His temperature is 37.3 ºC and he is otherwise asymptomatic.

Blood tests are as follows:

Hb	89 g/l	Na^+	138 mmol/l
Platelets	9 * 10 /l 9	K^+	3.2 mmol/l
WBC	0.8 * 10 /l 9	Urea	4 mmol/l
Neuts	0.2 * 10 /l 9	Creatinine	62 µmol/l
CRP	10 mg/ll		

What is the most likely cause for the rash?

A. Fungal infection
B. Graft vs host disease
C. Henoch Schonlein purpura
D. Meningitis
E. Thrombocytopenia

E. Thrombocytopenia

This man is on day 7 of his transplant and his blood counts are starting to drop, including his platelets. Thrombocytopenia typically causes small purpuric spots that are otherwise asymptomatic.

A fungal infection is possible in an immunosuppressed patient but would be more likely to cause an itchey or painful rash with a different appearance.

Graft vs host disease typical causes a dry scaley rash and develops when the patients immune system is starting to recover, around 2 weeks after transplant. Henoch Schonlein purpura typically affects children and is associated with a glomerulonephritis. It is immune mediated so unlikely in someone who is still profoundly immunosuppressed.

Meningitis can cause a non-blanching purpuric rash but the patient would be symptomatic with headache, fever, meningism and a CRP rise.

Question 61 of 89

A 45-year-old woman is admitted with chest pain three days after binge drinking 4 bottles of wine and 250mL of spirits.

She has a background of alcohol excess and systemic lupus erythematosus. She has a family history of G6PD deficiency on her father's side.

On examination, she is hemodynamically stable but jaundiced. She has pain on palpation over her right upper quadrant. Chest is clear and heart sounds are normal.

Hb	67 g/L	Male: (135-180)Female: (115 - 160)
Platelets	130 * 10 /L 9	(150 - 400)
WBC	9.8 * 10 /L 9	(4.0 - 11.0)
Bilirubin	72 µmol/L	(3 - 17)
ALP	360 u/L	(30 - 100)
ALT	70 u/L	(3 - 40)
Amylase	67 u/L	(40-140)
Triglycerides	5.8 mmol/L	(<1.7)
LDH	1095 IU/L	(105-333)
Direct anti-globulin test	Negative	

Spur cells and acanthocytes are present on blood film.

Given the likely diagnosis, what treatment from the following options would be most appropriate?

A. Abstinence from alcohol
B. Ascorbic acid
C. Intravenous fluids
D. Liver transplantation
E. Oral prednisolone

A. Abstinence from alcohol

Zieve syndrome usually resolves with abstinence from alcohol

This patient is presenting with jaundice, hyper-triglyceridaemia, and Coomb's negative haemolytic anaemia due to alcoholism and recent binge. The diagnosis here is Zieve syndrome - a rare complication of alcohol excess that is thought to be caused by changes in the red cell membrane due to the transient hyperlipidaemia seen following alcohol binges.

Abstinence from alcohol is the correct answer. Treatment of Zieve syndrome is with supportive management with blood transfusion and abstinence from alcohol. In rare cases, plasmapheresis may be required.

Ascorbic acid is incorrect. This can be used in the treatment of G6PD deficiency, however, this patient does not have this condition. G6PD is inherited in an X-linked recessive pattern and so a female child of a male with G6PD deficiency would be a carrier. G6PD deficiency would also not explain the cholestatic liver function tests and rise in triglycerides.

Intravenous fluids is incorrect. IV fluids would be indicated if there was evidence of pancreatitis, or if the patient was hemodynamically unstable. In this case, the patient has severe anaemia, but in the context of haemodynamic stability IV fluids would be inappropriate as they would lead to a further drop in Hb concentration via a dilutional effect.

Liver transplantation is incorrect. The King's college criteria state that for non-paracetamolinduced liver injury an INR >6.5 or three from; bilirubin of greater than 600µmol/L, an interval of >7 days between jaundice and encephalopathy, age <10 years or >40, INR >3.5, drug-induced or indeterminate cause of hepatitis, would be poor prognostic features and indicate liver transplant may be required.

Oral prednisolone is incorrect. This would be an option for alcoholic hepatitis or autoimmune haemolytic anaemia. In this case, the direct coomb's test is negative indicating that the low haemoglobin is not a result of immune-mediated haemolysis.

Question 62 of 89

A 52-year-old male was seen in the rapid access Transient Ischaemic Attack (TIA) clinic. He presented to his GP with new onset left leg and arm weakness three days ago. The weakness lasted for 90 minutes and fully resolved with no residual defect. He had a past medical history of hypertension, obstructive sleep apnoea and a left sided deep vein thrombosis eight years ago. His medication comprised ramipril 5mg OD. He smoked ten cigarettes per day and did not drink alcohol.

On examination, he had obvious truncal obesity and a flushed complexion. Blood pressure was 128/82 mmHg, heart rate 78/min, respiratory rate 16/min and oxygen saturations 99% on air. Cardiovascular examination revealed a regular pulse and nil else of note. Respiratory and gastrointestinal examination were normal, though examination of the abdomen was somewhat limited by the presence of truncal obesity. Neurological examination was unremarkable with normal cranial nerve, fundoscopy and peripheral neurological examinations.

Initial investigations revealed the following results:

Hb	191 g/l
MCV	98 fl
Hct	0.523
Platelets	502 * 10 /l
WBC	14.0 * 10 /l
Neutrophils	86%
Lymphocytes	10%
Monocytes	4%
HbA1c	43 mmol/mol
Fasting cholesterol	5.6 mmol/l

ECG: 76bpm normal sinus rhythm no other abnormality Chest x-ray: unremarkable

24 hr ECG: no arrhythmia seen

Echo: normal systolic function, mild aortic stenosis with pressure gradient of 42mmHg

CT head: normal intracranial appearances, no evidence of mass shift, space occupying lesion or haemorrhage

What is the most appropriate next investigation most likely to lead to the underlying diagnosis?

A. Cardiac catheterization
B. Testing for presence of JAK2 mutation
C. Bone marrow biopsy
D. Radioisotope scanning of circulating blood volumes
E. MRI scanning of the abdomen

B. Testing for presence of JAK2 mutation

This gentleman has polycythaemia rubra vera (PRV). Whilst all of the above investigations may facilitate the diagnostic process, this question asks *What is the most appropriate next investigation most likely to lead to the underlying diagnosis?*. Testing for JAK2 mutation has widely surpassed the use of radioisotope scanning and is diagnostic of PRV. It is, therefore, the best option

. Question 63 of 89

An 18-year-old man presents to the emergency department with headache and discolouration of his face. He has a past medical history of NADH methaemoglobinaemia reductase deficiency. He does not smoke cigarettes or drink alcohol.

His observations are as follows: heart rate 94 beats per minute, oxygen saturations 85% on room air, blood pressure 120/77 mmHg, respiratory rate 20/minute and temperature 37ºC.

Despite administration of 15L of oxygen via a non-rebreathe mask, the Sp2 remains 85%. On examination, he appears cyanotic. The cardiorespiratory examination is unremarkable.

Plain radiography of the chest is normal.

ABG results:

pH	7.36	(7.35-7.45)
pO2	11 kPa	(11-13)
pCO2	4 kPa	(4-6)
Hb	136 g/L	(135-175)
Lactate	2.0 mmol/L	(0-2)
MetHb	30%	(0.2-0.6)

What is the most appropriate treatment?

A. Antibiotic treatment
B. Ascorbic acid
C. Methylene blue
D. No specific treatment
E. Thrombolysis

B. Ascorbic acid

Ascorbic acid is the treatment of choice for NADH methaemoglobinaemia reductase deficiency

Ascorbic acid is correct. This patient has NADH methaemoglobinaemia reductase deficiency, which is a congenital form of methaemoglobinaemia. IV methylene blue is ineffective in this form of the disease. He has evidence of a deterioration in his condition requiring treatment with a methaemoglobin level >= 30%, cyanosis, headache and a low peripheral oxygen saturation level despite normal arterial oxygen content. Ascorbic acid has been shown to be effective in the treatment of this disorder.

Methylene blue is incorrect. This is not effective in this form of methaemoglobinaemia but is the typical treatment for acquired causes.

Antibiotics treatment is incorrect. The patient is apyrexial with a normal chest x-ray and there no history of cough or shortness of breath. An infection seems unlikely.

No specific treatment is incorrect. Symptoms and a methaemoglobin level >= 30% are both indications for treatment in this condition.

Thrombolysis is incorrect. While a pulmonary embolism is a plausible cause of low peripheral oxygen saturations with a normal examination and chest x-ray, the clinical context otherwise does not suggest this as the diagnosis. Furthermore, the typical indication for thrombolysis in pulmonary embolism is hypotension, which is absent in this case.

Question 64 of 89

A 34 year old man is admitted under the medics from the emergency department with central abdominal pain and vomiting not responding to IV morphine. He had been seen by the surgeons earlier in the day as an acute abdomen, but the CT scan they did of his abdomen and pelvis revealed no abnormalities, and his bloods suggested no surgical cause of the abdominal pain.

You note that the patient has presented to the emergency department five times in the past two years with similar problems, and no cause has ever been found, with the patient being discharged one or two days later with analgesia.

On examination his abdomen is generally tender with evidence of voluntary guarding. On further examination you note that he has a rash on the back of his hands, neck and cheeks. This rash consists of several small fluid filled bullae.

His past medical history includes depression - for which he is taking citalopram, and one short psychiatric inpatient stay for an episode of psychosis.

What is the most likely diagnosis?

A. Erythropoietic protoporphyria
B. Porphyria cutanea tarda
C. Hereditary coproporphyria
D. Acute intermittent porphyria
E. Congenital erythropoietic porphyria

D. Acute intermittent porphyria

The porphyrias are a group of rare inborn errors of metabolism caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of intermediate compounds called porphyrins.

Three patterns of symptoms occur clinically with porphyrias:

1) Neurovisceral - neuropathy, epilepsy, psychiatric disorders, abdominal, vomiting, constipation

2) Photosensitive - bullous eruption in sun exposed areas

3) Haemolytic

Neurovisceral only	Photosensitive only	Mixed
Acute intermittent porphyria	Porphyria cutanea tarda	Variegate porphyria
Aminolaevulinic acid dehydrogenase porphyria	Congenital erythropoietic porphyria	Hereditary coproporphyria
-	Erythropoietic protoporphyria	-

This patient has both photosensitive symptoms; his rash, and neurovisceral symptoms; abdominal pain and previous psychiatric history. The only mixed presentation porphyria given as a possible answer is hereditary coproporhyria, hence it is the correct answer.

Question 65 of 89

A 62 year old man is attending his GP as part of regular screening. He has a past medical history significant only for hypertension for which he has been taking amlodipine for many years. He reports no specific symptoms of note and is still working full time as an accountant. His blood pressure on this visit is 132/78mmHg and his urinalysis shows no abnormalities. Blood tests were taken for routine monitoring.

Hb	13.8 g/dl
Platelets	362 * 10 /l9
WBC	6.3 * 10 /l9
Na +	142 mmol/l
K +	4.2 mmol/l
Urea	4.6 mmol/l
Creatinine	84 µmol/l
Adjusted calcium	2.41mmol/l
Lactate Dehydrogenase	300 IU/l
Albumin	36 g/l
Globulin	52 g/l

An abnormal protein band is detected during analysis and the GP arranges for further review with the Haematologist at the hospital. Further investigations are undertaken:

Monoclonal paraprotein 18g/l

Bone Marrow examination showing 6% plasma cells Skeletal Survey showing no abnormalities

What is the diagnosis?

A. Multiple Myeloma
B. Hodgkins Lymphoma
C. Waldenstrom's macroglobulinemia (lymphoplasmacytic lymphoma)
D. Asymptomatic Myleoma
E. Monoclonal gammopathy on uncertain significance (MGUS)

E. Monoclonal gammopathy on uncertain significance (MGUS)

Monoclonal gammopathy on uncertain significance (MGUS) is a condition where an abnormal paraprotein is found in the blood, often during routine testing. It is on a spectrum that includes multiple myeloma but at the MGUS stage no treatment is indicated. The level of serum paraprotein is lower than in myeloma (under 30g/l) and the number of plasma cells in the bone marrow is also lower (less than 10%). The condition is totally asymptomatic. There is an annual risk of progression to myeloma of 1-2% and as such annual surveillance is recommended.

The diagnosis of MGUS can be made in patients who fulfil the following criteria –

- A monoclonal paraprotein band lesser than 30 g/L (< 3g/dL)
- Plasma cells less than 10% on bone marrow examination
- No evidence of bone lesions,anemia, hypercalcemia, or renal insufficiency related to the paraprotein
- No evidence of another B-cell proliferative disorder

In terms of myeloma this can be classified as below, taking note of both asymptomatic and symptomatic myeloma:

Symptomatic myeloma:

- Clonal plasma cells >10% on bone marrow biopsy or (in any quantity) in a biopsy from other tissues (plasmacytoma)
- A monoclonal protein (paraprotein) in either serum or urine (except in cases of true nonsecretory myeloma)
- Evidence of end-organ damage felt related to the plasma cell disorder (related organ or tissue impairment, ROTI, commonly referred to by the acronym 'CRAB'):
- hyperCalcemia (corrected calcium >2.75mmol/L)
- Renal insufficiency attributable to myeloma
- Anemia (hemoglobin <10 g/dL)

- Bone lesions (lytic lesions or osteoporosis with compression fractures)

Asymptomatic (smoldering) myeloma:

- Serum paraprotein >30 g/L AND/OR
- Clonal plasma cells >10% on bone marrow biopsy AND
- NO myeloma-related organ or tissue impairment

Question 66 of 89

You are the medical doctor on an acute admission unit. An elderly female with recently diagnosed ovarian cancer, who is on day 8 of cisplatin chemotherapy presents with a temperature of 39°C, tachycardia at 130 bpm, blood pressure 128/68 mmHg, respiratory rate 14/min, sats 98% on room air.

She is complaining of abdominal pain and has been vomiting today. Her bloods and blood culture have been sent and you are awaiting the results. Her chest x-ray was normal and urine dipstick clear.

What is the most appropriate antibiotic therapy to start her on?

A. IV benzylpenicillin + flucloxacillin
B. IV augmentin
C. IV ciprofloxacin
D. IV piperacillin/tazobactam
E. IV piperacillin/tazobactam + gentamicin

D. IV piperacillin/tazobactam

Piperacillin with tazobactam (Tazocin) is the empirical antibiotic of choice for neutropenic sepsis

The patient has presented with a systemic inflammatory response syndrome (SIRS) - tachycardia, pyrexia. The most likely cause for this would be an infection and she should be treated as a probable neutropenic sepsis until proven otherwise. Neutropenic sepsis tend to present on day 7- 10 post-chemotherapy. Given that we are unable to determine the source of infection, she should ideally be treated with a broad-spectrum antibiotic such as IV piperacillin/tazobactam. You would also normally add a stat dose of gentamicin but given that she was on cisplatin therapy, the combination of these 2 medications would be highly nephrotoxic and should be witheld until neutropenic sepsis is confirmed and renal function results are available.

Question 67 of 89

An 82-year-old man presents with a 6-month history of 8 kg of weight loss, fevers, and night sweats. On examination, he has cervical and inguinal lymphadenopathy and a mildly enlarged spleen. Blood results are as follows:

Hb	101 g/L	Male: (135-180)Female: (115 - 160)
Platelets	142 * 10 /L 9	(150 - 400)
WBC	40.5 * 10 /L 9	(4.0 - 11.0)
Neuts	2.8 * 10 /L 9	(2.0 - 7.0)
Lymphs	34 * 10 /L 9	(1.0 - 3.5)

Given the most likely diagnosis, what would be the diagnostic investigation of choice?

A. Bone marrow aspirate / trephine
B. CT neck, chest, abdomen and pelvis
C. Flow cytometry (immunophenotyping)
D. HIV test
E. Lymph node biopsy

C. Flow cytometry (immunophenotyping)

CLL - immunophenotyping is investigation of choice

The diagnosis is most certainly CLL which is the most common cause of significant lymphocytosis in an elderly patient.

CLL has a very specific immunophenotype and can thus be diagnosed on **flow cytometry** of peripheral blood.

Although a **bone marrow examination** and **lymph node biopsy** would also likely be diagnostic of CLL, they are invasive tests and thus should only be performed if immunophenotyping was nondiagnostic. A **CT neck, chest, abdomen, and pelvis** would be useful for staging, however, it would not be particularly helpful in making the diagnosis.

HIV can cause an early mild lymphocytosis (due to a CD8 lymphocytosis) however it is most often associated with lymphopaenia. The patient's age and presence of a marked lymphocytosis favour the diagnosis of CLL.

Question 68 of 89

A 39-year-old woman presents with anaemia secondary to menorrhagia. She has a past medical history of fibroids, rhesus incompatibility in pregnancy 9 years ago, and Hodgkin's lymphoma which has been in remission for 21 years.

She has a severe penicillin allergy. Her investigations show the following:

Hb	59 g/L	Female: (115 - 160)
Platelets	350 * 10 /L 9	(150 - 400)
WBC	4.7 * 10 /L 9	(4.0 - 11.0)

Pregnancy test: negative.

The consultant asks for you to prescribe her 2 units of packed red cells.

What requirement would apply to this patient's blood transfusion?

A. Give antihistamines with packed red cells
B. No special requirements
C. Use CMV negative packed red cells
D. Use irradiated packed red cells
E. Use washed red blood cells

D. Use irradiated packed red cells

Hodgkin lymphoma is an indication for irradiated blood products

The patient would require **irradiated** packed red cells due to her history of Hodgkin's lymphoma. Irradiated blood is treated with radiation which prevents lymphocyte division which can cause transfusion-associated graft-versus-host disease (TA-GvHD). A history of Hodgkin's lymphoma increases the risk of this reaction and hence all red cell, platelet, and granulocyte concentrates should be irradiated for life.

No special requirements is incorrect because this patient requires irradiated blood as explained above.

There is no indication for **antihistamines** to be given with packed red cells for this patient. Like all patients, she should be monitored for any signs of allergic reaction regularly during her transfusion but only treated for this if this occurs.

CMV negative blood is blood collected from donors who have tested negative for CMV IgG antibodies. CMV can cause serious infections in immunocompromised patients and is the most common cause of congenital infection cause developmental abnormalities in the UK. CMV negative blood should be used for intrauterine transfusions, neonates up to 28 days post expected delivery and for transfusions during pregnancy. There is no indication for CMV negative blood in this patient.

Washed red cells are used when there are recurrent and/or severe allergic reactions to transfusion and can also be used for IgA deficient patients with anti-IgA antibodies. This patient has a penicillin allergy but not to blood products.

Question 69 of 89

A 47-year-old woman with a background of obesity is admitted with left leg cellulitis. Blood cultures are taken and she is commenced on IV flucloxacillin.

Shortly afterwards, you are asked to see her as she has become itchy and light-headed in the last 5 minutes. Observations are as follows.

Respiratory rate 30 breaths per minute Oxygen saturations 90% on air Heart rate 127 beats per minute Blood pressure 75/42mmHg Temperature 36.8°C

Chest examination reveals widespread wheeze. The rest of the examination is unremarkable, other than her cellulitis which has not spread beyond the markings.

What statement is correct concerning the suspected diagnosis?

A. An elevated tryptase that remains at the same level after 2 hours supports the diagnosis
B. High tryptase now confirms the diagnosis
C. Normal tryptase at 24 hours excludes the diagnosis
D. Normal tryptase now excludes the diagnosis
E. Normal tryptase now that becomes elevated in 2 hours supports the diagnosis

A. Normal tryptase now that becomes elevated in 2 hours supports the diagnosis

Anaphylaxis - serum tryptase levels rise following an acute episode

The correct answer is **normal tryptase now that becomes elevated in 2 hours supports the diagnosis**. The features of cardiovascular collapse, breathing difficulty and bronchospasm following IV antibiotics are suggestive of anaphylaxis. Tryptase is released into the blood in the context of mast cell degranulation. In anaphylaxis, it is expected to rise quickly in the first minutes to hours before gradually falling. NICE recommend it is measured at baseline and after 1-2 hours (but no later than 4). If measured at onset, it may be normal - the key finding is the elevation over the first few hours. If measured after 4 hours, it may have returned to normal.

An elevated tryptase that remains at the same level after 2 hours supports the diagnosis is incorrect. Some patients have elevated tryptase at baseline, for example in the context of systemic mastocytosis. It can also cross-react, for example with rheumatoid factors, leading to elevated levels in the absence of anaphylaxis. The lack of a change over 2 hours is more suggestive of a high baseline rather than anaphylaxis, where we would expect a significant change from onset to 2 hours.

High tryptase now confirms the diagnosis is incorrect. A single elevated measurement does not confirm the diagnosis for the reasons described above - a second sample must be taken within the next few hours to check for a change from baseline.

Normal tryptase at 24 hours excludes the diagnosis is incorrect. By 24 hours, we would expect the tryptase level to have returned to baseline, even in a significant anaphylactic episode. A baseline level and a 1-2 hour level would be much more helpful.

Normal tryptase now excludes the diagnosis. Tryptase level at the onset of symptoms may be normal as it takes at least 15 minutes (but longer in some patients) to mount a response, and we are told the symptoms have lasted 5 minutes here. A single measurement has limited utility, and we would have to repeat the sample at 1-2 hours for more useful information.

Question 70 of 89

A 17-year-old man presents to the acute medical unit with shortness of breath. He takes no regular medicines and denies the use of any recreational, herbal, or over-the-counter medications. He has not been exposed to any local anaesthetics or chemicals. On examination, his chest was clear on auscultation and he was markedly cyanotic. Despite the cyanosis, his SpO2 is 92%.

You start the patient on 15L O2 via a non-rebreather mask. Blood gas analysis results are as follows:

pH	7.28	(7.35 - 7.45)
PaO2	66.5 kPa	(10.3 - 13.3 kPa)
PaCO2	2.8 kPa	(4.7 - 6 kPa)
HCO3	22 mmol/L	(22 - 28 mmol/L)
SaO2	52%	(94-98)

The patient moved to the UK from India 6 weeks ago. His medical records are not available. However, he advises you that he has a 'blood disorder' that runs in his family.

Given the most likely diagnosis, what is the treatment of choice?

A. 4-Dimethylaminophenol
B. Ascorbic acid
C. C1-inhibitor concentrate
D. Hydroxocobalamin
E. Hyperbaric oxygen

B. Ascorbic acid

Ascorbic acid is the treatment of choice for NADH methaemoglobinaemia reductase Deficiency

The striking feature, in this case, is the significant discrepancy between the PaO2 and SaO2. Given the patient is on 15L O2, the PaO2 is at a level expected indicating that gas exchange at the level of the alveoli is not impaired. However, the SaO2 is markedly low at 52% indicating impaired oxygen binding to haemoglobin. The main two causes of this picture are methaemoglobinaemia and carboxyhemoglobinemia. The family history is indicative of familial NADH methaemoglobinaemia reductase deficiency.

Ascorbic acid is the treatment of choice for NADH methaemoglobinaemia reductase deficiency.

Hyperbaric oxygen is the treatment of choice for severe carbon monoxide poisoning. Although carbon monoxide poisoning presents similarly and remains within the differential diagnosis, the positive family history makes congenital methaemoglobinaemia the more likely diagnosis.

4-Dimethylaminophenol and **hydroxocobalamin** can be used for the treatment of cyanide poisoning. Cyanide binds the ferric (Fe3+) ion of cytochrome oxidase causing 'histotoxic hypoxia' and lactic acidosis. It would not cause a marked reduction of SaO2 as seen in this case unless it was associated with coexistent carbon monoxide poisoning (e.g. due to smoke inhalation). There is nothing in this case to suggest that this is the case.

C1-inhibitor concentrate remains the gold standard treatment for the acute management of hereditary angioedema. The clinical and laboratory features, in this case, are not in keeping with hereditary angioedema which presents with recurrent attacks of self-limiting oedema affecting the skin, gastrointestinal tract, and airways.

Question 71 of 89

A 36-year-old man is brought to the emergency department following a motor vehicle accident. He is drowsy but conscious. He has an open fracture on the right anterior shin which is bleeding profusely. Vital sign monitoring reveals that he has a respiratory rate of 22 bpm, heart rate of 118 bpm, blood pressure of 92/55 mmHg and temperature of 37.1 degrees Celsius. In an attempt to resuscitate the patient, the doctor decides to transfuse 2 pints of group O negative blood. A few minutes after giving the blood, the nurse notices that the patients developed a generalized rash and swelling of the lips, associated with a loud breathing sound. His medical notes reveal that he has atopy and has been treated for giardiasis multiple times previously.

Which one of the following conditions could possibly represent a predisposition to the patient's condition?

A. Von Willebrand disease
B. Hairy cell leukemia
C. Selective IgA deficiency
D. Severe combined immunodeficiency
E. Wiskott-Aldrich syndrome

C. Selective IgA deficiency

IgA deficiency is associated with anaphylactic reaction to blood products

This patient presented after a motor vehicle accident with an open fracture wound. The vital signs pointed towards a hypovolemic shock secondary to blood loss from the fracture wound and also possibly secondary to an internal injury, such as a spleen laceration. The patient was transfused with group O negative blood, which is the universal donor blood group, but developed an anaphylactic reaction. This is quite unusual given that the blood was group O negative. Anaphylactic reactions to products are common among individuals with selective IgA deficiency. Selective IgA deficiency is the most common primary immunodeficiency and individuals with this condition have low IgA levels despite normal levels of the IgG and IgM. Patients often suffer from recurrent airway infections, atopy, autoimmune diseases and are prone to have giardiasis infection. To avoid this, these patients must receive blood products without IgA.

1: Von Willebrand disease is a coagulation disorder which affects intrinsic pathway and is due to deficient von Willebrand factor. This leads to an impairment in the formation of the platelet plug. There is no increased risk of anaphylaxis to blood products in patients with this condition.

2: Hairy cell leukemia is one type of lymphoid neoplasm with the cells having hair-like projections and hence the name of the condition. The disease leads to bone marrow fibrosis. There is no increased risk of anaphylaxis to blood products in patients with this condition.

4: Severe combined immunodeficiency is a type of immunodeficiency which involves both a B and T-cell disorder. There are different types comprising IL-2R gamma chain deficiency and adenosine deaminase deficiency. Patients often present with failure to thrive, thrush and diarrhea. They have an increased susceptibility to infections from several types of microorganisms such as viruses, fungi, protozoan, and bacteria. There is no increased risk of anaphylaxis to blood products in patients with this condition.

5: Wiskott-Aldrich syndrome is a type of immunodeficiency which involves both a B and T-cell disorder. It is due to a mutation on the WASp gene causing platelets and leukocytes to be unable to carry out antigen presentation due to a defective actin cytoskeletal reorganization. Patients often present with the triad of thrombocytopenia, recurrent pyogenic infections, and eczema. There is no increased risk of anaphylaxis to blood products in patients with this condition.

Question 72 of 89

A 35-year-old patient presents to a rural emergency department with abdominal pain and facial swelling. He has a past medical history of C1 esterase inhibitor deficiency. He has recently arrived from Belarus and does not have any of his regular medications. He does not smoke cigarettes or drink alcohol.

His observations are heart rate 88 beats per minute, blood pressure 122/78mmHg, respiratory rate 18/minute, oxygen saturations 96% on room air and temperature 37ºC.

On examination, there is facial swelling without airway compromise. There is mild abdominal tenderness without any evidence of peritonism. There is no rash or wheeze.

Unfortunately, there is no possibility of locating IV C1-inhibitor concentrate in this rural setting. Given the clinical history,

what is the most appropriate medication to abort the attack?

A. Adrenaline
B. Danazol
C. Fexofenadine
D. Fresh frozen plasma
E. Prednisolone

D. Fresh frozen plasma

Hereditary angioedema: the acute management is IV C1-inhibitor concentrate or fresh frozen plasma if this is not available

Fresh frozen plasma is the correct answer. This is an available option for treating acute attacks of hereditary angioedema (HAE) if IV C1-inhibitor concentrate is not available.

Danazol is incorrect. This is a gonadotropin inhibitor used in the prophylaxis of HAE rather than in the management of acute attacks.

Fexofenadine, prednisolone and adrenaline are all incorrect. They are ineffective in managing the swelling associated with this condition. The postulated theory is that histamine-mediated angioedema responds to these interventions but bradykinin mediated angioedema is resistant. Bradykinin is the principal mediator of symptoms in HAE.

Question 73 of 89

A 73-year-old woman is reviewed routinely in haematology clinic. She has a diagnosis of chronic lymphocytic leukaemia. She is not on any treatment but remains under regular review. She has lost 5% of her body weight in the last 9 months. She reports occasional fatigue. She does not smoke cigarettes or drink alcohol. She lives alone and is independent.

On examination, there are two 0.5cm lymph nodes palpable in her neck, which were palpable at her previous appointment.

Blood tests at the time of clinic review:

Hb	122 g/L	Male: (135-180)Female: (115 - 160)
Platelets	75 * 10^9/L	(150 - 400)
WBC	14 * 10^9/L	(4.0 - 11.0)
Neuts	6.0 * 10^9/L	(2.0 - 7.0)
Lymphs	7.8 * 10^9/L	(1.0 - 3.5)
Mono	0.2 * 10^9/L	(0.2 - 0.8)
Eosin	0.0 * 10^9/L	(0.0 - 0.4)

Blood tests two months ago:

Hb	123 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10^9/L	(150 - 400)
WBC	13.5 * 10^9/L	(4.0 - 11.0)
Neuts	6 * 10^9/L	(2.0 - 7.0)
Lymphs	7.3 * 10^9/L	(1.0 - 3.5)
Mono	0.2 * 10^9/L	(0.2 - 0.8)
Eosin	0.0 * 10^9/L	(0.0 - 0.4)

What patient-specific factor does this patient possess that warrants commencing treatment for her underlying malignancy?

A. Fatigue
B. Weight loss
C. Lymphadenopathy
D. Progressive lymphocytosis
E. Thrombocytopenia

A. Thrombocytopenia

Thrombocytopenia -> indication to start treatment in CLL

Thrombocytopenia is the correct answer. The development of thrombocytopenia is an indication to start treatment in CLL.

Fatigue is incorrect. While extreme fatigue may be an indication to start treatment, this patient reports only occasional fatigue and therefore treatment is not warranted on this basis.

Progressive lymphocytosis is incorrect. This patient has a < 50% increase in lymphocyte count over the course of two months and therefore does not meet criteria to start treatment on this basis.

Lymphadenopathy is incorrect. The lymphadenopathy needs to be either massive (>10cm) or progressive to warrant treatment and it is neither.

Weight loss is incorrect. This patient has lost 5% of her body weight in 9 months. She would need to have lost 10% in approximately six months to warrant treatment.

Question 74 of 89

A 67-year-old male with known chronic lymphocytic leukaemia (CLL) currently under monitoring only presents to his general practitioner. He has developed new fevers and reports his pillow being wet. He has a dry cough and has lost a few pounds in weight but otherwise feels well. He is otherwise well and has hypertension and type 2 diabetes. He was taking amlodipine, metformin and tolbutamide but has stopped these two weeks prior due to his prescription not being renewed. He is a smoker and drinks alcohol 10-14 units a week.

On examination, his temperature is 37.9ºC and his chest is clear. He is clammy but there are no visible rashes.

Hb	124 g/l
Platelets	378 * 10^9/l
WBC	13.2 * 10^9/l
Neuts	11.2* 10^9/l
CRP	9mg/L
LDH	857 U/L (normal range 180-360 U/L)

What is the likely explanation?

A. Drug withdrawal reaction
B. Richter's transformation
C. Lower respiratory tract infection (LRTI)
D. Glandular fever
E. Neutropaenic sepsis

B. Richter's transformation

New B-symptoms in CLL -> Richter's transformation

This gentleman presents with new fevers and night sweats on a background of CLL which is normally controlled. He notably has a raised lactate dehydrogenase (LDH) and these symptoms in the context of haematology are B-symptoms. He is not neutropenic. Glandular fever would not explain the night sweats and fevers and usually presents with fatigue and a sore throat. The medications would not cause isolated fever as a withdrawal reaction. A LRTI is possible but there is only a dry cough and no chest signs. We know that 5% of CLL will undergo Richter's transformation becoming a high grade lymphoma with new B-symptoms and crucially a rise in LDH which makes this the likeliest answer.

Question 75 of 89

A 53-year-old man presents with abdominal pain. He was seen six weeks ago by surgeons who diagnosed gastritis and offered omeprazole. He initially improved but the pain recurred and he has no benefit with omeprazole or gaviscon. He feels full quickly but has no dysphagia or regurgitation. He denies any heartburn. He reports general low energy and is sleeping more hours in the day and can fall asleep at any time.

On examination, a mass is palpable in the epigastrium. It has a palpable indent and you cannot get above it. There are bowel sounds and no other masses are felt. There are some isolated left axillary lymph nodes palpable. His temperature is 37.8ºC and heart rate is 78 beats per minute.

Hb	114 g/l
Platelets	289 * 10 /l9
WBC	51 * 10 /l9

What is the likeliest underlying diagnosis?

A. Gastric carcinoma
B. Visceral leishmaniasis
C. Chronic myelogenous leukaemia (CML)
D. Obstructive sleep apnoea (OSA)
E. Narcolepsy

C. Chronic myelogenous leukaemia (CML

CML may present with massive splenomegaly

This gentleman presents with abdominal pain and a new mass that based on location is likely spleen, stomach or left kidney. OSA and narcolepsy explain the sleepiness but not the abdominal symptoms. Gastric carcinoma with outlet obstruction can give a mass but usually there is vomiting or regurgitation of food contents. The mass is therefore likely to be spleen of which CML and leishmaniasis are the commonest causes. Leishmaniasis is less common making CML the likeliest diagnosis. Furthermore, the WBC is through the roof supporting CML as the cause.

Question 76 of 89

A 12-year-old boy is referred by his paediatrician to a tertiary immunology service. Since infancy, he has suffered from recurrent infections. He has required multiple courses of antibiotics for episodes of sinusitis, otitis media and pneumonia. Heel prick testing was normal perinatally. The referral was ultimately made after he had a prolonged admission to the paediatric intensive care unit with respiratory failure requiring intubation, where he was diagnosed with *Pneumocystis jirovecii* pneumonia. HIV testing was negative. In addition to recurrent infections, he has had chronic diarrhoea, for which no cause has been found. He is on no regular medications. He does not smoke or drink alcohol and is doing well in school despite his frequent illnesses. His parents attend the appointment with him.

Clinical examination revealed a thin adolescent. There was evidence of stomatitis and gingivitis. There was no organomegaly or lymphadenopathy. The cardiovascular and respiratory examination was unremarkable. There were no rashes. Neurological examination is unremarkable.

Blood tests:

Hb	124 g/L	Male: (135-180)Female: (115 - 160)
Platelets	144 * 10 /L	(150 - 400)
WBC	3.2 * 10 /L	(4.0 - 11.0)
Neuts	1.5 * 10 /L	(2.0 - 7.0)
Lymphs	0.8 * 10 /L	(1.0 - 3.5)
Mono	0.6 * 10 /L	(0.2 - 0.8)
Eosin	0.3 * 10 /L	(0.0 - 0.4)
Na	136 mmol/L	(135 - 145)
K	4.4 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	77 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	8 µmol/L	(3 - 17)
ALP	77 u/L	(30 - 100)
ALT	16 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	32 g/L	(35 - 50)
Immunoglobulin A	0.4 g/L	(0.6-5.0)
Immunoglobulin M	2.6 g/L	(0.53 - 2.47)
Immunoglobulin G	5.4 g/L	(6.60 - 15.90)

What is the likely diagnosis?

A. Coeliac disease
B. Cystic fibrosis
C. Hyper IgM syndrome
D. Malnutrition
E. X-linked congenital agammaglobulinaemia

C. Hyper IgM syndrome

Hyper IgM syndrome characteristically presents with infections e.g. *Pneumocystis* pneumonia, hepatitis, diarrhoea

Hyper IgM syndrome is correct. This is usually x-linked and therefore affects males. It is characterized by recurrent bacterial infections, chronic diarrhoea and infection with atypical organisms such as Pneumocystis. It may also be associated with autoimmune anaemia, neutropenia and thrombocytopenia. Patients often have stomatitis and gingivitis. IgM may either be normal or high. IgG and IgA will be low as the condition causes an inability to class switch from IgM.

Bruton's (x-linked) congenital agammaglobulinaemia is incorrect. This causes recurrent bacterial infections but all immunoglobulin subclasses will be low including IgM.

Cystic fibrosis is incorrect. While it would cause recurrent chest infections, heel prick testing as a newborn being normal makes this diagnosis unlikely.

Coeliac disease is incorrect. This can cause a thin habitus and diarrhoea but would not explain the other findings.

Malnutrition is incorrect. While this can predispose to infection, there is no reason to believe he is not being cared for properly. We are told he is doing well in school and has supportive parents that attend his hospital appointments.

Question 77 of 89

A 74-year-old man is seen in the haematology clinic. He was diagnosed with chronic lymphocytic leukaemia 6 months ago following an incidental finding of lymphocytosis on some routine blood tests with his General Practitioner. He is currently under surveillance monitoring.

Over the last 6 months he has generally been in good health. He has occasional fatigue particularly towards the end of the day but remains to have a good appetite and reports no change in his weight. Only for the last week has he reported to be feeling more unwell with intermittent fevers and chills.

On examination he is febrile at 38.3ºC. He is mildly tachycardic with a heart rate of 114bpm and a blood pressure of 133/79mmHg. His chest is clear and heart sounds are normal. His abdomen is soft and non-tender. There is palpable 2cm splenomegaly.

Full blood count (6 months ago):

Hb	148 g/L	Male: (135-180)Female: (115 - 160)
WBC	49.3 * 10 /L 9	(4.0 - 11.0)
Lymphocytes	46.3 * 10	(0.8 - 5.0)
Neutrophils	2.7 * 10	(2.5 - 7.5)
Platelets	200 * 10 /L 9	(150 - 400)

Full blood count (today):

Hb	127 g/L	Male: (135-180)Female: (115 - 160)
WBC	75.6 * 10 /L 9	(4.0 - 11.0)
Lymphocytes	69.4 * 10	(0.8 - 5.0)
Neutrophils	3.8 * 10	(2.5 - 7.5)
Platelets	102 * 10 /L 9	(150 - 400)

Blood film: smudge cells seen.

Which of the following is an indication to start treatment in this patient?

A. Splenomegaly
B. Presence of fever for 1 week
C. White cell count > 75
D. Presence of smudge cells on peripheral blood film
E. Thrombocytopenia

A. Thrombocytopenia

Thrombocytopenia -> indication to start treatment in CLL

This patient has a new thrombocytopenia compared to his blood tests 6 months ago. A new thrombocytopenia or sign of bone marrow failure is an indication to initiate treatment. Treatment options vary depending on the patient's overall health, co-morbidities and prognostic factors.

Massive splenomegaly > 5cm is an indicator to start treatment. However, this patient has a 2cm splenomegaly which does not make it an indicator for starting treatment.

Recurrent infections or fevers persisting beyond 2 weeks are indicators for starting treatment. This patient has had fevers for 1 week. However, if this continued then that would be a second indicator for starting treatment.

A rising lymphocyte count is an indicator for starting treatment. However, a doubling of lymphocytes in 6 months is needed which is not seen here.

Smudge cells are not an indicator for starting treatment.

Other indicators for starting treatment include: massive lymphadenopathy, constitutional symptoms including fever, weight loss or night sweats and the presence of haemolysis

Question 78 of 89

A 45-year-old man is referred to the haematology clinic with a 4-month history of easy bruising and prolonged bleeding. He denies any other symptoms and is otherwise feeling well. His past medical history includes rheumatoid arthritis that he reports is not well-controlled, with frequent flares. There is no family history of bleeding disorders.

Laboratory blood tests:

Hb	126 g/L	(135-180)
Platelets	201 * 10 /L 9	(150 - 400)
WBC	5.5 * 10 /L 9	(4.0 - 11.0)
Prothrombin time (PT)	12 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	45 secs	(25-35 secs)
Fibrinogen	2.2 g/L	(2 - 4)
D-Dimer	300 ng/mL	(< 400)
Von Willebrand Factor	100 IU/dL	(50-150)
Factor VIII levels	Reduced	

What is the most likely diagnosis?

A. Acquired haemophilia A

B. Beta thalassaemia trait

C. Christmas disease

D. Factor V Leiden

E. Von Willebrand's disease

A. Acquired haemophilia A

Acquired haemophilia A is diagnosed in patients without previous or familial histories of bleeding who have isolated prolongation of the activated partial thromboplastin time (aPTT), reduced FVIII levels as well as evidence of FVIII inhibitor activity

This patient has a diagnosis of acquired haemophilia A, an autoimmune disorder secondary to antibody production against factor VIII. Unlike congenital haemophilia A, acquired haemophilia A develops later in life. Up to 50% of cases of acquired haemophilia A are associated with co-existing autoimmune conditions such as rheumatoid arthritis, systemic lupus erythematosus and inflammatory bowel disease. The investigation findings are similar to congenital haemophilia A and include a raised aPTT and reduced FVIII levels. The presence of antibodies to factor VIII helps to differentiate between congenital and acquired causes.

Beta thalassaemia trait is a disorder of haemoglobin chain production, causing microcytic anaemia. Symptoms include those associated with anaemia such as pallor, shortness of breath and fatigue. Bruising and bleeding are not common features and beta thalassaemia trait does not explain this patient's clotting abnormalities.

Christmas disease (also known as haemophilia B) is an inherited coagulation disorder associated with reduced levels of factor IX. It has no impact on factor VIII levels and cannot explain this patient's laboratory findings.

Factor V Leiden (also known as activated protein C resistance) is the most common cause of thrombophilia. Rather than increasing bleeding, increased coagulation is seen, including an increased risk of deep vein thromboses. Therefore, factor V Leiden is incorrect.

Von Willebrand's disease is the most common inherited bleeding disorder. Symptoms include epistaxis, menorrhagia and gum bleeding. Similarly to this patient, coagulation studies demonstrate a prolonged APTT and reduced factor VIII levels. However, the presence of factor VIII inhibitor activity makes a diagnosis of Von Willebrand's disease less likely and points toward an autoimmune cause of this patient's symptoms.

Question 79 of 89

A 65-year-old female, known to have metastatic breast carcinoma presents to the hospital with a 24-hour history of increasing pain, swelling and erythema of her right calf. She is otherwise relatively well. She was diagnosed with breast carcinoma four years previously and was initially treated with surgery, radiotherapy and chemotherapy. She was found to have disease recurrence with distant metastasis 12 months previously. She is known to have liver and bone metastases.

On examination, she appears pale and has some hair loss following recent chemotherapy. Apart from her swollen, erythematous, tender right calf and a fentanyl patch examination is unremarkable.

Bloods on admission show:

Hb	100 g/l
Platelets	180 * 10 /l9
WBC	7.2* 10 /l9
D-Dimer	1276 µg/L (normal <500µg/L)
Na $^+$	132 mmol/l
K $^+$	4.5 mmol/l
Urea	7.2mmol/l
Creatinine	110 µmol/l

She is diagnosed with a right leg deep vein thrombosis.

Given her current clinical condition, what is the best method of anticoagulation?

A. Low molecular weight heparin (LMWH) and warfarin until warfarin therapeutic followed bywarfarin therapy for 6 months then reassess.
B. Low molecular weight heparin (LMWH) for 3-6 months then reassess
C. Warfarin therapy starting with a slow loading regime for 6 months then reassess
D. Direct oral anticoagulants (DOACs) for 3-6 months then reassess
E. Referral for inferior vena cava filter insertion

D. Direct oral anticoagulants (DOACs) for 3-6 months then reassess

Cancer patients with VTE - 6 months of a DOAC

Question 80 of 89

A 68-year-old woman is reviewed in haematology clinic routinely. She has a past medical history of chronic lymphocytic leukaemia (CLL), characterised by a deletion of the short arm of chromosome 17 (17p).

On examination, there is cervical lymphadenopathy and splenomegaly. Blood tests:

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	35.3 * 10 /L $_9$	(4.0 - 11.0)
Neuts	2.1 * 10 /L $_9$	(2.0 - 7.0)
Lymphs	33.0 * 10 /L $_9$	(1.0 - 3.5)
Mono	0.2 * 10 /L $_9$	(0.2 - 0.8)
Eosin	0.0 * 10 /L $_9$	(0.0 - 0.4)
Na $^+$	138 mmol/L	(135 - 145)
K $^+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.1 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Lactate dehydrogenase (LDH)	180 U/L	(140-280)

Given the clinical history and underlying diagnosis, which clinical feature is associated with the worst prognosis?

A. Female sex
B. Age > 60
C. Lymphocyte count > 30
D. Normal LDH
E. 17p deletion

A. 17p deletion

del 17p is associated with a poor prognosis in CLL

17p deletion is the correct answer. The patient has chronic lymphocytic leukaemia. This a type of cancer in which the bone marrow makes too many lymphocytes, as evidenced in this case. The cancer in this case is characterized by a genetic mutation causing deletion of 17p, which is a part of chromosome 17. This is associated with a poor prognosis in CLL. It is seen in 5-10% of patients. The absence of part of chromosome 17 results in absence of one allele of the TP53 tumour suppressor gene, predisposing to the development of CLL.

Age > 60 is incorrect. Poor prognosis is associated with those > 70 years of age.Lymphocyte count > 30 is incorrect. Poor prognosis is associated with those patients with lymphocyte counts > 50.Normal LDH is incorrect. A raised LDH implies a worse prognosis.Female sex is incorrect. Male sex implies a worse prognosis.

Question 81 of 89

A 24-year-old woman is admitted with a 1-hour history of worsening dyspnoea. On examination, you note stridor and marked angioedema of the lips and tongue. No rash is present. You immediately seek the assistance of the anaesthetic team to help secure the airway.

The patient has a history of hereditary angioedema. You are told that due to manufacturing issues, IV C1-inhibitor concentrate is not available.

What alternative treatment should be offered?

A. Danazol
B. Fresh frozen plasma
C. Intramuscular adrenaline
D. Intravenous methylprednisolone
E. Tranexamic acid

B. Fresh frozen plasma

Hereditary angioedema: the acute management is IV C1-inhibitor concentrate or fresh frozen plasma if this is not available

The correct answer is **fresh frozen plasma**. This is considered a second-line therapy where C1 inhibitor concentrate is not available as the plasma itself contains C1 inhibitor. No randomised control trials exist but a majority of case reports describe efficacy with signs of improvement described between 30 minutes and 12 hours.

Danazol is incorrect. This is a synthetic androgen that is used in prophylaxis of acute episodes in patients with hereditary angioedema. It has not been shown to provide any benefit in acute attacks.

Intramuscular adrenaline is incorrect. Similar to glucocorticoids, adrenaline is not effective in hereditary angioedema. Episodes of angioedema not responding to adrenaline may be one of the first clues to the diagnosis.

Intravenous methylprednisolone is incorrect. While glucocorticoids are used in histamine-driven angioedema, they are not effective in hereditary angioedema as the pathogenesis is driven by bradykinin rather than histamine. **Tranexamic acid** is incorrect. It has been used for prophylaxis but a minimal effect is seen when used for the treatment of acute attacks.

Question 82 of 89

A 35-year-old woman presents to the emergency department with a one day history of a fever. She has a past medical history of metastatic breast cancer and has received her most recent round of chemotherapy 8 days ago. She is not on any other regular medications.

Her observations are heart rate 111 beats per minute, blood pressure 96/58 mmHg, respiratory rate 22/minute, oxygen saturations 97% on room air and temperature 38.7ºC.

On examination, she is warm to touch with capillary refill time < 2 seconds. A bounding pulse is noted. There is no obvious localizing source of infection from the rest of the examination.

Urinalysis is unremarkable.

Plain radiography of the chest is normal. Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	389 * 10 /L 9	(150 - 400)
WBC	1.7 * 10 /L 9	(4.0 - 11.0)
Neuts	0.4 * 10 /L 9	(2.0 - 7.0)
Lymphs	0.9 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.2 * 10 /L 9	(0.0 - 0.4)
Na +	137 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Bicarbonate	20 mmol/L	(22 - 29)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	111 µmol/L	(55 - 120)
CRP	180mg/l	(<4)

What is the appropriate antibiotic choice?

A. Meropenem
B. Piperacillin/tazobactam
C. Piperacillin/tazobactam and gentamicin
D. Piperacillin/tazobactam and gentamicin and vancomycin
E. Piperacillin/tazobactam and vancomycin

B. Piperacillin/tazobactam

Piperacillin with tazobactam (Tazocin) is the empirical antibiotic of choice for neutropenic sepsis

Piperacillin/tazobactam is the correct answer. This patient has neutropenic sepsis secondary to chemotherapy treatment. This choice is supported by NICE guidelines and is first-line for the treatment of neutropenic sepsis.

Meropenem is incorrect. If the patient fails to respond after 48 hours then they may be escalated to meropenem.

Piperacillin/tazobactam and vancomycin is incorrect. Some units advocate giving vancomycin in addition to piperacillin/tazobactam if there is an indwelling central venous access device. This patient does not have such a device in situ and this procedure is not supported by NICE.

Piperacillin/tazobactam and gentamicin is incorrect. NICE specifically advise not adding an aminoglycoside unless local policy dictates.

Piperacillin/tazobactam and gentamicin and vancomycin is incorrect. This is not a treatment strategy supported by NICE.

Question 83 of 89

A 67-year-old woman presents to her GP with a lump in her armpit that she first noticed two months ago, and feels is getting bigger. She has not suffered from pyrexia, night sweats, weight loss or lethargy. The GP runs some blood tests, which can be seen below.

Hb	116 g/L	Male: (135-180)Female: (115 - 160)

Platelets	160 * 10 /L 9	(150 - 400)
WBC	72 * 10 /L 9	(4.0 - 11.0)
Neuts	5 * 10 /L 9	(2.0 - 7.0)
Lymphocytes	66 * 10 /L 9	(1.0 - 3.5)
Blood film	smudge cells	

Which of the following would imply a poor prognosis in this woman?

A. Female sex
B. Philadelphia translocation
C. Low B2-microglobulin
D. Del 17p
E. Age less than 70

D. Del 17p

del 17p is associated with a poor prognosis in CLL

This woman is suffering from chronic lymphocytic leukaemia (CLL), a slowly progressive disease. Most patients are either asymptomatic or present with lymphadenopathy. Only 10% of patients will have B symptoms of lymphoma. Half of the patients present with splenomegaly and about 15% with hepatomegaly. The key to making this diagnosis is the lymphocyte-predominant leukocytosis, with smudge cells on the blood film. Smudge cells, also known as smear cells, are cell remnants that arise during slide preparation and are the result of abnormally fragile lymphocytes in CLL.

From the options given above, the only poor prognostic indicator is del 17p mutation, which indicates resistance to standard chemotherapy regimens. B2-microglobulin levels are used in multiple myeloma where raised levels imply poor prognosis. It has also been included in the new (2016) CLL international prognostic index, where again high levels imply poor prognosis.

Philadelphia translocation, t(9;22), is a poor prognostic factor in ALL.Male sex, not female sex, is a poor prognostic factor.An age of fewer than 70 years old is a good prognostic marker

Question 84 of 89

A 16-year-old boy from Iran presents to the emergency department with dyspnoea, dry cough, and fevers.

On arrival, his oxygen saturations are 91% with a respiratory rate of 27/minute. His blood pressure is 110/70mmHg and heart rate 89/minute. There are widespread crackles on auscultation.

Chest x-ray shows diffuse bilateral interstitial infiltrates. You begin treatment for communityacquired pneumonia and send sputum samples for culture.

Blood tests:

Hb	95g/L	Male: (135-180)Female: (115 - 160)
Platelets	140* 10 /L 9	(150 - 400)
WBC	2.7* 10 /L 9	(4.0 - 11.0)
Neuts	0.7* 10 /L 9	(2.0 - 7.0)
Lymphs	1.7* 10 /L 9	(1.0 - 3.5)
Mono	0.1* 10 /L 9	(0.2 - 0.8)
Eosin	0.2* 10 /L 9	(0.0 - 0.4)
Na +	140mmol/L	(135 - 145)
K +	3.8mmol/L	(3.5 - 5.0)
Urea	9mmol/L	(2.0 - 7.0)
Creatinine	80µmol/L	(55 - 120)
CRP	234mg/L	(< 5)

His sputum sample grows *Pneumocystis jirovecii* and his antimicrobials are changed to include Cotrimoxazole.

You return to take a more detailed history. He denies any recent treatment with glucocorticoids or immunosuppressive agents. He denies intravenous drug use and informs you he is not yet sexually active. His mother is in attendance and tells you he has suffered from recurrent gastroenteritis throughout his childhood and she feels this led to him being smaller than his peers.

What is the most likely underlying unifying diagnosis?

A. Cryptosporidium
B. Hyper IgM syndrome
C. HIV
D. Acute lymphoblastic leukaemia
E. Malnutrition

A. Cryptosporidium

Hyper IgM syndrome characteristically presents with infections e.g. *Pneumocystis* pneumonia, hepatitis, diarrhoea

This patient has presented with pneumocystis pneumonia, an opportunistic infection caused by an underlying immune deficiency (hyper IgM syndrome).

Hyper IgM syndrome is a heterogeneous group of disorders characterised by defective classswitch recombination leading to raised serum IgM with low levels of IgG and IgA. The most common form is an X-linked recessive trait due to mutation of CD40LG gene affecting roughly 2/1,000,000 males. The mechanism involves impaired immune signalling between T and B cells leading to primary immune deficiency.

Hyper IgM typically presents in infancy as acute severe infection such as pneumocystis pneumonia or cryptosporidium. It may also present as chronic infections throughout childhood with failure to thrive. CMV is common and may lead to associated liver disease. It is also associated with increased risk of hepatocellular carcinoma, cholangiocarcinoma and neuroectodermal tumours. A minority of patients may present with autoimmune disease such as inflammatory bowel disease.

Acute lymphoblastic leukaemia is unlikely given the long history of recurrent infection. HIV is less likely as this patient denies any risk factors or exposure.

Cryptosporidium is an opportunistic infection and is commonly associated with hyper IgM syndrome. It is the likely causative organism for his recurrent gastroenteritis but does not explain his current presentation. Given the history of opportunistic infections, he should be investigated for causes of immunodeficiency.

Malnutrition is incorrect. Recurrent gastroenteritis in childhood may lead to malnutrition and secondary immunodeficiency. However, the question asks for an 'underlying unifying diagnosis'. This should include a cause for his history of recurrent gastroenteritis

Question 85 of 89

A 72-year-old woman presents to the emergency department with a painful and swollen leg. This has developed over two days, and she otherwise feels well in herself. She was recently away on holiday to Spain and returned four weeks ago. She is able to mobilise independently and has had no reduced periods of mobility. She has a background breast cancer diagnosed four years ago, which unfortunately relapsed and spread into her liver. She is now on hormonal treatment only.

On examination, her left leg is swollen and red, and the calf diameter is significantly larger on the left side. A doppler ultrasound scan demonstrates a left-sided deep vein thrombus.

What is the most appropriate anticoagulation strategy?

A. 2-4 months of low molecular weight heparin (LMWH)
B. 3-6 months of low molecular weight heparin (LMWH)
C. 3-6 months of a direct oral anticoagulant (DOAC)
D. Three months of warfarin
E. Six months of warfarin

3. 3-6 months of a direct oral anticoagulant (DOAC)

Cancer patients with VTE - 6 months of a DOAC

NICE updated their guidelines in 2020. DOACs are now preferred to LMWH for patients with active cancer.

As active cancer is likely to cause a continued pro-coagulopathic state, it is recommended to continue anticoagulation for longer than the standard 3 months

. Question 86 of 89

A 52-year-old woman presents to her GP complaining of fatigue and bruising. She has no significant medical co-morbidities. She is referred to the haematology clinic after an abnormal full blood count. Blood results are as follows:

Hb	112 g/L	Male: (135 - 180)Female: (115 - 160)
Platelets	150 * 10 /L 9	(150 - 400)
WBC	25.3 * 10 /L 9	(4.0 - 11.0)
Neuts	4.0 * 10 /L 9	(2.0 - 7.0)
Lymphs	16.2 * 10 /L 9	(1.0 - 3.5)
Mono	3.0 * 10 /L 9	(0.2 - 0.8)
Eosin	1.1 * 10 /L 9	(0.0 - 0.4)
LDH	250 U/L	(140 - 280 U/L)

Multicolour flow cytometry assay reports CD20+, CD23+,and CD5+ expression. She also undergoes fluorescence in situ hybridization (FISH) which reveals a deletion in the short arm of chromosome 17.

Which of the following features in this case is associated with a poor prognosis?

A. Age
B. FISH result
C. Flow cytometry assay result
D. Gender
E. LDH level

B. FISH result

del 17p is associated with a poor prognosis in CLL

The high white cell count composed mostly of lymphocytes points towards a diagnosis of chronic lymphocytic leukaemia (CLL). In CLL, deletion (del) of the short arm of chromosome 17 (17p) is found in under 10% of patients. This abnormality is associated with rapid progression of the disease, as well as a poor response to treatment strategies.

Prognosis is less favourable in those who are over the age of 70, rather than younger patients like this one.CD20+, CD23+, and CD5+ are surface antigens that are expressed in most CLL cases and shouldn't affect prognosis.Male sex, rather than female sex, is associated with a poor prognosis in CLL.Raised LDH is a marker for poor prognostic outcome, but it is normal in her case.

Question 87 of 89

An 18-year-old woman attends the emergency department with difficulty breathing.

On examination, she is cyanosed, her oxygen saturations are 84% on a finger probe, and her chest is clear.

She tells you that she has had a blue tinge around her mouth for her whole life and that she did have some investigations abroad before moving to the UK aged 4.

You take a blood gas, the sample is a dark brown colour. The results are as follows:

pH	7.35	7.35-7.45
PaCO2	4.5kPa	4.7 - 6.0
PaO2	12kPa	11 - 13

Given the likely diagnosis, what is the treatment of choice for the underlying condition?

A. 15L oxygen via a non-rebreathe mask
B. Ascorbic acid
C. Hyperbaric oxygen
D. IV methylthioninium chloride
E. Nitric oxide

B. Ascorbic acid

Ascorbic acid is the treatment of choice for NADH methaemoglobinaemia reductase deficiency

The chocolate brown blood sample, normal PaO2 but low oxygen saturations, and persistent cyanosis since childhood all point towards methaemoglobinaemia. Congenital NADHmethaemoglobinaemia reductase deficiency is usually diagnosed in childhood presenting withpersistent cyanosis with or without shortness of breath.Ascorbic acid is the correct answer, it is the treatment of choice for NADH methaemoglobinaemiareductase deficiency. **15L oxygen via a non-rebreathe mask** is incorrect. This patient may very well have 15L oxygen via a non-rebreathe mask applied in the emergency setting due to the low oxygen saturations, but this would not be the treatment for the underlying condition.

Hyperbaric oxygen is incorrect, this would be a treatment option for carbon monoxide poisoning.

IV methylthioninium chloride is incorrect, it would be the treatment of choice for acquired methaemoglobinaemia rather than congenital.

Nitric oxide is incorrect, this is actually a cause of acquired methaemoglobinaemia.

Question 88 of 89

An 83-year-old woman is seen in clinic by her oncologist. She has recently been diagnosed with chronic lymphocytic leukaemia (CLL). Her blood tests and clinical picture are stable and therefore she is being monitored and treatment has not been initiated. She is to undergo genetic testing to assess her prognosis.

Which of the following is associated with a poor prognosis in her condition?

A. IGHV mutation
B. t(8;21)
C. Trisomy 8
D. t(9;22)
E. del 17p

A. del 17p

del 17p is associated with a poor prognosis in CLL

In chronic lymphocytic leukaemia, del 17p is a poor prognostic factor. IGHV is associated with a good prognosis in CLL rather than a poor one. t(8;21) is associated with a good prognosis in acute myeloid leukaemia. Trisomy 8 is a poor prognostic factor in acute lymphoblastic leukaemia. It is very rarely found in CLL and the prognostic relevance is unknown. t(9:22) is the Philadelphia chromosome and is part of the diagnostic criteria for chronic myeloid leukaemia and carries a poor prognosis in acute lymphocytic leukaemia

Question 89 of 89

A 41-year-old patient receiving treatment for breast cancer presents to the Day Unit with a swollen right leg. She had a left mastectomy and axillary clearance 3 months ago and is currently receiving her second cycle of FEC (epirubicin, cyclophosphamide and fluorouracil) chemotherapy. Ultrasound doppler confirms a deep vein thrombosis of the right superficial femoral vein. The patients renal function is normal.

What is the most appropriate treatment for this patient?

A. Rivaroxaban for 4-6 weeks and reassess VTE risk
B. Warfarin for six months and reassess VTE risk
C. Rivaroxaban for 3-6 months and reassess venous thromboembolism (VTE) risk
D. Warfarin for 3 months and reassess VTE risk
E. Low molecular weight heparin for for 4-6 weeks and reassess VTE risk

C. Rivaroxaban for 3-6 months and reassess venous thromboembolism (VTE) risk

Cancer patients with VTE - 6 months of a DOAC

This patient is receiving treatment for active cancer. NICE guidance recommends that patients with active cancer and venous thromboembolism (VTE) should receive 3-6 months treatment with a direct oral anticoagulant such as rivaroxaban. Their risk of further VTE should then be reassessed and a decision made by the clinical team regarding ongoing VTE treatment or prophylaxis. Previously it was recommended that low-molecular weight heparin was used in this scenario.

Warfarin is avoided in patients with active cancer due to interaction with medications; the need for treatment pauses if patients become pancytopenic and increased bleeding risk.

ONCOLOGY

passmedicine PART 2

2024

Question 1 of 43

A 20-year-old asymptomatic woman is referred to the genetics clinic. Her grandmother died of breast cancer aged 54 and her mother and older sister have both recently been diagnosed with the disease.

Breast examination does not reveal any lumps and her recent ultrasound of the breasts did not reveal any suspicious lesions.

What should she be told about her breast cancer risk?

A. Her chance of having a BRCA1 mutation is 55-65%

B. Her chance of having a BRCA2 mutation is 55-65%

C. If BRCA1 positive, she has a 55-65% chance of developing breast cancer

D. If BRCA2 positive, she has a 55-65% chance of developing breast cancer

E. Given her family history, she has a 55-65% chance of developing breast cancer

C. If BRCA1 positive, she has a 55-65% chance of developing breast cancer

The BRCA1 and BRCA2 genes are tumour suppressor genes involved in DNA repair. Familial mutations in these genes are associated with an increased risk of breast and ovarian cancer. Carriers tend to develop these cancers at a younger age as they have an inherited germline mutation of one copy of the gene so only require a 'second hit' of damage to the second copy to inactivate it. BRCA mutations account for 20-25% of hereditary breast cancers and 5-10% of all breast cancer cases, They also account for 15% of all ovarian cancer.

If a woman with at least a 10% risk of breast or ovarian cancer (approximated from family history) will be offered genetic screening. This requires genetic counselling and living relative whose DNA can also be tested for the mutation, otherwise, the chance of identifying the mutation is too low. This has important ethical considerations with regard to consent.

The percentage risk of developing breast cancer by age 70 is 55-65% for BRCA1 and 45% for BRCA2 mutations.

The percentage risk of developing ovarian cancer by age 70 is 40% for BRCA1 and 15% for BRCA2 mutations.

Because of the high risks involved, women with a positive test result may choose to have enhanced screening for these cancers, prophylactic surgery (bilateral mastectomy and/or bilateral salpingo-oophorectomy) or chemoprevention with hormonal drugs.

Question 2 of 43

You are working as a registrar on the palliative care ward. A 58-year-old lady is admitted for symptom control. She has a past medical history of metastatic pancreatic cancer and diabetic nephropathy. She has been suffering from severe abdominal pain which has been unresponsive to titration of morphine, gabapentin and duloxetine.

Blood results are as follows:

Hb	75 g/l	Na +	138 mmol/l
Platelets	224 * 10 /l 9	K +	3.8 mmol/l
WBC	14.9 * 10 /l 9	Urea	18.6 mmol/l
Neuts	12.9 * 10 /l 9	Creatinine	288 µmol/l
eGFR	22 mL/min		

You decide to start an opioid which acts as a neuropathic agent by NMDA antagonism. What analgesic is most appropriate?

A. Methadone

B. Oxycodone

C. Buprenorphine

D. Paracetamol

E. Venlafaxine

A. Methadone

Methadone can be used as a third line opioid for patients with complex pain that is poorly responsive to other opioids and adjuvants

Methadone can be used as a third line opioid for patients with complex pain that is poorly responsive to other opioids and adjuvants. The patients pain has not responded to titration of morphine, combined with two neuropathic adjuvants. Methadone should therefore be considered.

The patients eGFR is les than 30 which also strengthens the decision to start methadone. Opioids which are safe in CKD 4 and 5 include fentanyl, buprenorphine and methadone.

Paracetamol and venlafaxine are not opioids.

Question 3 of 43

You are asked to provide advice on a patient who has metastatic renal cell carcinoma with pulmonary and bone metastases. They are being managed in their own home with community palliative care input, but their swallow has started to deteriorate. It is now felt that they are approaching the terminal phase of their illness and a decision has been made to start a syringe driver. They report good pain control with their current analgesia regime.

Their current analgesia regime is 60mg oxycodone modified release capsules twice a day with oxycodone instant release, taken as required. The oxycodone modified release is converted into the equivalent subcutaneous dose for an oxycodone syringe driver.

What would be the most appropriate dose of breakthrough analgesia to prescribe based on the current syringe driver dose?

A. Oxycodone I/R oral solution 20mg

B. Oxycodone I/R oral solution 10mg

C. Oxycodone subcutaneous injection 10mg

D. Morphine sulphate for injection 10mg

E. Morphine sulphate injection 20mg

C. Oxycodone I/R oral solution 10mg

Breakthrough dose = 1/6th of daily morphine dose

The breakthrough dose for analgesia should be one sixth of the total dose administered within 24 hours. If there are no changes to the total dose of oxycodone and it is converted to subcutaneous then the total dose is halved (120mg to 60mg). This is because the subcutaneous strength is twice that of oral oxycodone. The drug choice for breakthrough should match what is in the syringe driver as much as possible (stick with oxycodone) and the breakthrough should be a sixth of the total dose. Given that they need a syringe driver which is made up of oxycodone, the most appropriate drug choice would be subcutaneous oxycodone. Therefore, the breakthrough dose would be a sixth of 60mg= 10mg.

Question 4 of 43

You are looking after a 65-year-old man with a background of high-grade lymphoma who she is currently receiving R-CHOP chemotherapy for. She developed neutropaenic sepsis yesterday for which she was started on piperacillin/tazobactam, and gentamicin. She has been persistently pyrexial for the past 24 hours.

She has a background of complex pain for which she uses a 25micrograms/hour fentanyl patch. You are asked to review her due to confusion and visual hallucinations. On examination, she has pinpoint pupils, GCS 14 (M6, V4, E4), and you note myoclonic jerks.

Na +	136 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	130 µmol/L	(55 - 120)
Bilirubin	14 µmol/L	(3 - 17)
ALP	95 u/L	(30 - 100)
ALT	82 u/L	(3 - 40)
Î³GT	86 u/L	(8 - 60)
Albumin	35 g/L	(35 - 50)

You suspect opioid toxicity. What is the most likely explanation for this?

A. Acidosis

B. Fentanyl and piperacillin/tazobactam drug interaction

C. Increased fentanyl absorption due to pyrexia

D. Liver dysfunction

E. Renal dysfunction

C. Increased fentanyl absorption due to pyrexia

Transdermal fentanyl absorption is increased by heat (e.g. hot water bottle) or pyrexia, potentially leading to opioid toxicity

Transdermal fentanyl absorption is increased by heat or pyrexia (which results in vasodilation and increased blood flow), potentially leading to opioid toxicity. This is therefore the correct option.

Acidosis is incorrect. Acidosis is not known to exacerbate opioid toxicity.

Renal dysfunction is incorrect. Fentanyl is hepatically metabolised by CYP450 3A4 with no active metabolites. Therefore it is the opioid of choice in renal failure.

Liver dysfunction is incorrect. Although the patient has a mild transaminitis, their synthetic liver function is normal, making it an unlikely contributing factor.

Piperacillin/tazobactam is incorrect. Fentanyl has no known interactions with piperacillin/tazobactam.

Question 5 of 43

A 63-year-old woman presents with unrelenting thoracic back pain. She finds that the pain is debilitating, especially as she helps look after her grandchildren. She has a past medical history of breast cancer diagnosed two years ago, for which she underwent a mastectomy with reconstruction. She also had postoperative radiotherapy and endocrine therapy. As she was found to be BRCA1 positive, she underwent a hysterectomy with bilateral oophorectomy as well. On examination, she is tender over the spine at T4, but neurological examination is unremarkable.

What is the most appropriate imaging investigation for her back pain?

A. MRI of the whole spine within 7 days

B. MRI of the thoracic spine within 7 days

C. MRI of the whole spine within 24 hours

D. MRI of the thoracic spine within 24 hours

E. Bone scan of the whole body within 7 days

A. MRI of the whole spine within 7 days

The correct answer is MRI whole spine within 7 days. This is a patient with known cancer presenting with highly suspicious back pain but no evidence of spinal cord compression. The most appropriate modality is MRI which can not only detect metastasis but also demonstrate patency or compression of the spinal cord. The whole spine should be scanned as to exclude further metastasis as 30-50% of patients have multi-level involvement by the time of presentation. The timing of the scan depends on suspicion of cord compression. For this patient, there is no evidence of neurological compromise and therefore the scan does not have to occur within 24 hours.

Question 6 of 43

You are looking after a 68-year-old man with aggressive multiple myeloma. He has intractable vomiting which has not improved with regular subcutaneous metoclopramide.

Blood results are as follows:

Calcium	4.2 mmol/L	(2.1-2.6)

You decide to start him on a syringe driver. What would be your anti-emetic of choice?

A. Aprepitant

B. Cyclizine

C. Levomepromazine

D. Nabilone

E. Ondansetron

C. Levomepromazine

Metabolic causes of nausea and vomiting, for example uraemia and hypercalcaemia, cause nausea and vomiting by stimulating dopamine type 2 (D2) receptors on the chemoreceptor trigger zone. This pathway is most effectively blocked by using a central dopamine antagonist such as haloperidol

Metabolic causes of nausea and vomiting (e.g. hypercalcaemia) are particularly sensitive to central dopamine antagonists such as **levomepromazine** making this the favoured choice.

Levomepromazine is a very broad spectrum anti-emetic that acts as an antagonist to multiple receptors including histamine type 1, muscarinic-cholinergic, dopaminergic 2, alpha-1 adrenoceptor, and 5HT-2 receptors. Thus it is a powerful anti-emetic that can be used in many scenarios.

Aprepitant is a substance P/neurokinin 1 receptor antagonist used to prevent chemotherapyinduced and postoperative nausea and vomiting. The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Cyclizine is a histamine H1-receptor antagonist which may have effects directly on the vestibular system and on the chemoreceptor trigger zone. It also exerts a central anticholinergic action The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Ondansetron is a specific 5HT3-receptor antagonist which blocks 5HT3 receptors in the gastrointestinal tract and in the CNS. The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Nabilone is a synthetic cannabinoid which is used to treat nausea and vomiting caused by cytotoxic chemotherapy, which is unresponsive to conventional antiemetics.

Question 7 of 43

A 54-year-old-man with a history of granulomatosis with polyangiitis attends for his annual review in the rheumatology clinic. He was diagnosed at age 35 where he presented with rapidly progressive glomerulonephritis and pulmonary haemorrhage and was treated with cyclophosphamide and steroids. He required a period of haemofiltration on the intensive care unit but has remained well since.

Today, he feels well after recently quitting smoking but reports occasional blood in his urine. On examination, his abdomen is soft and non tender, there is no pallor or oedema and his chest is clear. His investigations are below and his urine appears clear.

Hb	105 g/l
Platelets	300* 10 /l9
WBC	5* 10 /l9
Urinalysis	blood 3+ protein -
Na +	139 mmol/l
K +	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	98 µmol/l

What is his likely diagnosis?

A. Recurrence of glomerulonephritis

B. Transitional cell carcinoma

C. Renal calculi

D. Faulty urinalysis recording

E. Rhabdomyolysis

B. Transitional cell carcinoma

Use of cyclophosphamide in granulomatosis with polyangiitis is associated with increased risk of bladder cancer

The use of cyclophosphamide is linked to transitional cell carcinoma in patients with vasculitis. Given that his U&Es are normal, a recurrence of glomerulonephritis is unlikely. Renal calculi would cause loin to groin pain. Haematuria can often not be visible to the eye even when present. While rhabdomyolysis could give a positive dipstick, there are no other features to suggest this

Question 8 of 43

A 68-year-old man is admitted to the unit with an exacerbation of severe pain around his abdomen. He describes it as a tight band like pain which is burning in character. He has a past medical history of metastatic prostate cancer. His drug history includes morphine modified release (100mg, twice daily), duloxetine (60mg, twice daily), pregabalin (200mg, three times per day). He states that the pain initially responded well to the analgesics he is on however over the past few weeks it has got progressively worse and culminated in a severe attack of pain today.

You suspect that he has got severe neuropathic pain secondary to spinal metastases. The pain is now poorly controlled with a large dose of opioids and two neuropathic agents. Your consultant decides to start him on ketamine.

What acute complication is it important to monitor for?

A. Bladder dysfunction

B. Liver dysfunction

C. Raised intracranial pressure

D. Cardiomyopathy

E. Pulmonary fibrosis

C. Raised intracranial pressure

Ketamine can cause raised intracranial pressure. It is important to monitor for side effects such as headache, papilloedema, and vomiting

Ketamine can be used for neuropathic pain poorly responsive to titrated opioids and oral adjuvant analgesics (e.g. antidepressant and/or anticonvulsant) particularly when there is abnormal pain sensitivity (e.g. allodynia, hyperalgesia or hyperpathia). Ketamine is an NMDA receptor antagonists. Side effects to be aware of include hypertension, raised intracranial pressure and hallucinations.

Bladder and liver dysfunction can occur with long term use of ketamine. Therefore, if a patient is anticipated to have a reasonably good prognosis, alternative options should be considered to replace the ketamine, for example lidocaine infusions.

Question 9 of 43

A medical consult was sought from the nursing staff concerning a 68-year-old gentleman admitted with a urinary tract infection. He was diagnosed with terminal adenocarcinoma of the pancreas six months ago. He had complained of increasing severe abdominal pain for the last few weeks for which his GP commenced and then titrated morphine sulphate tablets (MST) achieving a temporary analgesic effect with each increment. By the time of admission he had been using 150mg BD and was unable to tolerate any further dose increases owing to drowsiness.

His drug history comprised of ciprofloxacin 250mg BD started four days ago for the management of urinary tract infection, paracetamol 1g QDS, tramadol 100mg QDS, MST 150mg BD, senna 2 tabs ON & Movicol one sachet BD.

In view of the continuing abdominal pain investigations were organised by the inpatient team revealing the following findings:

Hb	135 g/l
Platelets	224 * 10 /l9
WBC	11.2 * 10 /l9
Bilirubin	23 µmol/l
ALP	189 u/l
ALT	326 u/l
γGT	178 u/l
Albumin	34 g/l

Chest x-ray: Normal heart borders and lung fields, no evidence of subdiaphragmatic air. Abdominal x-ray: presence of faeces, no evidence of dilatation.

USS abdomen: multiple hypoechoic lesions within the liver, nil else abnormal noted. What is the next most appropriate management option?

A. Commence syringe driver containing diamorphine

B. Refer for immediate surgical consult

C. Refer for palliative radiotherapy

D. Convert MST to fentanyl

E. Commence trial with dexamethasone

E. Commence trial with dexamethasone

This gentleman has evidence of extensive hepatic metastases most probably arising from known adenocarcinoma of the pancreas. Despite an escalating opiate regimen he is unable to obtain satisfactory pain relief. One of the sources of pain associated with liver metastases is due to stretching and irritation of the liver capsule for which a trial of dexamethasone may provide an analgesic effect. Option 5 is, therefore, the most suitable option.

There is no evidence of obstruction or perforation and thus a surgical consult is not warranted, and palliative radiotherapy is not specifically indicated here (in contrast with bone metastases).

Switching to fentanyl will probably not provide any additional benefit in terms of tolerance compared with MST; it is however indicated in patients with poor renal failure owing to its predominant hepatic route of metabolism. For further information:

Question 10 of 43

A medical consult was sought regarding a 58-year-old gentleman admitted with pneumonia complaining of relentless hiccups. He was diagnosed with hepatocellular carcinoma six months ago and was deemed not for curative treatment owing to the extent of the disease. He was initially comfortable with no discernible symptoms but over the last four weeks developed hiccups. In conjunction with the palliative care nurse his GP had initially trialled domperidone and then haloperidol but with no improvement in his symptoms. He denied the presence of any other symptoms other than fatigue, and upon questioning denied the presence of abdominal pain, heartburn or early satiety.

His past medical history was comprised of alcohol dependence syndrome, chronic liver disease, hypertension and hypercholesterolaemia for which he was prescribed thiamine 100mg TDS, lactulose 10mls BD, spironolactone 100mg OD, propranolol 40mg OD, simvastatin 20mg OD as well as intravenous co-amoxiclav 625mg TDS for the treatment of his pneumonia. Examination revealed the presence of a cachectic male. His blood pressure was 108/58 mmHg, heart rate 78 bpm, respiratory rate 18/min and temperature 36.6ºC. Examination of his gastrointestinal system revealed the presence of a palpable mass in the right upper quadrant inferior to the right sterna edge and ascites with no tenderness. Examination of his neurological system revealed the absence of any focal neurological symptoms; likewise, examination of cardiovascular and respiratory systems was unremarkable.

Recent investigations revealed the following results:

Bilirubin	22 µmol/l
ALP	221 u/l
ALT	278 u/l
Protein	62 g/l
Albumin	18 g/l

Chest x-ray: normal heart borders and lung fields

Surveillance upper GI endoscopy four months ago: normal stomach mucosal surface, no evidence of portal hypertension

Which of the following options is the best option with a view to managing his hiccups?

A. Commence treatment with proton pump inhibitor

B. Commence treatment with levomepromazine

C. Commence treatment with dexamethasone

D. Commence treatment with midazolam infusion

E. Commence treatment with baclofen

C. Commence treatment with dexamethasone

This gentleman has known advanced hepatocellular carcinoma and is complaining of distressing hiccups. He does not have any sign of gastro-oesophageal reflux and therefore a trial of proton pump inhibitor is unlikely to be of benefit. In the presence of hepatic or cerebral cancer a trial of dexamethasone may induce some remission and is therefore suggested as an appropriate next line given he has already had a trial of treatment with a prokinetic and a typical antipsychotic with no remission; see http://www.palliativecareguidelines.scot.nhs.uk/guidelines/symptomcontrol/Hiccups.aspx for further information. There is also limited evidence for treatment with baclofen and levomepromazine; subcutaneous midazolam should be reserved if all else proves futile. Note also the BNF has a very useful section regarding prescribing in palliative care scenarios; in this instance it also suggests the use of antacids or nifedipine in addition to the above options.

Question 11 of 43

A 47-year-old woman presents to the emergency department with sudden onset of shortness of breath and pleuritic chest pain. Observations demonstrate marked hypoxia and she is given oxygen and analgesia and undergoes a chest X-ray followed by a CT pulmonary angiogram which shows a pulmonary embolism. There is also an incidental finding of a nodule suspicious of metastatic disease.

She is started on a treatment dose of low molecular weight heparin and admitted under the medical team for further assessment. During a more detailed history, she explains that she has lost one stone in weight over two months and been feeling progressively more tired as well. She denies any other symptoms. She has a past medical history of asthma and also underwent a caesarean section three years ago. She has two children, of which she breastfed both, and has a long history of use of oral contraceptive use. She is an ex-smoker of 5 pack-years and has minimal alcohol intake. Her grandfather died of prostate cancer, and her sister developed breast cancer at the age of 52.

A complete further examination was completed and no abnormalities were found. Routine blood tests are currently pending, and a flexible bronchoscopy for biopsy of the lung nodule has been arranged.

How should this patient be further investigated?

A. Tumour markers AFP and hCG, and mammography

B. CT abdomen and pelvis, tumour markers AFP and hCG, and a myeloma screen

C. Ultrasound abdomen and pelvis, and tumours marker AFP and hCG

D. CT abdomen and pelvis, and tumour markers AFP and hCG

E. CT abdomen and pelvis, myeloma screen, and colonoscopy

D. CT abdomen and pelvis, and tumour markers AFP and hCG

The correct answer is CT abdomen and pelvis, and tumour markers AFP and hCG. These investigations complete all those recommended by NICE for an unknown primary. This question highlights how to investigate a malignancy of unknown origin. This patient has a likely metastatic disease causing a pulmonary embolism with unclear clinical findings as to the location of the primary malignancy.

NICE recommends the following investigations for all patients:

- FBC, U&E, LFT, calcium, urinalysis, LDH
- Chest X-ray
- CT of chest, abdomen and pelvis
- AFP and hCG

NICE recommends the following investigations for specific patients:

- Myeloma screen (if lytic bone lesions)
- Endoscopy (directed towards symptoms)
- PSA (men)
- CA 125 (women with peritoneal malignancy or ascites)
- Testicular US (in men with germ cell tumours)
- Mammography (in women with clinical or pathological features compatible with breast cancer)

A is incorrect because it does not include CT scanning of the abdomen and pelvis. Mammography is tempting but NICE does not recommend it without any clinical findings which are suggestive of a breast malignancy. B and E are incorrect because a myeloma screen is not indicated without lytic bone lesions. E is also incorrect as colonoscopy should be symptom directed. C is incorrect as US is not an appropriate investigation.

Question 12 of 43

A 62-year-old lady with metastatic breast cancer is admitted with a general decline. She is found to have a pneumonia and treated with IV fluids and antibiotics. She makes limited improvement with these and antibiotics are stopped. The decision is made to focus on control of her symptoms.

She is started on a syringe driver of morphine sulphate to treat breathlessness and pain related to liver metastases. She then develops nausea and hiccups.

Which medication is the best choice to add to the syringe driver?

A. Cyclizine

B. Domperidone

C. Midazolam

D. Metoclopramide

E. Ondansetron

D. Metoclopramide

Cyclizine, domperidone and ondansetron are anti-emetics, though domperidone does not come in a subcutaneous preparation for syringe driver. Midazolam is an anxiolytic.

Metoclopramide is the first choice to treat hiccup as well as nausea. Other options include baclofen, nifedipine and chlorpromazine.

Question 13 of 43

A 60-year-old man has been admitted under urology with difficulty passing urine and back pain. A post-void bladder scan shows 980mls in his bladder. He was catheterised by the admitting doctor and now has haematuria.

He has a background of metastatic prostate cancer, atrial fibrillation, previous NSTEMI, hypertension, hypercholesterolaemia and hypothyroidism. His medications include warfarin and modified-release morphine 30mg every 12 hours.

He has been seen by the urology consultant who has said to put a 3-way catheter in if the haematuria does not settle and refer to the palliative care team for pain management. The palliative care specialist advised increasing the modified release morphine to 45mg every 12 hours.

What dose of immediate-release morphine should the patient be prescribed for breakthrough pain?

A. 5mg

B. 7.5mg

C. 10mg

D. 15mg

E. 20mg

D. 15mg

Breakthrough dose = 1/6th of daily morphine dose

To answer this question, you need to calculate the total daily dose of morphine. The amount of immediate-release morphine for breakthrough pain should be one-sixth (1/6) of the total daily dose.

The patient was previously on 60mg of morphine per day. One-sixth of this would be 10mg of immediate-release morphine for breakthrough pain.

The modified release morphine has now been up titrated to 90mg per day. Whenever background morphine is increased, it is important to calculate the new breakthrough pain dosage for patients to receive the maximal benefit. In this case, one-sixth of 90 is 15mg. Therefore the correct answer is 15mg of immediate-release morphine.

Question 14 of 43

You are looking after an 82-year-old man with a background of metastatic colorectal carcinoma. He is in significant pain and is on a syringe driver containing 6mg of alfentanil. He has end-stage renal failure.

What breakthrough analgesic will you prescribe?

A. 1mg subcutaneous alfentanil

B. 25mg subcutaneous morphine

C. 25mg subcutaneous oxycodone

D. 2mg subcutaneous alfentanil

E. 50mg subcutaneous oxycodone

A. 1mg subcutaneous alfentanil

Breakthrough dose = 1/6th of daily morphine dose

Palliative care guidelines recommend using 1/6 of the daily dose as a breakthrough. Alfentanil is a potent drug and is particularly useful in renal failure as it is metabolised by the liver, has no active metabolites, and has a very short half-life.

Question 15 of 43

An 82-year-old man is reviewed by the palliative care team on the ward. He has a past medical history of metastatic lung cancer. He is not for any further chemotherapy, surgery or radiotherapy. He has deteriorated rapidly in the prior few days and is considered to be in the last days of life. He is suffering from intractable nausea, the cause of which is not clear.

What is the most appropriate medication to manage his symptoms?

A. Buscopan

B. Levomepromazine

C. Metoclopramide

D. Morphine

E. Ondansetron

B. Levomepromazine

Levomepromazine is a 'dirty drug' which blocks lots of different receptors (e.g. ACh, DA, 5HT). It is therefore a broad spectrum anti-emetic. It is first line in the last days of life.

Levomepromazine is correct. This is a broad-spectrum anti-emetic - a 'dirty drug' targeting many receptors. It is therefore the most suitable choice where the cause of nausea is unknown and in the last days of life.

Buscopan is incorrect. This is indicated in palliative care for excess secretions rather than nausea.

Metoclopramide is incorrect. This would be a rational choice for nausea due to gastric stasis. However, where the cause is unknown and in the last days of life, a more broad spectrum antiemetic is preferred. Therefore, levomepromazine is preferable.

Morphine is incorrect. This is indicated in palliative care for breathlessness and pain rather than nausea.

Ondansetron is incorrect. This is a rational choice for chemotherapy or post-operative related nausea. However, it is a specific serotonin 5-HT3 receptor antagonist, with a low affinity for dopamine receptors and therefore has a more narrow spectrum of action than levomepromazine and is, therefore, less preferable in this circumstance.

Question 16 of 43

A 65-year-old woman presents to the emergency department with reduced consciousness. Her husband reports that she has been unwell for the past 3 days with coryzal symptoms. She has a past medical history of hypertension and metastatic pancreatic cancer for which she is under the palliative care team. Her regular medications include amlodipine, bisoprolol, paracetamol and a fentanyl patch for pain.

On examination, her temperature is 38.1ºC with a heart rate of 101 beats/min and a blood pressure of 118/66mmHg. Auscultation of the chest is clear with a respiratory rate of 8 breaths/min and oxygen saturations of 92% on air. Her abdomen is soft and non-tender and she is visibly jaundiced. She has a GCS of 11/15 (E2V4M5).

What is the most likely cause of this patient's reduced consciousness?

A. Delirium
B. Hepatic encephalopathy
C. Hypoglycaemia
D. Meningitis
E. Opioid toxicity

E. Opioid toxicity

Transdermal fentanyl absorption is increased by heat (e.g. hot water bottle) or pyrexia, potentially leading to opioid toxicity

Opioid toxicity is correct. This patient has signs of opioid toxicity including drowsiness and a slow respiratory rate. There are multiple differential diagnoses for an acutely unresponsive patient and, therefore, it is key to take a thorough history and examination. From this patient's collateral history it is learned that she uses a fentanyl patch for pain control. It is important to note that transdermal fentanyl absorption is increased by heat whether that be secondary to the application of a hot water bottle or pyrexia. This patient has a fever of 38.1ºC which is a likely contributing factor to her toxicity.

Delirium is incorrect. This is a very reasonable differential diagnosis given the history of fever in a patient with a frail comorbid status. However, delirium is less likely to cause this patient's reduced respiratory rate compared to opioid toxicity. Generally, fever is associated with tachypnoea and the opposite response should raise suspicion.

Hepatic encephalopathy is incorrect. Although this patient is jaundiced, it is likely to be cholestatic jaundice secondary to the underlying malignancy rather than decompensated liver disease. Furthermore, the acute onset of symptoms and lack of signs of hepatic encephalopathy makes the diagnosis less likely.

Hypoglycaemia is incorrect. This is an important differential diagnosis given the history of advanced malignancy and the likelihood of reduced oral intake. However, the presence of bradypnoea and opioid use makes opioid toxicity more likely.

Meningitis is incorrect. Fever and reduced consciousness are features of meningitis. However, the presence of bradypnoea and the use of strong opioid analgesics make opioid toxicity more likely.

Question 17 of 43

A 56-year-old man with metastatic small cell lung carcinoma is admitted to hospital with vomiting, ankle swelling and pruritus. He recently completed a course of palliative chemotherapy. He has a background of chronic obstructive pulmonary disease and hypertension and takes morphine sulphate (MST) for pain relief.

On examination, he is cachectic with peripheral oedema and skin excoriations. Heart rate is 96 beats per minute and blood pressure is 140/85 mmHg.

Tests show:

Hb	134 g/l
Platelets	185 * 10 /l9
WBC	5.5 * 10 /l9
Na +	146 mmol/l
K +	5.4 mmol/l
Urea	23 mmol/l
Creatinine	420 µmol/l
Urine dip:	Blood +
Urine osmolality	350 mOsm/L
Urinary sodium	45 mEqL
Microscopy:	red cells; casts.

What is the most appropriate pain relief for this patient?

A. Fentanyl patch
B. Diamorphine
C. Oxycodone
D. Pregabalin
E. Tramadol

A. Fentanyl patch

This patient has an acute kidney injury secondary to cisplatin chemotherapy. As a result, he needs adjustments to his pain relief. He is on regular, long-acting MST, so the most appropriate substitution is a fentanyl patch.

Oxycodone can be used in moderate renal failure, but only as breakthrough pain relief. Modified release preparations should be avoided. Diamorphine and tramadol should be avoided in renal failure. Pregabalin can be administered at reduced dose, but would not be an appropriate first-line substitution for MST.

Alfentanil and methadone are safe even in severe renal impairment and are administered subcutaneously. Alfentanil would be appropriate for this patient if he had unstable pain and required dose titration.

Question 18 of 43

A 69-year-old male patient presents with worsening mouth soreness and painful swallowing, progressively getting worse over the last week. He started radical radiotherapy for a base of mouth squamous cell cancer three weeks ago. He also has a PEG in situ. He was recently seen by the dietician and is now having fluid and Ensure nutritional supplements via his PEG. He had been given soluble paracetamol by the specialist nurse, but this has failed to control his pain.

On examination, his oral cavity appears inflamed with multiple small ulcers posterior to his lower lip. There are no patches or plaques inside. You change the paracetamol to liquid co-codamol and give him a topical lidocaine gel at 2% strength.

What is the most appropriate next step in management to control his symptoms?

A. Benzydamine mouthwash
B. Menthol mouthwash
C. Chlorhexidine mouthwash
D. Fluconazole
E. Metronidazole

A. Benzydamine mouthwash

The correct answer is benzydamine mouthwash. This gentleman is suffering from radiotherapyinduced mucositis. Given the location of his tumour and the high dose of radiotherapy necessary for curative therapy, mucositis is not an uncommon side effect. Many of these patients will have a PEG inserted prophylactically in anticipation of the difficulties in maintaining an oral diet with mucositis and oesophageal involvement. For this patient, already on co-codamol, benzydamine mouthwash can be very helpful in treating his symptoms. Menthol and chlorhexidine mouthwashes, often bought over the counter, would increase oral irritation. There is no evidence of fungal or bacterial infection currently.

Question 19 of 43

A 75-year-old man is admitted to the palliative care unit for end of life care. He has a past medical history of metastatic prostate cancer. His drug history includes a syringe driver with morphine, levomepromazine and midazolam. During personal care the nurses have stated that he suffers excruciating pain when being turned onto his side. His pain throughout the day is otherwise well controlled.

What is the most appropriate way to manage his pain?

A. Titrate the syringe driver morphine

B. Morphine sulphate modified release tablets

C. Oxycodone modified release tablets

D. Morphine sulphate immediate release liquid

E. Paracetamol

D. Morphine sulphate immediate release liquid

Incident pain is defined as pain which comes on as a result of an action or activity, for example during personal care. Sublingual fentanyl has rapid onset and is a short-acting opioid, and is therefore a good choice for treating this type of pain

Incident pain is defined as pain which comes on as a result of an action or activity, for example during personal care. Sublingual fentanyl has rapid onset and is a short-acting opioid, and is therefore a good choice for treating this type of pain. Similarly, morphine sulphate immediate release liquid is also suitable.

The patients pain during the day is otherwise well controlled therefore titrating up the syringe driver with more morphine is not appropriate. Not only will this not be particularly effective at treating the incident pain, it will also give rise to unnecessary side effects such as sedation and constipation.

Similarly, morphine sulphate modified release tablets have an action time of approximately 12 hours so they are therefore inappropriate for breakthrough pain as they will cause accumulation of morphine in the system predisposing to toxicity.

Question 20 of 43

A 64-year-old cachectic lady presents to the emergency department with difficulty in breathing. She reports smoking since she was 14 years old. Chest X-Ray reveals a large right sided pleural effusion. A sample is obtained under ultrasound-guidance for evaluation. CT does not identify a cause. The results of the pleural aspiration demonstrate an exudative effusion and histology is suggestive of an adenocarcinoma with positive TTF-1 stain.

What is the most likely cause for the effusion?

A. Non-small cell lung cancer
B. Small cell lung cancer
C. Ovarian carcinoma
D. Breast carcinoma
E. Mesothelioma

A. Non-small cell lung cancer

TTF-1 (thyroid transcription factor 1) is a protein which regulates the transcription of genes specific for the thyroid and lung. Lung adenocarcinomas and small cell carcinomas are usually TTF-1 positive. The histology in the above example is suggestive of an adenocarcinoma and therefore this is mostly likely a lung primary given the TTF-1 stain and history of smoking.

Non-small cell lung cancers include adenocarcinoma, large cell and squamous cell carcinoma.

Question 21 of 43

A 76-year-old woman with metastatic transitional cell carcinoma of the bladder is admitted to hospice with a 3-day history of hallucinations, confusion and pruritus. Her only other symptoms are intermittent vomiting and pelvic discomfort. She has a past medical history of hypertension and has recently completed a course of radiotherapy for bone metastases. She takes paracetamol, morphine sulphate, cyclizine, dexamethasone and a herbal flower remedy for anxiety.

On examination, she is cachectic and frail. The lungs are clear and heart sounds are normal. Pulse rate is 85 beats per minute and blood pressure 130/80mmHg. She is afebrile.

Neurological examination reveals myoclonus. She is mildly hypotonic and all reflexes are diminished. There is miosis on cranial nerve examination.

Blood tests show:

Hb	12.1 g/dl
Platelets	250 * 10 /l9
WBC	12 * 10 /l9
Na +	135 mmol/l
K +	4.3 mmol/l
Urea	5 mmol/l
Creatinine	80 µmol/l
Calcium (unadjusted)	2.1 mmol/l
Bilirubin	15 µmol/l
ALP	45 u/l
ALT	15 u/l
AST	20 u/l
Albumin	28 g/l

Urine dip: no abnormality What is the most likely diagnosis?

A. Hypercalcaemia
B. Opioid toxicity
C. Sepsis
D. Corticosteroid psychosis
E. Brain metastases

B. Opioid toxicity

This lady is presenting with opioid toxicity. She has vomiting, confusion, hallucinations and pruritus. Her symptoms have been precipitated by a reduction in her opioid requirement. This is a common occurrence in patients who have radiotherapy for bone metastases if their medication dose is not adjusted.

Hypercalcaemia could cause a similar presentation, but the corrected calcium is 2.4 mmol/L. This lady is hypoalbuminaemic due to her advanced cancer. The patient no symptoms of infection. She is apyrexial and her slightly raised white cell count is due to her advanced disease and dexamethasone treatment. Corticosteroid psychosis is possible, but would not cause the neurological signs or pruritus. Transitional cell carcinomas of the urothelial tract only rarely metastasise to the brain; the neurological signs suggest opioid toxicity rather than a focal lesion.

Question 22 of 43

A 65-year-old man is referred to the oncology team after presenting to the emergency department. The patient described a three-week history of progressive thoracic back pain. The pain was localised to a point between the patient's shoulder blades, and was exacerbated by movement and coughing.

In addition, over the previous 6 hours, the patient reported that he had been struggling to stand up unassisted, and was having difficultly walking. The sudden change in his mobility had been the event that had prompted his attendance at hospital. When questioned directly, the patient described intermittent tingling sensations in his lower legs, but denied any loss of sensation. There had been no dysfunction of his bladder or bowels.

The patient had been diagnosed with prostate cancer five years previously. This had been treated with a radical prostatectomy and hormone therapy. The patient had moved area two years previously, and had subsequently been lost to urological follow-up. Despite his previous cancer treatment, the patient stated that he was very fit and active, playing golf three times a week and taking an active role in the care of his grandchildren.

Peripheral nerve examination of lower limbs: tone generally increased bilaterally; power generally slightly reduced (4+/5) bilaterally; normal coordination; no impairment of light touch or sharp touch sensation; knee and ankle jerks brisk bilaterally, plantar responses up going bilaterally.

Digital rectal examination: preserved peri-anal sensation and normal tone. Bed-side bladder scan: 50 ml

MRI whole spine: metastatic invasion and collapse of T10 vertebral with spinal cord compression.

The patient was treated with analgesia and dexamethasone while definitive treatment was planned.

What is most appropriate first-line treatment of patient's spinal cord compression?

A. Surgical tumour resection and spinal cord stabilisation with adjuvant radiotherapy
B. Radiotherapy: single dose 8 Gy
C. Chemotherapy: docetaxel
D. Best supportive care
E. Chemotherapy: cabazitaxel

A. Surgical tumour resection and spinal cord stabilisation with adjuvant radiotherapy

The best predictor of neurological outcome with treatment in metastatic spinal cord compression is neurological status at the initiation of treatment. The patient in the question has presented very promptly and has only limited neurological compromise. Therefore, it is imperative that definitive treatment is provided promptly (ideally, within 24 hours) to optimise long-term outcome.

Definite treatment of metastatic spinal cord compression can include any combination of radiotherapy, surgery and chemotherapy. Recent evidence indicates that surgery is superior to radiotherapy in retaining or regaining neurological function and relieving pain. In the case of this patient, who has an excellent performance status, surgery followed by radiotherapy would likely offer a better outcome than radiotherapy alone.

Radiotherapy may be considered as first-line treatment in some circumstances. Recommended regimen vary, for example 20 Gy in five daily fractions. The radiotherapy regime offered as a answer to the question would be appropriate as palliative treatment for pain-control, making it an incorrect answer for this patient.

Chemotherapy have a role in the management of spinal-cord compression secondary to chemosensitive malignancies (for example, small-cell lung cancer or germ cell tumours), but would not be optimal treatment for this patient.

Question 23 of 43

A 56-year-old patient presents to hospital with confusion. He is a long-term smoker. He has a past-medical history of chronic obstructive pulmonary disease, hypertension, bipolar disease and long-term muscular back pain.

On examination he is confused with a Glasgow Coma Scale score of 14 out of 15. He has a pulse rate of 97 beats per minute with a blood pressure of 145/97 mmHg. Respiratory rate is 14 per minute with oxygen saturations of 95% on room air. He has bilateral vesicular breath sounds on auscultation with normal percussion. His abdomen is soft and non-tender with no masses. He has no focal neurology.

Investigations

Hb	102 g/dL
WCC	8.2 *10^9/l
Platelets	133 *10^9/l
Na+	146 mmol/L
K+	5.4 mmol/L
Cr	132 µmol/L
Ur	10.1 mmol/L
Albumin	26 g/L
Adjusted Calcium	3.78 mmol/L
Alkaline Phosphatase	76 IU/L
PTH	Undetectable
Serum ACE	45U/L (10-50)
Serum Electrophoresis	IgG 18 g/L (5-13 g/L) - Polyclonal
Urinary Electrophoresis	Undetectable
Chest X-ray	Right parahilar opacification 3x4cm
Lumbar Spine X-ray	Normal

What is the likely underlying diagnosis?

A. Squamous Cell Carcinoma
B. Multiple Myeloma
C. Sarcoidosis
D. Drug induced hypercalcaemia
E. Prostate carcinoma

A. Squamous Cell Carcinoma

The patient has severe hypercalcaemia. The commonest causes are hyperparathyroidism and cancer. The patient has a normal alkaline phosphatase without evidence of fracture or bone disease making bone metastases unlikely. The patient has a normal serum ACE with an atypical chest X-ray for sarcoidosis, although unilateral chest findings are possible.

The patient has features of multiple myeloma including anaemia, renal insufficiency and hypercalcaemia. However, there is a polyclonal, rather than a monoclonal increase in paraprotein.

The chest x-ray findings with a background of smoking suggest an underlying respiratory malignancy. This patient has squamous cell carcinoma of the lung with parathyroid related protein secretion causing hypercalcaemia. PrPTH is not deteced on a PTH assay. Hypercalcaemia can induce confusion and renal impairment.

Question 24 of 43

A 65-year-old man with metastatic squamous cell lung cancer is admitted to the Acute Medical Unit for the management of hypercalcaemia. He is currently taking slow-release morphine sulphate (MST) 90mg bd to control his pain along with regular naproxen and paracetamol. During his admission he complains of pain in his right arm which is the site of a known skeletal metastasis.

What is the most appropriate medication to prescribe to treat his acute pain?

A. Oral morphine solution 30mg
B. Oral morphine solution 15mg
C. Oral morphine solution 10mg
D. Add alendronate 70mg weekly
E. Tramadol 50mg

A. Oral morphine solution 30mg

This patient is describing break-through pain. Whilst bisphosphonates have a role in bone metastases they are not suitable for acute pain. A suitable break-through dose is therefore 1/6th of the total daily morphine dose i.e. 1/6th of 180mg = 30mg.

Question 25 of 43

A 77-year-old female is electively admitted for investigation of bilateral lower limb swelling onset over the past 3 years associated with limitation of exercise as a result. Her past medical history includes bilateral pulmonary emboli in 2010 and type 2 diabetes mellitus. On examination, nonpitting bilateral lower limb oedema is noted to the high thighs without abdominal involvement. Her heart sounds are normal with no added sounds, her chest is clear. Her abdomen is soft and non-tender without ascites or superficial swelling. A transthoracic echocardiogram demonstrates normal left ventricular function but was unable to produce good views of the right heart. A CT pulmonary angiogram demonstrates no embolus, a ventilation-perfusion scan demonstrates a low probability of pulmonary emboli. Ultrasound abdomen is unremarkable. The patient undergoes a right heart catheter, demonstrating a mean pulmonary arterial pressure of 14mmHg.

What is the likely cause of her lower limb swelling?

A. Left heart failure
B. Idiopathic pulmonary arterial hypertension
C. Right heart failure
D. Pelvic malignancy
E. Lymphoedema

E. Lymphoedema

Interpretation of the various investigations this patient has undertaken allows lymphoedema as a diagnosis of exclusion. The patient would have been referred to this standard set of investigations for pulmonary hypertension after clinically presenting as progressive exercise limitation and peripheral oedema, with the primary concern being right heart failure secondary to an increased pressure within the pulmonary vasculature.

Most importantly, the pulmonary arterial pressure is normal on the right heart catheter, ruling idiopathic pulmonary hypertension. Left heart dysfunction is excluded by a normal echocardiogram evaluation of the left ventricular function. CTPA and normal abdominal ultrasound, predominantly investigating the portal circulation, rule out causes of pulmonary hypertension. Lastly, the non-pitting nature of the oedema suggests a non-cardiac cause, making lymphoedema the most likely cause of lower limb swelling.

Question 26 of 43

A 65-year-old man is admitted to the hospital for palliative radiotherapy. He has a squamous cell carcinoma of the tongue that has metastasized to his neck and surrounds the carotid artery. There are no surgical options to treat his disease.

On day 2 of the admission, he experiences a catastrophic bleed from his neck.

What is the most appropriate medication to administer in this circumstance?

A. Buscopan
B. Chlorpromazine
C. Haloperidol
D. Midazolam
E. Morphine

D. Midazolam

In a massive terminal haemorrhage, a large dose of midazolam (10mg) can be given as part of 'crisis management' to relieve distress. Red or green towels or blankets should be available to soak up and mask the colour of blood

Midazolam is the correct answer. The patient has experienced a terminal haemorrhage as a consequence of his tumour eroding through the carotid artery. Given the lack of surgical options available to treat his condition, urgent symptom control is warranted to manage this distressing event. Intravenous midazolam is indicated in this horrific situation as a consequence of its anxiolytic and sedative effects, along with the rapidity of its onset.

Haloperidol is incorrect. This can be used to treat agitation in palliative care. However, intravenous midazolam is preferred in this catastrophic situation due to its rapidity of onset.

Morphine is incorrect. This is typically used to treat pain and breathlessness in a palliative care setting, rather than agitation.

Chlorpromazine is incorrect. This can also be used to treat agitation in a palliative care setting. However, midazolam is preferred in terminal haemorrhages.

Buscopan is incorrect. This is used to decrease the burden of secretions in palliative care. It is not used to treat agitation.

Question 27 of 43

A 64-year-old Nepalese woman who emigrated to the United Kingdom six months prior arrives to her GP. She has known multinodular goitre which has been untreated. However, her daughter who translates for her reports that she has noticed a tight sensation like she is being strangled. This is worse in the mornings and her daughter has noticed that her face does appear puffy. She has no weight loss, fevers or night sweats. She is otherwise well and has never smoked.

On examination, there is a large multinodular goitre that occupies a large part of the neck and measures 15-20cm in width. There is no audible stridor but there are several neck veins visible. You ask her to stretch out her hands up high to observe for a tremor and she starts to complain of the tightness. becoming worse. Her chest sounds are quiet and her chest is clear. There is dull percussion under the top third of the sternum.

TSH	0.07 mU/L (normal range 0.05-5.0)
T4	10 pmol/L (normal range 9-50)
T3	4.0 pmol/L (normal range 3.5-7.8)
D-dimer	0.15 (normal range 0-0.25)
Chest x-ray	Widened mediastinum, no focal lung lesion

What is the underlying cause of these new symptoms?

A. Multinodular goitre
B. Lymphoma
C. Thoracic artery aneurysm
D. Lung carcinoma
E. Superior vena cava thrombus

A. Multinodular goitre

Enlarged goitre can be a rare cause of SVC obstruction

This presentation is classical for superior vena cava obstruction and the worsening of her symptoms when she lifts her hands up is Pemberton's test which is positive in this case. The next decision is to seek the cause. The obvious cause here is a huge goitre which is recognised as a rare cause of superior cava obstruction. Lung carcinoma is possible but this lady is a non smoker and there is no cough or weight loss. Thoracic artery aneurysm would show a widened mediastinum but there would often be a history of connective tissue disease or uncontrolled hypertension. Lymphoma causing SVC obstruction would typically have mediastinal lymphadenopathy on chest x-ray. SVC thrombus would be unlikely given that the D-dimer is negative

Question 28 of 43

A 78-year-old gentleman with known metastatic prostate cancer is admitted due to lower back pain that is worse on sitting upright. He denies any sensory changes or weakness but is woken at night and cannot sleep. He takes aspirin, paracetamol and bicalutamide regularly.

On examination, he has normal tone, full power and downgoing plantars in both lower legs. He is exquisitely tender in the midline at L2 and L3.

Bilirubin	34 µmol/l
ALP	450 u/l
ALT	56 u/l
Albumin	32 g/l
Calcium	3.1mmol/l
MRI spine	sclerotic lesions seen in T9, L2 and L3

What medical therapy would offer greatest benefit to him?

A. Intravenous fluids
B. Denosumab
C. Spinal decompressive surgery
D. Omeprazole
E. Transcutaneous electrical nerve stimulation (TENS)

B. Denosumab

Denosumab is an unlicensed medication for bony metastasis pain

This gentleman has bony pain associated with bony metastases. This is a key question in identifying the problem and how to help him. There is no sign of nerve compression so spinal surgery will not benefit him. He is asymptomatic from his hypercalcaemia so

IV fluids would not benefit. Omeprazole will help protect his stomach from ulceration. For bony pain, NSAIDs usually are a good first line. Bisphosphonates and radiotherapy help but are not an answer. Denosumab is a third line when the above fail. TENS can be useful for all pains but is not evidence based for bony pain.

Question 29 of 43

You are fast-bleeped to the oncology ward to review a 72-year-old man with a background of metastatic, fungating buccal cancer. During initial MDT, it was deemed inoperable due to carotid artery involvement. He was initially admitted with hypercalcaemia but has deteriorated during his admission and is on the end-of-life pathway.

On your arrival, you note a large amount of blood around the patient with staff using towels and applying pressure to the neck. Nursing staff report that there was a sudden 'pop' and large volume bleeding began at the site of the fungating cancer. They state that bleeding has occurred before but not to this extent.

What is the most appropriate next step in management?

A. Adrenaline
B. Midazolam
C. Morphine
D. Terlipressin
E. Vascular surgery opinion

B. Midazolam

In a massive terminal haemorrhage, a large dose of midazolam (10mg) can be given as part of 'crisis management' to relieve distress. Red or green towels or blankets should be available to soak up and mask the colour of blood

This is an example of a catastrophic, terminal haemorrhage likely arising from carotid artery involvement. In these circumstances, patients can become very distressed and unfortunately, often there is very little that can be done. To aid in relieving stress it is advised to use red or green towels to help soak up blood as well as obscuring the colour of the blood, as well as giving a large dose of midazolam for relaxation.

Adrenaline can be used in specific circumstances of major haemorrhage but is not used in terminal haemorrhage. Given that the history explains that the patient is on the end of life pathway and that he is not for surgical intervention, adrenaline is not appropriate.

Morphine can be used for pain and breathlessness in palliative care but is not used in terminal haemorrhages.

Terlipressin can be used for major haemorrhage, particularly of gastrointestinal bleeding, however again, this is not appropriate in terminal haemorrhages.

The MDT has already decided that surgical intervention is not appropriate and therefore a vascular surgery opinion at this time would not be appropriate.

Question 30 of 43

A 60-year-old woman presented to the emergency department with recurrent episodes of severe headache and vomiting over past 3-4 days. She was known to have underlying metastatic breast cancer for which she was receiving palliative chemotherapy. She was also known to have underlying type 2 diabetes mellitus and osteoarthritis of bilateral knee joints.

On examination, her pulse rate was 105/min, respiratory rate was 16/min, blood pressure was 120/80 mmHg. Fundoscopy revealed early papilloedema.

A contrast enhanced CT brain was done which showed a solitary mass of 3 cm in the left cerebral hemisphere.

What is the next appropriate management?

A. Start 16 mg of i.v dexamethasone and prophylactic anticonvulsants
B. Start 16 mg of dexamethasone and arrange urgent MRI brain
C. Refer to neurosurgery for biopsy of the brain lesion
D. Refer to radiation oncologist for Whole brain radiotherapy
E. Stereotactic radiosurgery

B. Start 16 mg of dexamethasone and arrange urgent MRI brain

High dose dexamethasone is the mainstay of immediate management of brain metastasis. For lesions identified as solitary on contrast enhanced CT brain, MRI with gadolinium is indicated to assess the extent of intracranial disease. Patients presenting with seizure activity should be given anticonvulsant therapy. Patients with limited number of lesions(<4) can be considered for more aggressive treatment like neurosurgery or stereotactic radiotherapy but not the immediate step. Biopsy of the lesion is indicated if primary is unknown.Whole brain radiotherapy is indicated for multiple brain metastasis (>4).

Question 31 of 43

A 48-year-old woman is currently undergoing various cycles of chemotherapy for breast cancer. She asks the oncology team for advice as, 2-3 days post-chemotherapy, she experiences severe nausea and vomiting that lasts for several days. This is debilitating, despite taking antiemetics during the chemotherapy and afterward.

What is the most appropriate drug to prevent this delayed reaction?

A. Dexamethasone
B. Levopromazine
C. Lorazepam
D. Metoclopramide
E. Ondansetron

A. Dexamethasone

Dexamethasone is the most useful agent in preventing the delayed phase of chemotherapyinduced emesis

Dexamethasone has been shown by numerous trials to be the most effective agent in preventing delayed nausea and vomiting. As opposed to more immediate nausea and vomiting, for which antiemetics are useful, the delayed reaction (between 24 hours and 1-week post-chemotherapy) is not as effectively reduced by antiemetics.

Levopromazine is a 'dirty drug', acting at multiple receptor sites. It is a useful antiemetic, particularly parenterally, but sedates patients quite significantly and is generally reserved for palliative care and intractable symptoms.

Lorazepam, a benzodiazepine, has mild antiemetic properties and is not considered effective at reducing the delayed phase. It is generally used for its anti-anxiolytic properties.

Metoclopramide is a dopamine antagonist and an effective antiemetic. It may be used first-line for immediate nausea and vomiting. However, in the context of the delayed phase, dexamethasone is more useful.

Ondansetron is a serotonin receptor antagonist and another effective antiemetic used for chemotherapy-induced nausea and vomiting. With regards to the delayed phase, however, dexamethasone is the most effective agent.

Question 32 of 43

A 68-year-old man with metastatic prostate cancer is due to go for radiotherapy in an hour. The nurses tell you that he complained of pain during the transfer yesterday. His pain has been otherwise well controlled on a total of 60mg morphine daily.

How is it best to manage his pain control for the transfer today?

A. Nothing as it is only temporary pain
B. An additional dose of 10mg morphine 30 minutes prior to his transfer
C. An additional dose of 15mg morphine 1 hour prior to his transfer
D. An additional dose of 10mg morphine 1 hour prior to his transfer
E. An additional dose of 15mg morphine 30 minutes prior to his transfer

B. An additional dose of 10mg morphine 30 minutes prior to his transfer

A breakthrough dose of morphine should be given 30 minutes prior to his transfer as indicated in the BNF. 1 hour is too long prior as it should last him the transfer back and 30 minutes prior is enough for the morphine to have the desired effect. A breakthrough dose should be 1/6th of his total daily dose which in this case is 10mg. Therefore, 15mg is too high a dose for this patient.

Although it is temporary pain, it should still be treated as the patient's comfort and quality of life are important aspects of his care.

Question 33 of 43

A 72-year-old man presents to the emergency department with shortness of breath. He describes his breathlessness has progressively become worse over the last two weeks and is especially troublesome when leaning forward. His wife has commented that his appearance has changed too, with his face becoming more swollen and different in colour. He has a past medical history of right-sided heart failure, myocardial infarction, type two diabetes, COPD and small cell lung cancer diagnosed three months ago. He is an ex-smoker of 20 pack-years and drinks moderate amounts of alcohol.

On examination, he appears settled at rest. His face is swollen and slightly purple. His neck veins are distended and his JVP is markedly elevated to 4cm. Auscultation reveals bibasal crepitations. There is pitting oedema at the ankles. A chest X-ray demonstrates a widened mediastinum.

What investigation is most appropriate to establish the diagnosis?

A. ECG
B. Trans-thoracic echocardiogram
C. Trans-oesophageal echocardiogram
D. Bronchoscopy
E. CT chest

E. CT chest

The correct answer is CT chest as the patient has a clinical history consistent with obstruction of the superior vena cava (SVC). There are several symptoms and signs consistent with SVC obstruction, including breathlessness worse, leaning forward, distended neck veins and a swollen face. This, in combination with known lung cancer, suggests progression of the primary malignancy or lymph nodes compressing the SVC. Whilst some of the finds could be suggestive of acute pulmonary oedema, the chest X-ray is consistent with SVC obstruction. As a cardiac cause is unlikely, an echocardiogram or ECG is unlikely to be diagnostic. A bronchoscopy is a possible approach for obtaining a biopsy if an SVC obstruction is diagnosed and the source of the obstruction is unclear, but as this patient is known to have lung cancer this is not going to be helpful for this patient.

Question 34 of 43

A 40-year-old man is seen in the Emergency Department with breathlessness.

He was diagnosed with non-Hodgkin lymphoma 6 months ago and has been receiving chemotherapy. He is awaiting an appointment in haematology outpatients to assess his response to chemotherapy.

He describes becoming more breathless over the last week and feeling that his arms and face are puffy. He has had no chest pain, cough or fevers.

On examination his oxygen saturations are 92% on air and his heart rare is 112 beats per minute. His chest is clear and he is unable to lay flat for his abdomen to be examined due to is breathlessness. His face appears flushed and he has oedema of the arms and hands. His neck veins appear engorged.

Chest x-ray shows a widened mediastinum with extensive lymphadenopathy.

A CT scan of the thorax confirms superior vena cava obstruction (SVCO). The scan is reviewed by the haematology team who explain to him that his lymphoma has progressed despite chemotherapy.

He is started on steroids and a proton pump inhibitor.

What is the next step in the management of this gentleman's SVCO?

A. Chemotherapy
B. Observation
C. Radiotherapy
D. Stent insertion
E. Surgery

D. Stent insertion

SVCO is an oncological emergency and is most common in lung cancer and lymphomas. The immediate management is steroids with proton pump inhibitor cover for gastric protection.

Further options include stent insertion, radiotherapy and chemotherapy.

This gentleman is unable to lay flat so would not be able to tolerate radiotherapy. Radiotherapy also has the disadvantage of causing increased swelling acutely before it causes long term shrinkage.

Lymphomas are highly chemotherapy responsive tumours and this gentleman has only had firstline chemotherapy, therefore second-line chemotherapy should be planned in order to shrink his mediastinal disease.

Stent insertion is the most immediate management for relieving SVCO until chemotherapy can take effect. The patient's haemoglobin, platelets and clotting must be checked and optimised. In patients with end-stage disease, stents can still become blocked.

Surgery is not generally part of the management for SVCO.

Question 35 of 43

A 71-year-old woman is referred by her GP to the rapid access chest clinic with progressive shortness of breath and reduced exercise tolerance over 3 months and a chronic productive cough. When asked about her past medical history she states that she has had some pain for the past month or so in her left shoulder, which has been present at a constant level. She has been taking paracetamol and codeine for the pain which helps slightly. Otherwise, the patient has moderate COPD, for which she taken ipratropium bromide and salmeterol and mechanical back pain. She has a 15 year pack-history and drinks 1-2 units of alcohol per day.

Examination reveals some wasting of the hypothenar eminence of the left hand, although the chest sounds clear bilaterally with no added sounds. Heart sounds 1 and 2 are present with no murmurs.

What would be the most useful investigation following a chest x-ray?

A. Electromyogram studies
B. Computed tomography of the thorax
C. Bronchoscopy
D. Myeloma screen
E. Sputum microscopy, culture and sensitivity

B. Computed tomography of the thorax

The most likely diagnosis in this case is lung malignancy, in particular a Pancoast tumour, given this patient's wasting of the hypothenar eminence, shortness of breath and cough. The most useful investigation is a CT of the thorax - bronchoscopy is not as useful as the cancer is often too peripheral.

Question 36 of 43

You are asked to review a 67-year-old gentleman who was admitted to the medical emergency unit with pneumonia. He had been diagnosed with terminal small cell cancer of the lung which had extensively metastasised to his liver, thoracic vertebrae and femur bones. His past medical history was comprised of ischaemic heart disease, hypertension, hypercholesterolaemia and COPD.

His main complaint was of progressively worsening pain in his spine and legs. This was particularly bothersome at night; a trial of bisphosphonate therapy and radiotherapy did not provide any symptomatic relief. He was commenced initially on oral morphine sulphate solution which was converted to morphine sulphate tablets (MST); he had been on 60mg BD but this was titrated by the palliative care community nurse to 70mg BD a couple of days prior to admission with excellent analgesic effect. He was also using Oramorph solution 10mg on average 5-6 times a day for breakthrough pain.

He had been accordingly treated with intravenous antibiotics whilst on the ward making a full recovery. Prior to discharge, he was very keen on commencing transdermal treatment so as to minimise the number of oral medications taken.

What is the most appropriate starting dose to commence, with a view to completely discontinuing all oral opiate medication?

A. Commence Fentanyl 12 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain
B. Commence Fentanyl 25 72 hr patch, paracetamol 1g QDS and oramorph solution PRN forbreakthrough pain
C. Commence Fentanyl 50 72 hr patch, paracetamol 1g QDS and oramorph solution PRN forbreakthrough pain
D. Commence Fentanyl 75 72 hr patch, paracetamol 1g QDS and oramorph solution PRN forbreakthrough pain
E. Commence Fentanyl 100 72 hr patch, paracetamol 1g QDS and oramorph solution PRNfor breakthrough pain

D. Commence Fentanyl 75 72 hr patch, paracetamol 1g QDS and oramorph solution PRN forbreakthrough pain

This gentleman was on a rather complicated opiate analgesia regimen and the key to this question is calculate the total daily dose of morphine salt, to then convert it to the appropriate amount of fentanyl.

His total morphine salt intake was thus:

MST 70mg BD = 140mg of morphine Oramorph 10mg PRN = 50-60mg of morphine

Total = 190-200mg daily morphine salt intake

The BNF states that a fentanyl 75 patch is equivalent to 180mg daily intake of morphine salt whilst a fentanyl 100patch is equivalent to 240mg daily morphine salt intake. So as to avoid opiate toxicity the correct answer is thus to commence a fentanyl 75 patch and to supplement this with PRN Oramorph solution.

Question 37 of 43

A 68-year-old man presents with a five-week history of lower back pain that is worse with coughing. He has noticed that he has been requiring more painkillers to the point where he is struggling to manage, especially at night. The pain is worse when straining to pass stool. He lost three kg over the last four months as well. He has a past medical history of COPD, hypertension, type two diabetes mellitus, and hypercholesterolemia. He has been admitted three times in the last year for exacerbations of COPD requiring the recurrent use of oral prednisolone. His regular medications include Symbicort, tiotropium, atorvastatin, metformin, paracetamol, codeine and Movicol. He is an ex-smoker with a 50 pack-year history and recently opted for early retirement from his job as an accountant as he was struggling with tiredness. On examination, he appears tired and his clothes appear loose fitting. Examination of his chest is unremarkable, but there is a 1cm swelling above his left clavicle. His abdomen is soft, there is no tenderness over his spine, and a neurological examination is unremarkable.

Observations:

Saturations	95%
Respiratory rate	15/min
Blood pressure	148/87mmHg
Heart rate	74/min
Temperature	37.4°C

Blood tests:

Hb	128 g/l
MCV	72 fl
Platelets	327 * 10 /l9
WBC	12.4 * 10 /l9
Na +	136 mmol/l
K +	4.2 mmol/l
Urea	4.1 mmol/l
Creatinine	77 µmol/l

What is the most likely diagnosis that explains his symptoms?

A. Osteoporotic vertebral collapse
B. Spinal cord metastasis
C. Myeloma
D. Degenerative changes
E. Discitis

B. Spinal cord metastasis

The answer is spinal cord metastasis. This question highlights multiple subtle red flags in a history with back pain. He is over >55 and describes nocturnal and progressive pain worse with coughing and straining in the context of immunosuppression from repeated steroid use, weight loss, and increasing fatigue. Due to the high suspicion, the most diagnostic imaging investigation would be a whole spine MRI, which would differentiate between the above diagnoses. Osteoporotic fracture is suggested by the use of steroids but overall does not fit with the progressive nature and microcytic anaemia, nor do degenerative changes. There are very few symptoms to suggest infection such as fever and night sweats, but discitis cannot be fully excluded without imaging. Myeloma is a possible diagnosis, but so far there are no specific factors to suggest it, such as lytic bone lesions or deteriorating renal function.

Question 38 of 43

A 56-year-old male with non-hodgkin's lymphoma is on his third cycle of R-CHOP chemotherapy. He has struggled previous times with nausea but is two days following the most recent cycle and attended hospital due to intractable vomiting.

He is vomiting 20+ times a day with green to clear fluid. He does not feel hungry and struggles to swallow water. He is not having diarrhoea. He takes regular indapamide and as required ondansetron and this has not helped him despite the oncologist suggesting he double his dose of ondansetron.

On examination, he looks pale and has dry mucosa. He is alert, has a clear chest and soft abdomen but begins to retch on sitting forward. He last passed urine 6 hours ago and his observations show a heart rate of 115 beats per minute and blood pressure 90/65mmHg. He is started on intravenous fluids by the emergency department.

Na +	135 mmol/l
K +	3.5 mmol/l
Urea	6.5 mmol/l
Creatinine	98 µmol/l

What medical intervention would offer greatest benefit?

A. Cyclizine
B. Potassium salt replacement
C. Elective terminal ileostomy
D. Dexamethasone
E. Delay next course of chemotherapy

D. Dexamethasone

Dexamethasone with ondansetron is effective in refractory chemotherapy-induced vomiting

This gentleman has refractory vomiting despite ondansetron. He need assistance to ensure he can maintain fluids. Cyclizine is an antiemetic but bind histamine receptors so is most useful in labyrinthitis and motion sickness. Potassium salt replacement will probably make him vomit more but does replace his lost salts. Delaying the course of chemotherapy would be an option if nothing else could be offered. Surgery is not the way forward here. Dexamethasone is proven as an effective second line antiemetic in chemotherapy related nausea and vomiting. it is often given in lymphoma to prevent tumour lysis syndrome.

Question 39 of 43

A 38-year-old man presents with increasing shortness of breath and ankle swelling. He reports he is more short of breath, especially on exertion, which is not being relieved by the use of his salbutamol inhaler. He has also noticed his ankles are swollen by the end of the day.

His past medical history includes asthma, which is usually well controlled, and lymphoma, which was treated with chemotherapy several years ago. His only medications are his beclometasone and salbutamol inhalers. The results of his blood tests are shown below:

Hb	140 g/L	(135-180)
Platelets	359 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Urea	5.9 mmol/L	(2.0 - 7.0)
Creatinine	119 µmol/L	(55 - 120)

His ECG showed sinus rhythm with left axis deviation. An echocardiogram was done which showed dilation of all four chambers of the heart and a left ventricular ejection fraction of 40%.

Which drug can be attributed to causing this man's presentation?

A. Cyclophosphamide
B. Vincristine
C. Doxorubicin
D. Docetaxel
E. Bleomycin

C. Doxorubicin

Anthracyclines (e.g. doxorubicin) may cause cardiomyopathy

This man is presenting with features of heart failure and the echocardiogram results would be in keeping with a diagnosis of dilated cardiomyopathy. Doxorubicin (an anthracycline) is used in the treatment of lymphoma and is known to be cardiotoxic.

Cyclophosphamide can also be used to treat lymphoma and other haematological conditions such as leukaemia. A well-known side effect is haemorrhagic cystitis.

Vincristine can be used with doxorubicin to treat lymphoma and is associated with peripheral neuropathy.

Docetaxel is often used in the management of breast and lung cancers and can cause neutropenia.

Bleomycin can be used as part of lymphoma management and is associated with the development of pulmonary fibrosis.

Question 40 of 43

You are reviewing a 65-year-old man who has recently started treatment for urological cancer with Nivolumab (Opdivo) a type of checkpoint inhibitor.

He has been having treatment for 1 month and has had no side effects so far. He would like to know what to expect from this treatment.

What is the most common side effect this patient is likely to experience?

A. Dry itchy skin and rashes
B. Depression and anxiety
C. Dry cough
D. Retinal damage
E. Skin discolouration

A. Dry itchy skin and rashes

The most common side effect of immune checkpoint inhibitors is dry itchy skin and rashes

Immune checkpoint inhibitors are a type of immunotherapy that are increasingly being used to treat certain types of cancer, as an alternative to cytotoxic chemotherapy. They are currently only used to treat solid tumours. They work by enhancing the bodies own T-cell population to destroy the cancer cells. Their side effect profile reflects their mechanism of action and are, therefore, inflammatory and autoimmune in nature. They include:

- Dry, itchy skin and rashes (most commonly)
- Nausea and vomiting
- Decreased appetite
- Diarrhoea
- Tiredness and fatigue
- Shortness of breath and a dry cough.

Therefore, option one is the only correct answer.

Question 41 of 43

A 54-year-old male presents to the emergency department with sudden onset palpitations and shortness of breath which began whilst he was watching television a few hours previously. He describes an odd fluttering sensation in his chest with mild dyspnoea but no chest pain. He denies having experienced this before. On systems review, he also complains of severe muscle cramps and a slight tremor in his hands over the last few days. His past medical history includes hypertension and gout for which he takes amlodipine and allopurinol. He denies any history of exertional dyspnoea but does occasionally get central chest pain on exertion for which he has not sought help. He has recently been diagnosed with small cell lung cancer and underwent his first round of chemotherapy last week; although he is unsure which drugs are being used. He used to smoke a pipe until his recent diagnosis of cancer and drinks a few measures of whisky most evenings.

On examination, his respiratory rate is 22 breaths/min and his oxygen saturations are 96% breathing two litres of oxygen. His heart rate is irregularly irregular and approximately 130 beats/min, his blood pressure is 152/78 mmHg. An ECG shows atrial fibrillation with no ischaemic changes.

What is the most likely cause for his new atrial fibrillation?

A. Ischaemic heart disease
B. Chemotherapy induced hypokalaemia
C. Chemotherapy induced hypomagnesaemia
D. Chemotherapy induced cardiomyopathy
E. Alcohol

C. Chemotherapy induced hypomagnesaemia

The most common chemotherapy regime for small cell lung cancer is etoposide and cisplatin. A common side effect of cisplatin is hypomagnesaemia which can result in muscle cramps, tremor, cardiac arrhythmias, confusion amongst other features. This gentleman appears to have angina and may well have some level of ischaemic heart disease in the background which would increase his risk of atrial fibrillation. However, it seems logical given the strong temporal relationship between the chemotherapy and the other symptoms of hypomagnesaemia that this is the cause.

Question 42 of 43

A 63-year-old man is diagnosed with colorectal cancer. Following successful resection he starts adjuvant capecitabine but after six doses develops severe diarrhoea, weakness and desquamation of the hands, feet and face. On admission, he is pancytopenic and has electrolyte abnormalities requiring IV replacement. His initial blood tests are shown bellow.

Na +	140 mmol/l
K +	3.6 mmol/l
Urea	9.2 mmol/l
Creatinine	125 µmol/l
Hb	75 g/l
Platelets	35 * 10 /l9
WBC	0.4 * 10 /l9
Neutrophils	0.03 * 10 /l9
Adjusted Ca 2+	1.5 mmol/l
Mg 2+	0.32 mmol/l
Glucose	4.0 mmol/l

What is the most likely cause?

A. DPD (dihydropyrimidine dehydrogenase) deficiency
B. Infective gastroenteritis
C. Cancer recurrence
D. Pityriasis alba
E. Neutropenic sepsis

A. DPD (dihydropyrimidine dehydrogenase) deficiency

Capecitabine is the oral analog of 5-fluorouracil, a chemotherapeutic agent which is broken down, predominantly, by dihydropyrimidine dehydrogenase (DPD). Deficiency is autosomal recessive and will lead to a toxin buildup which in homozygous patients is usually fatal. The severe toxicity experienced by this patient are likely due to a heterozygous DPD deficiency.

Question 43 of 43

A 53 year old patient has undergone six cycles of R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisolone) chemotherapy and is now attending the lymphoma follow up clinic. He complains of an ongoing and unrelenting tingling in his feet and legs as well as his right hand. This is associated with pain in the extremities that is worsened by the cold weather.

Examination reveals normal motor strength throughout all 4 limbs but marked reduction in proprioception in both legs below the knee and also the right hand. The is a 'glove and stocking' distribution of loss when tested for pin-prick sensation and a reduced joint position sense to the ankle in both lower limbs. Plantar reflexes are normal. During the examination you it is noted that the patient has sustained an injury to the sole of foot which he was unaware of.

What is the most likely causative agent for these symptoms?

A. Rituximab
B. Cyclophosphamide
C. Doxorubicin
D. Vincristine
E. Prednisolone

D. Vincristine

The symptoms being experienced above are classical for chemotherapy induced peripheral neuropathy. This is a condition that can occur in up to 40% of patients being given chemotherapy with agents such as platinum based drugs (cisplatin and oxaliplatin), vinca alakloids (vincristine and vinblastine), thalidomide and taxanes (paclitaxel and docetaxel). The treatment of chemotherapy induced peripheral neuropathy is difficult with patients having severe problems long after the causative agent has been given. In most cases it is irreversible. The best medication for treatment is gabapentin or pregabalin which should be titrated up to therapeutic levels and used in conjunction with another analgesic agents.

There are ongoing trials aiming to find a prophylactic agent to help prevent this painful sequealae of treatment, but as yet there has been no convincing evidence to suggest any one treatment.

Question 1 of 277

A 44-year-old man is brought to the emergency department by his wife with an acute onset of confusion. She reports that her husband had only just recently recovered from a bout of nausea and vomiting for the last 10 days since returning home from visiting family in Vietnam. He has no past medical history of note and takes no regular medications. His sister was treated for tuberculosis 6 months ago.

His observations are as follows:

- Temperature 38.3ºC
- Heart rate 116 beats/min
- Blood pressure 112/76 mmHg
- Respiratory rate 16 breaths/min
- Saturations 96% on air

On examination, he is disoriented to time and place but recognises his wife. He complains of a severe headache but the remainder of his neurological examination is unremarkable. On auscultation, his chest is clear and heart sounds are normal. His abdomen is soft and non-tender.

What is the most likely diagnosis?

A. Dengue fever
B. Disseminated tuberculosis
C. Japanese encephalitis
D. Meningitis
E. Yellow fever

C. Japanese encephalitis

Confusion in returned traveller from Asia -> Japanese encephalitis

This patient has **Japanese encephalitis**. Spread by Culex mosquitoes that breed in rice paddy fields, Japanese encephalitis is the most common cause of encephalitis in South East Asia, China and India. Most cases are asymptomatic. However, in more severe cases, symptoms include headache, fever, seizures and confusion. A prodrome of nausea and vomiting may be seen initially, as described by this patient. This patient is presenting with acute confusion and headache following a trip to Vietnam and therefore, a diagnosis of Japanese encephalitis is likely.

Dengue fever is a viral illness that presents with fever, headache and myalgia. A maculopapular rash early on in the illness is common, along with facial flushing. In some patients, the disease can progress to a viral haemorrhagic fever and dengue shock syndrome. However, it does not present with symptoms of acute encephalitis.

Disseminated tuberculosis is a less likely answer. Typically tuberculosis affects the respiratory system and systemic symptoms are present including fever, night sweats and weight loss. Although his sister was recently treated for tuberculosis, the absence of these constitutional symptoms and the more abrupt onset of illness suggests an alternative diagnosis.

Meningitis can have a viral or bacterial cause. However, the presenting symptoms are similar and include fever, headache and meningism. Vomiting may also feature. However, the absence of photophobia and meningism and the acute onset of confusion makes a diagnosis of encephalitis more likely than meningitis.

Yellow fever is a viral haemorrhagic illness common in Central and South America. It presents as a mild flu-like illness followed by a brief remission period before the onset of haematemesis, jaundice and oliguria. The presenting symptoms in this question do not describe any form of haemorrhage and are not typical of yellow fever, suggesting that it is not the underlying diagnosis.

Question 2 of 277

A 34-year-old man presents to the emergency department with a three-week history of mild right upper quadrant (RUQ) pain. He feels sweaty and feverish. He reports a three-week holiday to Indonesia one-year ago.

His observations are:

- Respiratory rate: 19/min
- Oxygen saturation: 98% on room air
- Heart rate: 104bpm
- BP: 138/72mmHg
- Temperature: 38.0 C
- GCS: 15/15

On examination, the patient is tender in the RUQ and appears sweaty. Otherwise, he examines normally.

An abdominal ultrasound is performed which shows a 7cm abscess in the right lobe of the liver. Stool microscopy shows spherical cysts.

What is the most appropriate treatment?

A. Abscess aspiration
B. Amoxicillin + ciprofloxacin + metronidazole
C. Metronidazole for 1 week
D. Metronidazole for 1 week, then diloxanide for 1 week
E. Praziquantel

D. Metronidazole for 1 week, then diloxanide for 1 week

Treatment for invasive amoebiasis should be followed by a luminal amoebicide to eradicate the cystic stage which is resistant to metronidazole and tinidazole (which are used against the invasive stage)

Metronidazole for 1 week, then diloxanide for 1 week is the correct answer. This patient has amoebiasis, with the spherical cysts representing *Entamoeba histolytica* cysts. The incubation period is from days to years. Amoebiasis has a worldwide distribution but is more common in tropical and subtropical regions. Metronidazole treats Entamoeba trophozoites (but has insufficient activity against cysts). Diloxanide or paromomycin are luminal agents that are active in the bowel - they treat the Entamoeba cysts but are poorly absorbed, and so are ineffective against organisms outside the bowel. Therefore a combination of medications is required.

Abscess aspiration is the incorrect answer. Indications for abscess aspiration in amoebiasis are:

- Abscesses in the left liver lobe (possible rupture into pericardium)
- Abscesses >10cm in diameter
- Severe pain
- Marked diaphragm elevation
- Abscesses that fail to respond to medical management Impending abscess rupture

Amoxicillin + ciprofloxacin + metronidazole is the incorrect answer. This is the recommended treatment for bacterial liver abscesses, but this will not treat amoebiasis. Patients with bacterial liver abscesses are likely to be significantly more unwell (septic). They will also not have the characteristic cysts or trophozoites on stool microscopy.

Metronidazole for 1 week is the incorrect answer. Metronidazole will treat the Entamoeba trophozoites, but not the cysts.

Praziquantel is the incorrect answer. Praziquantel is an anti-helminthic drug and will not treat *Entamoeba histolytica*, which is a protozoan. Praziquantel (in combination with percutaneous aspiration) can be used to treat hydatid liver cysts caused by *Echinococcus granulosus*. Hydatid cysts tend to be multi-loculated and asymptomatic.

Question 3 of 277

A 54-year-old man presents to the emergency department with two days of pain and a rash on his right thigh. He has recently had the chickenpox for the first time and was given a course of aciclovir, which he has now completed. The lesions have now healed. He has type 2 diabetes and is on metformin. He smokes ten cigarettes daily.

His observations are heart rate 121 beats per minute, respiratory rate 24/minute, blood pressure 85/45 mmHg, oxygen saturations 97% on air and temperature 39.4ºC.

On examination, he appears unwell. He is diaphoretic and anxious. There is a tense erythematous area on his right thigh, which is severely painful. His pulse is bounding and there is a flow murmur heard in the aortic area.

Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	580 * 10 /L ^{9}	(150 - 400)
WBC	25.2 * 10 /L ^{9}	(4.0 - 11.0)
Na $^+$	137 mmol/L	(135 - 145)
K $^+$	4.1 mmol/L	(3.5 - 5.0)
Urea	11.4 mmol/L	(2.0 - 7.0)
Creatinine	176 µmol/L	(55 - 120)
CRP	380 mg/L	(< 5)
Bilirubin	25 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	89 u/L	(3 - 40)
Î³GT	45 u/L	(8 - 60)
Albumin	29 g/L	(35 - 50)

Despite aggressive fluid resuscitation, his blood pressure remains 86/51 mmHg. \

Given the likely diagnosis, what is the most important treatment?

A. Hyperbaric oxygen therapy
B. Intravenous flucloxacillin
C. Intravenous immunoglobulin
D. Surgery
E. Tazocin and clindamycin

D. Surgery

Chickenpox is a risk factor for invasive group A streptococcal soft tissue infections including necrotizing fasciitis

Surgery is the correct answer. This man has septic shock secondary to necrotizing fasciitis as evidenced by fever, hypotension, rash and pain out of proportion to the clinical findings. Furthermore, he has evidence of end-organ dysfunction (acute kidney injury). The most important treatment for necrotizing fasciitis is surgical debridement of infected tissue. All other treatments are considered adjunctive. Both recent chickenpox infection and diabetes are risk factors for this condition.

Hyperbaric oxygen therapy is incorrect. There have been case reports of this treatment being used for necrotizing fasciitis but it is not the mainstay of treatment.

Intravenous flucloxacillin is incorrect. This antibiotic would be a good choice for simple cellulitis but necrotizing fasciitis is a more severe infection, typically caused by gram-negative, grampositive and anaerobic bacteria and therefore requires a broader antibiotic cover.

Intravenous immunoglobulin is incorrect. This can be used as adjunctive treatment to antibiotics and surgery in severe skin and soft tissue infections but is not initial therapy or most important.

Tazocin and clindamycin are incorrect. This is the correct antibiotic choice for necrotizing fasciitis as it gives a broad cover against aerobic and anaerobic organisms and clindamycin has the added benefit of inhibiting toxin production. However, the literature on necrotizing fasciitis is clear in regarding surgery as the most important intervention.

Question 4 of 277

A 31 year-old male originally from Russia who is known to be HIV positive presents with a rash. On examination there are purple-red cutaneous macules and papules on the back, neck and oral mucosal membrane.

Blood results reveal:

Hb	141 g/l
Platelets	327 * 10 /l^9
WBC	4.2 * 10 /l^9
Na $^+$	141 mmol/l
K $^+$	3.7 mmol/l
Urea	4.6 mmol/l
Creatinine	59 µmol/l
Bilirubin	27 µmol/l
ALP	97 u/l
ALT	44 u/l
Albumin	30 g/l
HIV viral load	14,000 copies / ml
CD4 cell count	124 cell/mm^3

A skin biopsy is performed and the report is below:

Spindle cells present. Mitotic activity is moderate. Abnormally dense and irregular blood vessels. Intracellular hyaline bodies present.

Which virus is likely to be responsible for these lesions?

A. CMV
B. EBV
C. HIV-2
D. HHV-8
E. HPV-8

D. HHV-8

Kaposi's sarcoma - caused by HHV-8 (human herpes virus 8)

Intracellular hyaline bodies present.

This is a description of AIDS-related Kaposi's sarcoma.

Kaposi sarcoma is a disease of blood vessels that was considered very rare before the start of the AIDS pandemic. AIDS is due to infection with human immunodeficiency virus (HIV).

There are four types of Kaposi sarcoma:

- The classic type of Kaposi sarcoma affects elderly men of Mediterranean and Middle European descent and in men in Sub-Saharan Africa.
- AIDS-associated Kaposi sarcoma.
- Endemic or African Kaposi sarcoma arises in some parts of Africa in children and young adults.
- Iatrogenic Kaposi sarcoma is due to drug treatment causing immune suppression.

Classic Kaposi sarcoma is rare and unassociated with HIV infection. It most often arises in middleaged to elderly men of Mediterranean or Jewish descent (less than 10% are women), particularly if they come from a rural environment. They have a higher than expected rate of diabetes mellitus.

AIDS-related Kaposi sarcoma, unlike other forms of the disease, tends to have an aggressive clinical course. It is the most common presentation of Kaposi sarcoma. It has become less common in the US and Europe because of effective HAART treatment for HIV disease.

Kaposi's sarcoma is caused by infection with human herpesvirus 8 (HHV8), also known as Kaposi sarcoma-associated herpesvirus (KSHV) or KS agent

Typical histologic findings include proliferation of spindle cells, prominent slit-like vascular spaces, intracellular hyaline bodies and extravasated red blood cells.

Question 5 of 277

A 24-year-old man presents to the emergency department with a sudden onset of fever, headache and malaise, in association with diarrhoea and cramping abdominal pain. He has no past medical history and is on no regular medications. He returned from the 'python cave' in the Maramagambo Forest in western Uganda six days previously. He had visited the cave to view the colonies of Egyptian fruit bats. He tells you he strictly followed precautions to prevent mosquito bites and took malaria prophylaxis for the duration of his time there.

His observations are heart rate 120 beats per minute, blood pressure 83/59 mmHg, respiratory rate 21/minute, oxygen saturations 95% on room air and temperature 39.4ºC.

On examination, he is confused with a Glasgow coma scale of 14/15 and is mildly jaundiced. There is no meningism or nuchal rigidity. His abdomen is moderately tender without evidence of peritonism. Chest auscultation is normal. His capillary refill time is 4 seconds, he has dry mucus membranes and decreased skin turgor. His heart sounds are normal with a soft systolic flow murmur audible.

Intravenous access is obtained and it is noted that he is oozing blood from his cannulae sites and also from his oral mucosa.

Urinalysis is unremarkable.

An ECG demonstrates sinus tachycardia.

Blood tests:

Hb	98 g/L	Male: (135-180)Female: (115 - 160)
Platelets	487 * 10 /L 9	(150 - 400)
WBC	3.8 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	5.1 mmol/L	(3.5 - 5.0)
Urea	13.1 mmol/L	(2.0 - 7.0)
Creatinine	280 µmol/L	(55 - 120)
CRP	50 mg/L	(< 5)
Bilirubin	84 µmol/L	(3 - 17)
ALP	267 u/L	(30 - 100)
ALT	432 u/L	(3 - 40)
Î³GT	180 u/L	(8 - 60)
Albumin	28 g/L	(35 - 50)
Prothrombin time	18.4 seconds	(11-14)

Plain radiography of the chest is normal. Three thick and thin blood films are negative.

What is the most likely diagnosis?

A. Hepatitis A
B. Leptospirosis
C. Malaria
D. Marburg virus
E. Typhoid

D. Marburg virus

Exposure to bats/caves is a risk factor for Marburg virus, which results in a viral haemorrhagic fever

Marburg virus is the correct answer. The patient has been to a specific region in Uganda that has previously been associated with outbreaks of Marburg virus. Exposure to bats and caves is also a risk factor for this viral hemorrhagic fever. This condition typically presents with an abrupt onset of fever, headache and malaise and progresses to include gastrointestinal symptoms, arthralgia/myalgia and subsequently haemorrhagic complications with multi-organ dysfunction as evidenced in this case. The incubation period before the onset of symptoms is typically 3-10 days. In addition to the geographic and zoonotic risk factors, it is the only diagnosis listed that could account for the haemorrhagic complications in this scenario (oozing from venepuncture sites and bleeding from mucosal membranes). Treatment is supportive and the condition is associated with a high mortality rate.

Hepatitis A is incorrect. While this could account for jaundice and transaminitis, it is typically a selflimiting illness and associated with fulminant liver failure only in very rare cases. It is not associated with haemorrhagic complications.

Leptospirosis is incorrect. While this condition can present with fever, headache and liver dysfunction, the traditional vectors for transmission are mice, rats, cows and pigs. It is transmitted classically by coming into contact with infected urine. While it is associated with subconjunctival haemorrhage, it is not usually associated with more diffuse haemorrhage as seen in this case. It is treated with antibiotics.

Malaria is incorrect. While this is the most common cause of the fever in the returning traveller, the patient has taken malaria prophylaxis and has had negative testing for malaria in addition to experiencing haemorrhagic complications, all of which make a diagnosis of malaria unlikely.

Typhoid is incorrect. While this is a common cause of fever in the returning traveller and is associated with fever and diarrhoea, it would not account for the haemorrhagic complications detailed in this scenario.

Question 6 of 277

A 35-year-old man presents to the travel walk-in centre due to a week of diarrhoea following a recent holiday to Brazil. He had a stool sample sent for ova, cysts, and parasites which tested positive for *Strongyloides stercoralis*.

What medication should be prescribed for the patient?

A. Azithromycin
B. Diethylcarbamazine
C. Ivermectin
D. Praziquantel
E. Triclabendazole

C. Ivermectin

Ivermectin is the drug of choice for treatment of strongyloidiasis

Ivermectin is the drug of choice for strongyloidiasis which acts by deactivating chloride channels which result in paralysis and death of the parasite either directly or by causing the worms to starve.

Azithromycin is an effective antibiotic for *Typhoid*, *Campylobacter* and often treatment of choice for traveller's diarrhoea. It is not effective for treatment of *Strongyloides*.

Diethylcarbamazine is not used to treat Strongyloides. It is the treatment of choice for *Wuchereria bancrofti*, *Loa Loa*, *Toxocara canis*.

Praziquantel is also not an effective treatment for Strongyloides. It is used to treat *Schistosoma haematobium*, *Paragonimus westermani* and *Clonorchis sinensis*.

Triclabendazole is the treatment of choice for *Fasciola hepatica* (the liver fluke) and is not the treatment of choice for Strongyloides.

Question 7 of 277

A 29-year-old man presented with fever, headache, a dry cough, and bloody diarrhoea. Symptoms started eight days ago. Eight weeks earlier he had been on an adventure holiday in Zambia with a group of friends, which involved rafting and visiting a game reserve. A couple of his friends had developed a similar illness. On examination, he was febrile, and was noted to have an urticarial rash on his trunk. He had a polyphonic wheeze in both lung fields and the tip of his spleen was palpable.

Hb	134g/l (130 - 180)
Platelets	350 * 10 /l (150 - 400)9
WBC	12.2 * 10 /l (4.0 - 11.0)9
Neutrophil	6.5 * 10 /l (1.5 - 7.0)9
Lymphocyte	1.7 * 10 /l (1.5 - 4.09
Eosinophil	3.4 * 10 /l (0.04 - 0.4)9
Monocyte	1.5 * 10 /l (0<0.8)9

What is the pathogen causing the patient's symptoms?ssMedicine

A. Dengue virus
B. Epstein-Barr virus
C. Human immunodeficiency virus
D. Leptospira icterohaemorrhagica
E. Schistosoma mansoni

E. Schistosoma mansoni

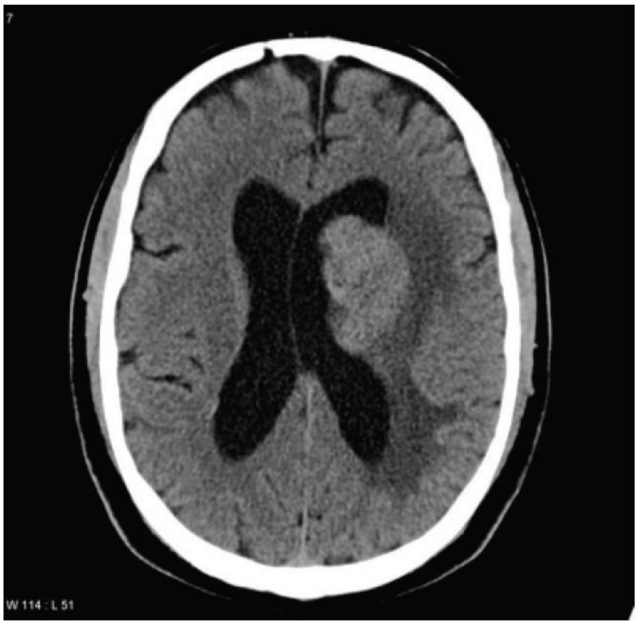
Acute schistomiasis is usually associated with marked eosinophilia, cough, bloody diarrhoea, and splenomegaly

The patient has a marked eosinophilia, and presents with systemic symptoms, cough, bloody diarrhoea, and splenomegaly eight weeks after exposure to fresh water in Africa. The most likely diagnosis in this scenario is Katayama syndrome, or acute schistosomiasis, caused by infection with a small blood fluke. It most often occurs with Schistosoma japonicum and schistosoma mansoni infections but can occur with any species. Acute schistosomiasis should be treated with praziquantel 40-60 mg/kg as a single dose and short course of steroids to control the inflammatory reaction. The dose of praziquantel should be repeated after six weeks when flukes are fully mature because immature flukes are relatively resistant to treatment.

Eosinophilia is not a feature of glandular fever, acute dengue, EBV infection, or HIV. The incubation period is too long for leptospirosis and dengue, which typically is 3-14 days.

Question 8 of 277

A 41-year-old man is admitted to the Emergency Department after having a seizure. He has no history of epilepsy but is known to be HIV positive. On examination he is still slightly confused post-ictally but there are no focal neurological signs. He is apyrexial and haemodynamically stable. His current medications includes efavirenz, tenofovir, lamivudine and co-trimoxazole. His latest CD4 count is 38 cells/µl. CT scan (without contrast) is shown below:



What is the most likely diagnosis?

A. Cerebral toxoplasmosis
B. Progressive multifocal leukoencephalopathy
C. Cryptococcal infection
D. CNS lymphoma
E. Cerebral tuberculosis

D. CNS lymphoma

HIV, neuro symptoms, single brain lesions with homogenous enhancement - CNS lymphoma

A hyper-attenuating mass adjacent to the left lateral ventricle is seen. The homogenous appearance, position and history (low CD4 count and current use of co-trimoxazole prophylaxis) are suggestive of primary CNS lymphoma rather than cerebral toxoplasmosis.

Question 9 of 277

A 32-year-old nurse presents to the the emergency department on the advise off occupational health. She contacted occupational health after she was coughed upon by a 25-year-old patient who is being treated with empirical antibiotics for bacterial meningitis. She felt contact on her face with droplets at the time. She has been feeling entirely well in herself. She has had appendicitis in the past as well as polycystic ovaries, but has no other medical problems. She takes metformin and oral contraception pills.

The 25-year-old patient was admitted 12 hours ago and has had a lumbar puncture which has confirmed meningococcal meningitis.

What is the most appropriate plan for the nurse?

A. Monitor for symptoms
B. Lumbar puncture
C. Give oral ciprofloxacin
D. Admit to hospital for IV antibiotics

E. Advise that the risk of transmission is not significant

C. Give oral ciprofloxacin

People who have been exposed to a patient with confirmed bacterial meningitis should be given prophylactic antibiotics if they been exposed to respiratory secretion, regardless of closeness of contact

This is a patient who has had a close contact with respiratory secretions of a person with confirmed meningococcal meningitis. Despite the fact that she has not had prolonged exposure, prophylaxis in the form of oral ciprofloxacin is needed.

The risk of transmission by this route is sufficiently significant to make monitoring for symptoms or not giving any treatment inappropriate.

A lumbar puncture is unlikely to be a helpful investigation for her as it cannot exclude that she will develop meningitis.

IV antibiotics are used to treat meningitis, whilst oral antibiotics can be used for prophylaxis of meningococcal meningitis.

Question 10 of 277

A 35-year-old woman presents to the ambulatory medical care unit with a 6-week history of an ulcer on the back of her right hand. It started as a 1cm painful nodule and gradually enlarged. It is now 3cm in diameter and is a firm raised purple/red lesion with some central ulceration. There are no lesions anywhere else and she is systemically well. She has no known past medical history and has not travelled outside of the UK in the last 5 years. She has no pets but works in a pet shop which specialises in tropical fish.

What organism is the most likely cause of this lesion?

A. Herpes simplex virus
B. Leishmania braziliensis
C. Mycobacterium marinum
D. Mycobacterium ulcerans
E. Sporothrix schenckii

C. Mycobacterium marinum

Fish tank granuloma is caused by *Mycobacterium marinum*

This presentation is typical of fish tank granuloma, which is caused by *Mycobacterium marinum*. The main clue is her exposure to fish tanks and lack of risk factors for the other organisms. As well as via contact of skin with the water in fish tanks or aquariums, the infection can less commonly be acquired through preparing fish or shellfish, or contact with fishing equipment. It generally presents as a slow-growing lesion, although it may disseminate or progress more quickly in immune-suppressed people. *Mycobacterium marinum* grows most effectively at 30 degrees, and so the lesions are usually found at the extremities.

Herpes simplex virus can cause lesions on the hand if the skin of the hand comes into contact with infected skin around the mouth or genitals - this is called herpetic whitlow. However, the lesion would usually be on the fingertips rather than the back of the hand, would start with vesicles rather than a nodule, and would generally progress more quickly.

Leishmania braziliensis causes cutaneous and mucocutaneous leishmaniasis and is found in Central and South America. Cutaneous leishmaniasis may present similarly to fish tank granuloma, however, the patient has not travelled abroad.

Mycobacterium ulcerans causes painful ulcers on the skin which are often called Buruli ulcers - however, it is found predominantly in tropical regions.

Sporothrix schenckii: is a dimorphic fungus which can cause similar lesions on the hands and arms after contact with infected plant matter - it is often referred to as rose gardener's disease. There tend to be several lesions which spread up the lymphatic system.

Question 11 of 277

A 23 year-old student presents with a febrile illness, seven days after return from holiday in Thailand. He delayed seeking medical attention because he thought it was 'just a virus', and he had experienced similar self-limiting symptoms when travelling to Vietnam several years earlier. He did not take malaria prophylaxis due to a previous adverse reaction to mefloquine. The illness began two days after his return, when he recorded his temperature at 38.4°C. He also complains of severe generalised joint pains and headache which he describes as 'behind the eyes'. Today he has developed nosebleeds and when he brushed his teeth this morning he noticed that his gums bled.

On examination his temperature is 38.2°C and there is a widespread macular rash with islands of sparing. There are some petechial haemorrhages on the limbs. Cardio-respiratory examination is unremarkable except for tachycardia of 114. Blood pressure is 123/79 mmHg. On palpation of the abdomen you discover tender hepatomegaly. Neurological examination is unremarkable.

On application of a tourniquet to take a blood sample you notice that the area under the tourniquet has become bruised.

Results of blood tests are as follows:

Hb	14.1 g/dl
MCV	94.2 fl
Haematocrit	0.57
Platelets	23 x10^9/l
WCC	6.1 x10^9/l
Na +	134 mmol/l
K +	4.6 mmol/l
Urea	3.8 mmol/l
Creatinine	80 µmol/l
ALT	64 IU/l
ALP	78 IU/l
Bilirubin	13 mol/l
Albumin	28 g/l
Rapid Malaria test	Negative

Thick and thin blood films	Pending

What is the most likely diagnosis?

A. Non-falciparum malaria
B. Dengue haemorrhagic fever
C. Lassa fever
D. Meningococcal septicaemia
E. HIV seroconversion

B. Dengue haemorrhagic fever

Retro-orbital headache, fever, facial flushing, rash, thrombocytopenia in returning traveller → ?dengue

This is a viral haemorrhagic fever, and the clinical picture is classic for dengue. The disease is endemic in South-East Asia. A defective immune response in secondary infections means that individuals who have been infected with one viral serotype may develop more severe disease when later infected with a different serotype. This patient may have developed self-limiting dengue fever on a previous trip to Vietnam, and now has secondary infection.

Dengue fever typically begins 7-10 days after infection with a rapid onset of fever, severe myalgia, and retro-orbital headache. A maculopapular rash with islands of sparing is characteristic. In the majority of cases there is self-resolution after 2-7 days. In a proportion of cases however, especially in secondary infection, the disease progresses to a more fulminant form known as dengue haemorrhagic fever. There is widespread vascular breakdown, with easy bleeding and bruising. Thrombocytopaenia is typical. Plasma leakage results in haemoconcentration, raising the haemocrit, and loss of plasma proteins into the extracellular space is reflected by the low albumin. The liver is often enlarged and tender, with deranged liver function tests. In severe cases this progresses to circulatory collapse and dengue shock syndrome. Diagnosis is by PCR (polymerase chain reaction) during the initial febrile phase and serology during the later stages. Management is supportive.

Non-falciparum malaria includes disease caused by *Plasmodium vivax* and *ovale*, and to a lesser extent *malariae* and *knowlesi*. *Vivax* is common in Thailand and typically causes less severe disease. Most malaria rapid diagnostic tests are antigen assays that detect only falciparum. Microscopy is the only way to confirm or exclude the diagnosis.

Lassa fever is a viral haemorrhagic fever endemic to West Africa.

Meningococcal septicaemia is a possibility, although one would expect him to be more unwell after five days of disease.

HIV seroconversion illness does not commonly cause bleeding manifestations.

Question 12 of 277

A 45-year-old man is urgently referred to dermatology clinic by his general practitioner after presenting with erythema migrans on his left calf. The patient was very concerned about the possibility that he had contracted Lyme disease following his recent walking holiday in the Scottish highlands.

The patient reported returning from his holiday 2 weeks ago and first noticed the rash within the last 24 hours. The patient reported that he had undertaken long walks in the countryside wearing shorts but that he had not noticed any ticks becoming attached to his body during his holiday. Aside from the rash on his leg (described below) the patient reported no other symptoms at the present time or during recent weeks. In particular, the patient denied any symptoms involving the central or peripheral nervous systems.

The patient was in generally good physical health and his only past medical history was hypertension treated with ramipril by his GP. The patient had no known allergies to any medications.

Examination of the patient's left leg demonstrated a circular erythematous rash 15 cm in diameter. The rash demonstrated an appearance typical for erythema migrans, featuring a central spot surrounded by a ring of clear skin and an outer ring of erythema. The patient reported that the area covered by the rash had expanded significantly in the 24 hours since he had first noticed it. A detailed examination of the remaining surface of the patient's skin did not identify any other significant rashes. Examination of the peripheral and central nervous system did not demonstrate any signs of focal neurology. Examination of the cardiovascular, respiratory and abdominal systems was unremarkable. There was no evidence of palpable lymphadenopathy.

What is the appropriate management of this patient's erythema migrans?

A. Serological testing for pathogenic Borrelia species
B. Treat with doxycycline for 14 days
C. No further investigation or treatment required due to absence of history of tick bite
D. Review patient in two weeks and arrange serological tests if onset of symptoms or signs ofLyme borreliosis
E. Review patient in two weeks and treat with doxycycline if onset of symptoms or signs of Lyme borreliosis

B. Treat with doxycycline for 14 days

First line treatment for early Lyme disease is a 14-21 day course of oral doxycycline

Lyme borreliosis is the commonest tick-borne infection in the northern hemisphere. It is relatively rare in the UK, with risk being greatest in rural forested areas such as the Scottish highlands, New Forest and Lake District. The illness is caused by pathogenic *Borrelia* species, members of the spirochete phylum.

Clinical features of Lyme borreliosis include erythema migrans in 90% of symptomatic individuals, which tends to occur to 2-40 days following exposure. Erythema migrans has the classical appearance described in the question but may be homogeneous in the early phase and can be confused for cellulitis or a simple insect bite. Rarely, a non-specific febrile illness without rash can occur. Neurological involvement consisting of meningitis or cranial nerve palsy can occur in early infection.

Erythema migrans is a clinical diagnosis and does not require serological confirmation. Therefore, the patient should be treated immediately with a 2-3 week course of oral doxycycline or amoxicillin, even in the absence of a history of tick attachment. Early treatment of erythema migrans is associated with a good clinical outcome and it would be inappropriate to delay treatment until the onset of other symptoms.

Serological testing should be reserved for individuals in which there is diagnostic uncertainty, neurological symptoms or those who are immunocompromised. Individuals presenting following a tick bite should not be treated or undergo investigation in the absence of erythema migrans or other symptoms of Lyme borreliosis.

Question 13 of 277

An 80-year-old man presents to the Emergency Department with a 3-day history of headache, photophobia and vomiting. He is pyrexial and tachycardic on arrival. He has a past medical history of hypertension, type 2 diabetes and ischaemic heart disease. He was born in the UK and has never lived outside the UK. On examination, he has neck stiffness and photophobia and is mildly confused.

A lumbar puncture is carried out immediately after the administration of antibiotics and shows results as below. Blood glucose at the same time is 7.8 mmol/L.

Red blood cells	5	(0)
White cells	150	(<3)
Cell count differential	90% lymphocytes	(N/A)
Protein	1.5 g/L	(0.18 - 0.45)
Glucose	2.6 mmol/L	(Relative to blood glucose)

What is the most likely causative organism?

A. Haemophilus influenzae
B. Listeria monocytogenes
C. Mycobacterium tuberculosis
D. Neisseria meningitidis
E. Herpes simplex virus

B. Listeria monocytogenes

Listeria may be suggested by CSF showing a lymphocytic pleocytosis, raised protein and reduced glucose

This patient clearly has clinical meningitis, as evidenced by his headache, neck stiffness, photophobia and fever. A degree of confusion suggests that there may also be some encephalitis. The correct answer is ***Listeria monocytogenes***. This diagnosis is suggested by the CSF results showing predominantly lymphocytes, with reduced glucose. Listeria meningitis tends to occur in neonates, pregnant women, the elderly and the immunocompromised. It most commonly presents

with sepsis and meningism and is more likely than other bacterial causes of meningitis to also cause encephalitis or focal neurological deficits.

Haemophilus influenzae is incorrect. This organism can cause meningitis but it mainly does so in infants and children. The CSF would be expected to contain predominantly neutrophils rather than lymphocytes.

Herpes simplex virus is incorrect. HSV might explain why the patient is encephalitic as well as meningitic and you would expect to see a lymphocytosis in the CSF, but the CSF glucose would be normal not low.

Mycobacterium tuberculosis is incorrect. Tuberculous (TB) meningitis could give a similar CSF picture as in this patient, but is less likely given that the patient has no epidemiological risk factors for TB acquisition. TB meningitis also tends to present less acutely.

Neisseria meningitidis is incorrect. In this case, you would expect to see a predominance of neutrophils in the CSF. Lymphocytes can sometimes also be present if there has been a delay between starting antibiotics and performing the lumbar puncture (partially treated meningitis) but this is not the case here where we are told that the lumbar puncture has been done immediately after giving antibiotics.

Question 14 of 277

A 23-year-old man presents to the emergency department with a fever and shortness of breath. He has a past medical history of type 1 diabetes and has had a recent hospital admission with diabetic ketoacidosis. He now has an insulin pump. He does not smoke or drink alcohol.

Observations:

- Heart rate 120 beats per minute \
- Blood pressure 92/48 mmHg
- Respiratory rate 22/minute
- Oxygen saturations 94% on room air
- Temperature 38.4C

On examination, he appears diaphoretic and unwell. Chest auscultation reveals coarse crackles at the right base.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	14.7 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	8.2 mmol/L	(2.0 - 7.0)
Creatinine	99 µmol/L	(55 - 120)
CRP	221 mg/L	(< 5)

A chest -ray demonstrates consolidation in the right lower zone.

He is commenced on empirical broad-spectrum antibiotics to treat sepsis secondary to pneumonia.

At 24 hours, a blood culture grows *Klebsiella pneumoniae* , which is identified as producing carbapenemase.

What is the most appropriate antibiotic choice?

A. Ceftriaxone
B. Co-amoxiclav
C. Meropenem
D. Piperacillin/tazobactam
E. Tigecycline

E. Tigecycline

Carbapenemase producing enterobacteriaceae (CPE) are multi-drug resistant coliforms. They can be treated with polymyxins (e.g. colistin), tigecycline, fosfomycin or aminoglycosides (e.g. gentamicin)

Tigecycline is the correct answer. The patient has developed pneumonia and sepsis secondary to infection with *Klebsiella pneumoniae* , which has been identified as a carbapenemase-producing organism. This is a class of bacteria known as carbapenemase-producing enterobacteriaceae. These are gram-negative bacteria that are resistant to carbapenem and extended-spectrum cephalosporin antibiotics. Effective antibiotics against this class of bacteria include polymyxins (e.g. colistin), tigecycline, fosfomycin or aminoglycosides (e.g. gentamicin). Risk factors for CPE infection include immunosuppression (e.g. diabetes) and previous hospital admission.

Meropenem is incorrect. This bacteria is carbapenem-resistant. Meropenem is a carbapenem.

Ceftriaxone is incorrect. CPE are resistant to the cephalosporin class of medication. This is effective against a wide variety of gram-negative and gram-positive aerobes and anaerobes and would be a reasonable choice for the treatment of hospital-acquired pneumonia on an empirical basis. However, it is not effective against CPE.

Piperacillin/tazobactam is incorrect. This class of antibiotic is effective against a broad spectrum of gram-positive and negative bacteria including *Pseudomonas* but is not effective against CPE.

Co-amoxiclav is incorrect. This has a wide spectrum of activity against various gram-negative and gram-positive aerobes but is not effective against CPE.

Question 15 of 277

A 31-year-old gentleman presents with fever, headache, abdominal pain and a rash on the chest 3 weeks after visiting South America.

On examination the temperature is 38.2ºC. There is a rash on the chest consisting of rose-coloured blanching papules. The respiratory rate is 20 breaths/min and the heart rate is 58 beats per minute. The chest is clear to auscultation. The abdomen is diffusely tender and there is mild splenomegaly.

Initial blood results are as follows:

Hb	128 g/l
Platelets	184 * 10 /l9
WBC	3.9 * 10 /l9
Na +	131 mmol/l
K +	3.3 mmol/l
Urea	7.2 mmol/l
Creatinine	141 µmol/l
Bilirubin	46 µmol/l
ALP	147 u/l

ALT	96 u/l
Albumin	38 g/l
CRP	52 mg/l

What is the most appropriate initial antimicrobial therapy?

A. Ampicillin
B. Chloramphenicol
C. Trimethoprim-sulfamethoxazole
D. Cefotaxime
E. Streptomycin

D. Cefotaxime

This is a fairly classical presentation of typhoid fever, also known as enteric fever. This is a potentially fatal multisystemic illness caused primarily by *Salmonella enterica*.

The rash here refers to rose spots which occur in up to 30% of people infected with this organism. Characteristically, rose spots are seen in untreated typhoid fever. They usually occur between the second and fourth week of the illness. They characteristically present as groups of 5-15 pink blanching papules distributed between the level of the nipples and umbilicus.

The treatment of choice is cefotaxime or ceftriaxone.

Ciprofloxacin may be used as an alternative in sensitive organisms.

Question 16 of 277

A 48-year-old farmer presents with a four-day history of headache, pyrexia and vomiting. He has recently been undergoing chemotherapy for chemotherapy for mantle cell lymphoma and successfully completed his fourth cycle three days ago. During his treatment, he has tried to maintain an active lifestyle and has continued to work on his dairy farm. He has no other past medical history, he does not smoke or drink. On examination, the patient is drowsy and pyrexic at 38.6 degrees. You note no rashes on his skin. His displays neck stiffness and photophobia. You are unable to formally perform a neurological examination but you note no obvious facial asymmetry and the patient is moving all four limbs. Both plantars are downgoing.

Blood tests are as follows:

Hb	98 g/l
Platelets	78 * 10 /l9
WBC	0.9 * 10 /l9
Neutrophils	0.3 * 10 /l9
Na +	146 mmol/l
K +	4.3 mmol/l
Urea	8 mmol/l
Creatinine	99 µmol/l
CRP	170 mg/l

A lumbar puncture is performed and the cerebrospinal fluid examination is as follows:

WCC	200 x 10 /litre (70% neutrophil 25% lymphocytes)6
RBC	4 x 10 /litre6
Glucose	1.7 mmol/l (normal 3.3-4.4 mmol/l)
Microscopy	No organisms on gram stain
Appearance	cloudy

The patient is immediately commenced on intravenous ceftriaxone for suspected bacterial meningitis. At 48 hours after initial admission, blood and cerebrospinal fluid cultures are still awaited. The patient has demonstrated no change in clinical state.

What is an appropriate additional therapy?

A. Hourly neurological monitoring
B. Intravenous acyclovir
C. Intravenous ampicillin
D. Intravenous rifampicin
E. Intravenous amphotericin B

C. Intravenous ampicillin

A diagnosis of meningitis is clear. However, the context is that of a patient who is immunocompromised with recent chemotherapy, presenting with a relatively subacute cause of neutropenic sepsis. The additional information that he continues to work on a dairy with possible exposure to unpasteurised milk increases the chance of listeria exposure, for which intravenous ampicillin is the most appropriate treatment. The patient has demonstrated no improvement in 48 hours; antibiotic escalation would be appropriate. It should be noted that on CSF examination, the absence of an organism on Gram staining does not equate to the absence of an organism! Only one-third of listeria meningitis patients are likely to grow an organism on Gram stain. In addition, listeria meningitis is a classic example of bacterial meningitis when a significant proportion of lymphocytes may be in CSF (>25%), instead of predominant neutrophilia. These include TB, rickettsial and cryptococcal meningitis. With no mention of previous or active TB exposure and no pulmonary symptoms on a relatively short history, TB meningitis is only a low-risk possibility. Intravenous amphotericin B would be appropriate for fungal meningitis only.

Question 17 of 277

Jenna is an 18-year-old woman who was initially admitted with a fever and disseminated rash. She had not been previously vaccinated and was in contact with her 2-year-old cousin who had developed a fever and disseminated blisters and vesicles containing clear fluid. She began to have a fever and flu-like symptoms 2 weeks after seeing her cousin. Similar clear-fluid filled vesicles and blisters developed 3 days later and she was admitted for further observation.

After 3 days, she noticed that while most of her skin lesions are healing, one of the lesions on the thigh appears to be red and becoming hot to touch. An area of skin approximately 3x3cm was erythematous. The skin was marked and she was commenced on IV flucloxacillin. Over the coming 12 hours, the erythema around this lesion continued to spread. The pain around her leg increased in intensity, requiring morphine to take the edge off the pain. A blueish discolouration begins to develop around the rash.

Given the likely complication that has developed, what is the likely organism that has caused the complication?

A. Enterococcus faecalis
B. Clostridium perfringens
C. Staphylococcus aureus
D. Streptococcus bovis
E. β- haemolytic Group A Streptococcus

E. β- haemolytic Group A Streptococcus

Chickenpox is a risk factor for invasive group A streptococcal soft tissue infections including necrotizing fasciitis

The development of fevers along with blisters and vesicles raises the suspicion that this is caused by chickenpox. Besides, this is more likely as she has been exposed to a child who has had similar symptoms. Chickenpox tends to be milder in children but can cause significant morbidity in adults.

The development of a rapidly evolving rash along with significant pains out of proportion to the rash seen should always raise alarm bells for necrotising fasciitis. Blueish discolouration of the skin is also suggestive of this. A surgical review should be sought immediately.

Invasive group A *Streptococcus*, a β-haemolytic *Streptococcus*, has been implicated as the cause for necrotizing fasciitis in patients with chickenpox. Extremely broad-spectrum antibiotics are initially used with the choices tailored to bacterial sensitivities when known.

Staphylococcus aureus can also result in necrotising fasciitis but is more commonly associated with patients who have other underlying medical conditions like diabetes.

Enterococcus faecalis does not tend to cause skin infections and are often associated with infections like endocarditis.

Streptococcus bovis is a gamma-haemolytic *Streptococcus* is most often associated with colorectal cancer associated endocarditis. It is not associated with skin infections.

Clostridium perfringens can cause necrotising fasciitis and presents as gas gangrene. This will present with crepitus under the skin which is not seen here.

Question 18 of 277

A 44-year-old vet presents with a fever to his GP. He has had the fever for 4 days and it seems to come and go. He also mentions that he has felt generally lethargic for the past week, with occasional lower back pain and aching limbs. On examination, he is tender in his sacral region and has an enlarged liver and spleen. Blood tests reveal the following:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	160 * 10 /L 9	(150 - 400)
WBC	3.8 * 10 /L 9	(4.0 - 11.0)
Bilirubin	7 µmol/L	(3 - 17)
ALP	50 u/L	(30 - 100)
ALT	23 u/L	(3 - 40)
Î³GT	10 u/L	(8 - 60)
Albumin	43 g/L	(35 - 50)

Which of the following pathogens is the most likely cause of this man's presentation?

A. Cryptosporidium
B. Brucella
C. Bartonella henselae
D. Echinococcus granulosis
E. Leptospira

B. Brucella

Unwell vet with fever, malaise, arthralgia and lower back pain ? Brucellosis

This man presents with features suggestive of brucellosis, including fluctuating fevers, malaise, arthralgia, sacroiliitis, hepatosplenomegaly and mild leukopenia. Brucellosis is a zoonosis: an infectious disease that jumps from a non-human animal to humans. It is caused by the gramnegative, rod-shaped *Brucella* species of bacteria. It is more common in the Middle East and in those that work with animals, such as this man. It is spread by aerosol and considered a bioterrorism agent. Rose Bengal plate test is used in suspected Brucellosis. One can remember this as B-Rose in B-Ruce-losis.

Cryptosporidiosis is a protozoal disease that typically affects the immunocompromised and causes diarrhoea.

Bartonella henselae is a bacteria that causes cat-scratch disease, another disease that is more common in vets. Although it may present with flu-like symptoms, it does not typically cause hepatosplenomegaly. There is typically a history of a bite or scratch from a cat, with a lesion developing over the area and painful lymphadenopathy. As a side note *Bartonella bacilliformis* can cause Oroya fever, which may present with hepatosplenomegaly and fever, but typically there is lymphadenopathy also, with marked haemolysis.

Echinococcus granulosis is a tapeworm that causes hydatid disease, another disease that is more common in vets. However, hydatid disease causes cysts that typically affect the liver or lungs, and is more likely to present with abdominal pain, jaundice, weight loss, and if affecting the lungs then a cough and shortness of breath.

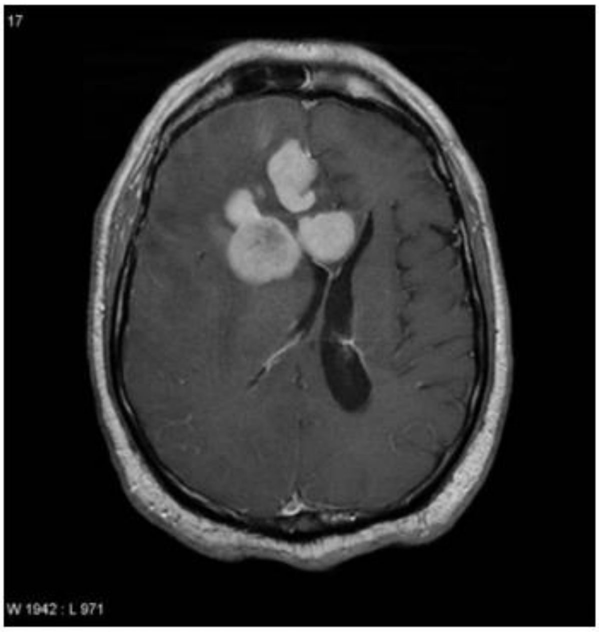
Leptospirosis is a possible diagnosis here, as it often presents in vets, and can present with flu-like illness and hepatosplenomegaly. The sacral tenderness, leukopenia and normal LFTs make this less likely. Leptospirosis will typically cause leukocytosis, anaemia, thrombocytopenia, even in the absence of DIC. Even when clinical manifestations are mild, hyperbilirubinemia is often present and mild elevations of serum transaminases are frequently seen. In exams, leptospirosis will normally present with bilateral conjunctival suffusion, which is conjunctivitis without exudate. However, in reality, this occurs in <60% of patients.

Question 19 of 277

A 45-year-old man is reviewed in the HIV clinic. He was diagnosed with HIV 25 years ago and has enjoyed good health on highly active antiretroviral treatment until around 4 years ago when he had an episode of *Pneumocystis jirovecii* pneumonia.

Today he is somewhat confused. His partner reports that he has been complaining of headaches for several weeks and has also been uncharacteristically aggressive.

His latest CD4 count is 29 cells/µl. An MRI (T1 C+) is requested:



What is the most appropriate treatment?

A. Sulfadiazine + pyrimethamine
B. Sulfadiazine + pyrimethamine + steroids
C. Steroids + methotrexate
D. Rifampicin + isoniazid + pyrazinamide + ethambutol + steroids

E. Amphotericin B

C. Steroids + methotrexate

HIV, neuro symptoms, single brain lesions with homogenous enhancement - CNS lymphoma

The MRI scan demonstrates a large multilobulated mass in the right frontal lobe. It homogeneously enhances and extends to involve the caudate and the periventricular area. There is also a significant mass effect. These findings in addition to the history are highly suggestive of primary CNS lymphoma. The most appropriate initial treatment is steroids (which should reduce tumour size and hence mass effect) and methotrexate. Other future options include whole brain irradiation and surgery.

You would not expect the enhancement to be homogenous with toxoplasmosis, it is usually in a ring pattern.

Question 20 of 277

A 34-year-old man presents to the emergency department with two weeks of fevers, malaise, myalgia, arthralgia and low back pain. He has no significant past medical history. He does not take any medications. He works as a veterinarian. There is no recent travel.

Observations:

- Heart rate 94 beats per minute
- Blood pressure 121/88 mmHg
- Respiratory rate 19/minute
- Oxygen saturation 96% on room air
- Temperature 38.2ºC

On examination, there is focal tenderness at the left sacroiliac joint. Cardiovascular, respiratory and abdominal examinations are unremarkable. He is diaphoretic and an associated foul smell is noted. There is no joint swelling.

Urinalysis is unremarkable.

Plain radiography of the chest is normal. Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	3.4 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	45 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	89 u/L	(30 - 100)
ALT	35 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

What is the likely diagnosis?

A. Brucellosis
B. HIV seroconversion
C. Leptospirosis
D. Q fever
E. Tuberculosis

A. Brucellosis

Unwell vet with fever, malaise, arthralgia and lower back pain ? Brucellosis

Brucellosis is the correct answer. The patient presents with fevers, malaise, arthralgia, myalgia and low back pain. The location of the back pain suggests sacroiliitis. Profuse sweating associated with a foul smell is typical of this condition. It is often said to be 'hay-like'. His work as a veterinarian is a relevant occupational exposure.

Leptospirosis is incorrect. This can cause a febrile illness with arthralgia and myalgia. However, it is typically associated with subconjunctival haemorrhages and headache and pulmonary haemorrhage and jaundice in severe cases. Foul-smelling sweat is not a typical feature.

Q fever is incorrect. While he works as a vet and this is a relevant occupational exposure, this condition is typically characterised by an atypical pneumonia, which is absent in this case. Sacroiliac involvement is not a feature.

Tuberculosis is incorrect. This can cause arthralgia, fevers and in rare cases can involve the sacroiliac joint. However, the occupational exposure and foul-smelling sweat making brucellosis the more likely diagnosis, especially in the absence of a relevant travel history.

HIV seroconversion is incorrect. While this can cause a febrile illness, myalgia, arthralgia and a low white blood cell count. However, the relevant occupational exposure, sacroiliac joint involvement and foul-smelling sweat make a diagnosis of brucellosis more likely.

Question 21 of 277

A 32-year-old man has been brought to the hospital with severe shortness of breath.

Initial observations with the paramedics were taken. These included a respiratory rate of 32/min, oxygen saturations of 72% on room air, a pulse of 120/min, a blood pressure of 123/72mmHg, and a temperature of 38.3ºC.

On examination in the emergency department, he is sat on the bed leaning forwards. There is evidence of drooling and a vomit bowl full of saliva is next to him. There is audible stridor from the edge of the bed. Oxygen has now been applied and saturations are 90% on 15L.

A neck x-ray was performed due to concerns for a foreign body and has shown a 'thumb sign'.

What is the most appropriate next step in management?

A. Continuous positive airway pressure (CPAP)
B. Endotracheal intubation
C. High flow oxygen
D. Intramuscular adrenaline
E. Nebulised adrenaline

B. Endotracheal intubation

Endotracheal intubation may be necessary to protect the airway in acute epiglottitis

The above scenario describes a severe case of acute epiglottitis. Patients approaching extremis tend to lean forwards to aid their breathing and may have pooling of saliva due to an inability to swallow. The 'thumb sign' on the neck x-ray is indicative of an oedematous epiglottitis. Given the significant desaturation in oxygen along with audible stridor, the most appropriate intervention would be endotracheal intubation.

Given the degree of obstruction in this case, urgent anaesthetic input should be sourced due to the high likelihood that this patient will require intubation. This should not be delayed to trial CPAP. It is also possible that CPAP will lead to the displacement of the epiglottis and worsen the obstruction.

High flow oxygen can be used in patients that have low oxygen saturation who are otherwise stable. This would not be appropriate in the above scenario given the stridor and a need to urgently secure the airway.

Intramuscular adrenaline would be beneficial if this was stridor associated with anaphylaxis, however, there is no evidence of this from the scenario.

Nebulised adrenaline can be used in croup but is not a part of management in epiglottitis.

Question 22 of 277

A 25-year-old woman is started on antiretroviral therapy for HIV. She attends the GP 1 week later complaining of dizziness and nightmares. She is unable to work due to feeling muddled and disconnected.

Which drug is responsible?

A. Abacavir
B. Efaverinz
C. Lamivudine
D. Tenofovir
E. Zidovudine

B. Efaverinz

Efaverinz is a non-nucleoside reverse transcriptase inhibitor (NNRTI) and is frequently known to cause disturbing dreams and other cognitive disturbances in 50% of patients in the first month of treatment.

The most concerning side effect of Abacavir is a hypersensitivity reaction that can lead to fever, malaise, nausea and skin rash which can be very severe. It is strongly associated with a specific allele at the human leukocyte antigen B locus, HLA-B*57:01.

Lamivudine and Zidovudine are nucleoside analogue reverse transcriptase inhibitors (NRTIs). The NRTIs were the first class of antiretroviral drugs developed. As with all drugs in their class, they can cause a potentially fatal lactic acidosis & severe hepatomegaly with steatosis when used alone or in combination with other antiretrovirals.

Tenofovir is a nucleotide analogue reverse transcriptase inhibitors (NtRTI), it is a prodrug, the commonest side effects are gastrointestinal.

Question 23 of 277

A 57-year-old male with chronic hepatitis B infection presents to the Emergency Department with increasing confusion. His wife states that his specialist has not started him on antivirals yet. He was diagnosed six months ago. His past medical history includes tuberculosis that has been successfully treated 10 years ago.

His wife stated also that he slept more than usual in the last week and he was more lethargic. On examination the patient was confused, disoriented with a yellowish discoloration of his eyes. There is moderate peripheral oedema and moderate ascites with no signs of hepatomegaly.

Blood investigations were as follows:

Hb	102 g/l
Platelets	250 * 10 /l9
WBC	9.5 * 10 /l9
Bilirubin	42 µmol/l
ALP	135 u/l
ALT	370 u/l
γGT	70 u/l
Albumin	32 g/l
α-fetoprotein	15 kU/l

What is the most likely cause of this presentation?

A. Portal vein thrombosis
B. Budd-Chiari syndrome
C. Hepatitis D infection
D. Hepatocellular carcinoma
E. Normal progression of the disease

C. Hepatitis D infection

This patient has developed acute liver decompensation. Hepatitis D infection is an uncommon but important cause of this presentation. It typically occurs in a patient with a history of stable chronic hepatitis B infection that suddenly acutely deteriorates.

Budd-Chiari syndrome (BCS) and portal vein thrombosis are not the correct options because it is unlikely to have any of them in the absence of hepatomegaly. In addition, the high level of the transaminase enzyme suggests viral infection rather than thrombus formation. Note that the transaminase enzyme should be only mildly elevated in BCS. Fever and nausea are also important symptoms that are usually present in BCS.

Hepatocellular carcinoma usually presents with very high levels of alpha-fetoprotein.

Question 24 of 277

A 32-year-old woman attends the infectious diseases clinic for an urgent review. The patient had presented to the emergency department the previous weekend complaining of various constitutional symptoms. A set of blood cultures had been taken as the patient was febrile at presentation. Assessment in the emergency department had not identified a clear cause for the patient's illness and she had been discharged home with advice to attend her GP surgery if her symptoms did not resolve in the coming days. The patient had been recalled to hospital for review after the blood cultures taken during her presentation yielded a positive result. Selected investigation results from the patient's emergency department attendance are given below.

At her review appointment, the patient recounted her recent symptoms. She described a 3-week history of intermittent fever, malaise and reduced appetite. On direct questioning, she did recall experiencing excessive overnight sweating on a few occasions but had not experienced joint pains. The patient denied other symptoms, including those associated with the respiratory, urinary tract and neurological systems.

The patient was otherwise healthy, with no significant past medical history. She took no regular medications and had no known medication allergies. The patient was a chartered accountant and lived with her husband and 5-year-old daughter. The patient had returned from a holiday in Turkey 4 weeks previously. During her holiday she had visited relatives in a rural village and recalled consuming local dairy products that she suspected had not been pasteurised.

On general examination, the patient appeared to be tired and pale. Examination of the patient's abdomen revealed palpable hepatomegaly and splenomegaly. Examinations of the respiratory, cardiovascular, neurological and musculoskeletal systems were unremarkable. Selected investigation results from the patient's emergency department attendance are given below.

Haemoglobin	117 g / dL
White cell count	3.9 x 10>3 / microlitre
Neutrophils	2.1 x 10>3 / microlitre (reference 1.8-7.8)
eGFR	> 90 ml / min / 1.73 m2
Alkaline phosphatase	134 U / L (reference 35-100)
ALT	57 U / L (reference 3-36)
Bilirubin	24 micromol / L (reference < 26)
C-reactive protein	68 mg / L (reference < 7)
Urine dipstick	No abnormality detected
Blood cultures	Small gram-positive coccobacilli; consistent with *Brucella* species
Chest x-ray	Clear lung fields; no evidence of consolidation or effusion

The likely diagnosis of Brucellosis was discussed with the patient. She expressed a very strong preference to receive treatment on an outpatient basis so that she would not be separated from her family.

What is the appropriate treatment regime?

A. Doxycycline monotherapy for 2 weeks
B. Proguanil with atovaquone for 3 days
C. Clarithromycin and amoxicillin for 1 week
D. Isoniazid, rifampicin, pyrazinamide and ethambutol for 8 weeks
E. Doxycycline and rifampicin for 6 weeks

E. Doxycycline and rifampicin for 6 weeks

Brucellosis is the most common bacterial disease contracted from contact with animals, most commonly sheep and goats. Infection can be acquired from consumption of unprocessed animal products in endemic countries of the Mediterranean and middle East such as Syria, Iraq, Turkey, Greece and Tunisia. Brucellosis can also be acquired by occupational exposure of laboratory workers or individuals with close contact with animals.

Brucellosis presents with non-specific symptoms and signs and so cases can go undiagnosed for several months. In addition to the typical symptoms and signs experienced by the patient in the question, brucellosis can also cause migratory arthritis, lymphadenopathy and malodorous perspiration. Rare complications include pneumonia, pulmonary effusion, peripheral neuropathy, meningoencephalitis and endocarditis. Positive blood cultures provide the most definitive diagnosis of brucellosis, although various serological tests are also available. Microbiological diagnosis is also possible from the culture of samples obtained from infected organs (for example, synovial fluid or cerebrospinal fluid). Brucellosis also causes non-specific abnormalities of routine blood tests as in the case of the patient in this question.

Oral treatment of brucellosis is possible with a 6-week course of doxycycline and rifampicin. An alternative treatment regime combines 6 weeks of oral doxycycline with 3 weeks of either intramuscular streptomycin or intravenous gentamicin. Treatment involving parenteral antibiotics has a lower failure rate but is less convenient for the patient.

The other possible answers are antimicrobial treatment regimes for *Helicobacter pylori*, tuberculosis, Lyme disease and malaria.

Question 25 of 277

A 35-year-old man is reviewed in respiratory clinic with symptoms of a chronic cough with occasional haemoptysis, night sweats and significant unintentional weight loss. The patient is originally from the Russian Federation and on direct questioning through an interpreter discloses that he had spent five years in a Moscow prison for drugs offences. Aside from a period of alcohol abuse in his early twenties, the patient denies any other medical history and takes no medications. He currently is living in shared accommodation and works on a building site, although he is struggling to continue to work due to his current illness.

General inspection showed the patient to be cachexic with tobacco stained fingernails. Auscultation of the chest revealed some reduced air entry in the upper zones bilaterally. There was palpable lymphadenopathy in the anterior cervical chain.

Please see results of investigations below.

Chest x-ray: patchy shadowing in both upper lobes with evidence of cavity formation on the right side; no pneumothorax; normal mediastinal shadow.

Sputum microscopy: acid fast bacilli

Phenotypic indirect drug susceptibility testing: rifampicin (resistant); ofloxacin (sensitive); moxifloxacin (sensitive); isoniazid (resistant); amikacin (sensitive); capreomycin (sensitive).

What is the most appropriate treatment regime for this patient?

A. Combination therapy with 5 drugs for 24-36 months
B. Combination therapy with 5 drugs for 18-24 months
C. Combination therapy with 4 drugs for 24-36 months
D. Combination therapy with 4 drugs for 12 months
E. Combination therapy with 4 drugs for 18-24 months

B. Combination therapy with 5 drugs for 18-24 months

The patient presents with a typical history for active pulmonary tuberculosis. His history of incarceration in a prison in the Russian Federation makes him at high risk of having contracted a multi-drug resistant strain of TB. Microbiology results confirm resistance to rifampicin and isoniazid consistent with multi-drug resistance, however without resistance to any fluoroquinolone or second line injectable agents that would suggest extensively drug resistant TB.

Recommended treatment for multi-drug resistant TB requires 18-24 months of at least 5 drugs. Depending on the microbiological testing services available, the regime may be individualised to an individual patients infection or based on a standardised regime based on local resistance patterns.

Question 26 of 277

A 72-year-old man presents to the tuberculosis clinic.

He has a 6-month history of lower back pain that has been gradually getting worse. He has tried taking analgesia, but this is now no longer helping the pain and he is becoming less able to mobilise.

He lives with his wife on their farm. He has been fully independent until his recent deterioration in mobility.

Past medical history includes hypertension, diet-controlled type 2 diabetes mellitus and benign prostatic hypertrophy.

He reports that he had tuberculosis when he was 24, but this was treated. He can't remember what he was treated with.

An MRI spine shows a lumbar 4/5 discitis and a biopsy of this tissue is arranged. Acid-fast bacilli are grown on culture of the biopsy.

What treatment regime should be started?

A. 2 months of isoniazid, rifampicin, pyrazinamide and ethambutol with a further 4 months of isoniazid and rifampicin
B. 6 months of isoniazid, rifampicin, pyrazinamide and ethambutol with a further 6 months ofisoniazid and rifampicin
C. 6 months of isoniazid, rifampicin, pyrazinamide and ethambutol
D. 2 months of isoniazid, rifampicin, pyrazinamide and ethambutol with a further 7 months ofisoniazid and rifampicin
E. 3 months of isoniazid, rifampicin, pyrazinamide and ethambutol with a further 6 months ofisoniazid and rifampicin

A. 2 months of isoniazid, rifampicin, pyrazinamide and ethambutol with a further 4 months of isoniazid and rifampicin

Treatment for bone and joint tuberculosis is recommended to continue for 2 months with the initial phase consisting of quadruple therapy and the remaining 4 months of dual therapy.

It is recommended not to extend treatment for residual complications such as collapsed discs or bending of the spine, although there is some debate about this.

Immune reconstitution disease occurs typically 3-6 weeks after starting treatment often presents with enlarging lymph nodes

Question 27 of 277

A 45 year old man is diagnosed with HIV following attendance at Genitourinary clinic. As part of his routine HIV work up his HLA B*5701 result is reported as positive.

Which drug will not be included in his ART regimen as a result of this information?

A. Tenofovir

B. Emtricitabine

C. Lamivudine

D. Stavudine

E. Abacavir

E. Abacavir

Abacavir can cause a severe and sometimes fatal hypersensitivity reaction. It is a cell mediated delayed hypersensitivity reaction which occurs around 6 weeks after starting treatment. Symptoms are of fever, rash, malaise and gastrointestinal symptoms.

Patients without HLA B*5701 are highly unlikely to develop hypersensitivity. Those with the HLA B*5701 allele have a 50% risk and therefore in these individuals abacavir should be avoided.

It is therefore routine to test HLA B*5701 status on all newly diagnosed patients with HIV.

Question 28 of 277

A 54 year old Caucasian man with HIV, is stable on Tenofovir, Emtricitabine and Kaltera (Lopinavir/Ritonavir). He has a 60 pack year smoking history and has been told his blood pressure is high previously but had never previously been to see his GP about it to get it treated. His GP is unaware of his HIV diagnosis and his main point of healthcare contact is with the Genito-urinary medicine services.

However over the last two years he has been troubled by gradually worsening cough, and shortness of breath. He has not lost weight. This has spurred him to start seeing his GP. He says that his GP initially gave him a blue inhaler and did some tests and told him he had COPD. Six weeks ago his GP gave him a Seretide 500 inhaler (one puff twice a day) and started him on Rampril (2.5mg daily) for his high blood pressure. The purple inhaler had provided some relief to his breathlessness but four days ago it ran out and he hasnt yet been back to see his GP. He still has two weeks worth of Ramipril tablets.

For the last few days he has been feeling faint and dizzy especially when standing up. His breathlessness and cough are no worse than usual. He has no fever. On examination his blood pressure is 91/76 his pulse is 94. He is afebrile, his respiratory rate is 24 and his oxygen saturations are 92% on room air. He has a mild wheeze on auscultation of his chest. His heart sounds are faint and his JVP is visible 3cm above his sternal angle. There is no pitting odema. There is nothing else of note on examination.

An ECG on admission is normal.

Hb	14.0 g/dl
Platelets	199 * 10 /l9
WBC	6.2 * 10 /l9
Na +	130 mmol/l
K +	5.9 mmol/l
Urea	5.6 mmol/l
Creatinine	85 µmol/l
CRP	7 mg/l

What is the diagnosis?

A. Adrenal tuberculosis
B. Pericardial tuberculosis
C. Adrenal insufficiency secondary to inhaled corticosteroid withdrawal
D. Ramipril induced hypotension
E. WaterhouseFriderichsen syndrome

C. Adrenal insufficiency secondary to inhaled corticosteroid withdrawal

A very difficult question. The timing of events is key.

Fluticasone in Seretide is metabolised by P450 and Ritonvir inhibits this allowing very high levels of systemic steroid with consequent adrenal insufficiency. Cessation of Seretide has caused this Addisonian event (low sodium, high potassium is the clue).

Disseminated TB would be unusual with no fever or weight loss but is an important differential, especially in the context of HIV infection. All of his findings on examination are consistent with COPD.

Waterhouse-Friderichsen syndrome is bilateral adrenal haemorrhage in the context of meningococcal septicaemia.

Question 29 of 277

You see Mr Smith, a 35-year-old man-who-has-sex-with-men (MSM) in clinic. He was diagnosed with HIV 5 years ago, commencing combination antiretroviral therapy (cART). Following a number of alterations to his cART due to side effects he responded well to a combination of tenofovir, emtricitabine and ritonavir boosted atazanavir. His plasma viral load (pVL) of HIV RNA has remained undetectable and his adherence has been good.

In clinic today Mr Smith reports 5 weeks of drenching night sweats, a dry cough and some subjective weight loss, going up a belt buckle during this time period. On examination you note that he appears pale and auscultation of the chest elicits crepitations in the left upper zone. Your perform a chest X-ray which demonstrates a cavitating lesion in the left upper lobe. You arrange induced sputum samples which confirm a diagnosis of pulmonary tuberculosis.

You explain your diagnosis to Mr Smith and the need to urgently commence him on antituberculosis chemotherapy. Whilst he is happy to commence treatment, he is adamant that he does not want to risk his viral control and states that he is not willing to consider altering his cART regime at present.

What is the most appropriate management step to treat Mr Smith?

A. Hold his ART
B. Commence rifabutin, isoniazid, ethambutol and pyrazinamide
C. Commence isoniazid monotherapy
D. Switch protease inhibitor to an novel ARV agent
E. Commence rifampicin, isoniazid, pyrazinamide and ethambutol

B. Commence rifabutin, isoniazid, ethambutol and pyrazinamide

The correct answer for this scenario is to commence rifabutin, isoniazid, ethambutol and pyrazinamide.

This scenario tests your knowledge of rifamycins in the treatment of tuberculosis. Rifamycin containing anti-tuberculosis chemotherapy regimes are superior to those which do not contain a rifamycin agent. However, in this scenario the patient is also taking taking a protease inhibitor as part of their antiretroviral therapy.

Rifampicin, the common rifamycin agent in anti-tuberculosis regimes, is a potent inducer of liver enzymes, such as cytochrome P450. Furthermore, it up-regulates the expression of P-glycoprotein in the gastrointestinal tract. This leads to reduced absorption and increased metabolism of certain medications, protease inhibitors being one of these (ritonavir booster atazanavir). Coadministration of a protease inhibitor with rifampicin therefore will often lead to subtherapeutic levels of the protease inhibitor.

In this scenario, the patient is stable on his current antiretroviral treatment and not keen to switch at present. Therefore, the British HIV Association (BHIVA) suggest the substitution of rifampicin for an alternative rifamycin agent (rifabutin or rifapentine), which has less inducing action of cytochrome P450 and therefore allows the patient to continue their current HIV treatment regime. Regimes containing rifabutin (dose 150mg three times a week) have been shown to have equivocal in outcomes of treatment in the few small observational studies performed in patients with HIV/TB co-infection.

Question 30 of 277

A 28-year-old man attends clinic for his 6 monthly HIV check. He was diagnosed with HIV 4 years ago and has been stable on Eviplera (emtricitabine/rilpivirine/tenofovir). He was recently started on a new medication by his GP.

Blood results are as follows:

Hb	134 g/l	Na +	136 mmol/l
Platelets	345 * 10 /l 9	K +	4.2 mmol/l
CD4	580 * 10 /l (normal range 500-1500) 9	Urea	6.5 mmol/l
Viral load	1480 copies/ml* 10 /l 9	Creatinine	65 µmol/l

What new medication was started which would explain these results?

A. Omeprazole
B. Ciclosporin
C. Tacrolimus
D. Celecoxib
E. Diclofenac

A. Omeprazole

PPIs are contraindicated in patients on Eviplera (emtricitabine/rilpivirine/tenofovir). They reduce the absorption of rilpivirine which can cause viral blips, with subsequent virological failure and resistance

Concurrent use of tenofovir with ciclosporin, tacrolimus, celecoxib or diclofenac, can increase the risk of nephrotoxicity.

Proton pump inhibitors are absolutely contraindicated in patients on Eviplera (emtricitabine/rilpivirine/tenofovir). They reduce the absorption of rilpivirine which can cause viral blips, with subsequent viro00 logical failure and resistance.

Question 31 of 277

A 23-year-old medical student attends the emergency department after accidentally cutting herself in the kitchen, with significant blood loss. In addition to first aid for the wound, routine blood tests are checked. Results are as follows:

Hb	145 g/L	Male: (135-180)Female: (115 - 160)
Platelets	235 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Eosinophils	0.91 * 10 /L 9	(0.0-0.4)

Follow-up is organised in the infectious diseases clinic. The patient has recently returned from her elective in Malawi, where she spent 6 weeks with 2 friends. She reports taking all recommended vaccines before travel. Malaria prophylaxis was taken as advised and she completed the course. She denies swimming in any water but did frequently walk barefoot around the banks of the lake. She recalls one episode where her foot became itchy and developed a serpiginous rash, advancing up the foot over several hours before resolving. She did not seek medical help.

What treatment is recommended first-line for this condition?

A. Artemisinin combination therapy
B. Ivermectin
C. Melarsoprol
D. Nifurtimox/eflornithine combination therapy
E. Praziquantel

B. Ivermectin

Ivermectin is the drug of choice for treatment of strongyloidiasis

The correct answer is **ivermectin**. This patient is likely to have developed strongyloidiasis, a parasitic infection caused by the nematode Strongyloides stercoralis. This is a widely-distributed helminth but the majority of cases are seen in sub-Saharan Africa and South America. Infection is frequently asymptomatic and the first clue is peripheral eosinophilia. In this case, the episode described in Malawi is consistent with larva currens, a rash that develops when the worm penetrates the skin before entering the bloodstream. From here they spread through the lungs, over the epiglottis, are swallowed, and settle in the small intestine, where they lay their eggs. Respiratory symptoms are rare but cough and wheeze may develop during pulmonary migration. In chronic infection, abdominal pain and diarrhoea may occur. In the context of immunocompromise, Strongyloides hyperinfection syndrome can occur, presenting with bloody colitis and pneumonitis, often with pleural effusions. The treatment of choice in all cases is ivermectin, although albendazole and thiabendazole are alternatives.

Artemisinin combination therapy is incorrect. This is the treatment of choice for most cases of uncomplicated malaria. Malaria does not tend to cause eosinophilia or skin lesions, and she has been compliant with prophylaxis. These factors suggest this is very unlikely to be the diagnosis.

Melarsoprol is incorrect. This is an arsenic-based treatment option for East African sleeping sickness, caused by Trypanosoma brucei rhodesiense. This is a rapidly progressive form of sleeping sickness, initially causing an influenza-like illness with arthralgia and lymphadenopathy but quickly progressing to altered mental status and death. Melarsoprol is associated with significant toxicity and would not be used for strongyloidiasis.

Nifurtimox/eflornithine combination therapy is incorrect. This is a treatment option for West African sleeping sickness, caused by the protozoan parasite Trypanosoma brucei gambiense. This causes a slowly progressive illness characterised by behavioural change, alterations to the sleepwake cycle, and finally coma. There are no symptoms here to suggest this and it is not typically associated with eosinophilia.

Praziquantel is incorrect. This is the treatment of choice for schistosomiasis, a tapeworm infection caused by a variety of species of schistosomes. The organism uses freshwater snails as an intermediate host before being released into the water, where it penetrates human skin and settles in the gastrointestinal or genito-urinary tract depending on the species. There may be an itchy rash at the time of infection, known as cercarial dermatitis, but this would not move up the limb or be described as serpiginous. Schistosomiasis often presents with eosinophilia, but in this case, the patient has been careful to avoid going in the water, making this unlikely to be the cause.

Question 32 of 277

A 53-year-old lady has been admitted under isolation to a tertiary infectious diseases centre in London. She has recently arrived back to the United Kingdom following 2 years of ecological work in lowland Nepal and has presented with 4 weeks of worsening malaise, fevers, night sweats, pallor and abdominal pain. She had lived during her time in Nepal in a small village where she reported numerous fly bites during the evening hours. She reports taking her malaria prophylaxis consistently.

Examination shows her to look pale, unwell and her skin appears to have an unnatural grey tinge. No rash nor joint swelling was noted. She has a temperature of 37.9ºC, oxygen saturation 97% on air, heart rate 84 beats per minute, respiratory rate 23 breaths per minute and blood pressure 128/75 mmHg. Auscultation of the chest reveals bilateral vesicular breath sounds and her heart sounds are normal with no murmurs. Abdominal examination reveals a soft abdomen with tenderness in the upper quadrants. Her liver edge is palpable 5cm below the right costal margin and an additional mass is palpable in the umbilical area which moves with ventilation.

Investigation results are as follows:

Hb	102 g/L	Female: (115 - 160)
Platelets	$134 * 10^9/L$	(150 - 400)
WBC	$3.6 * 10^9/L$	(4.0 - 11.0)
Na^+	144 mmol/L	(135 - 145)
K^+	3.7 mmol/L	(3.5 - 5.0)
Urea	6.3 mmol/L	(2.0 - 7.0)
Creatinine	105 µmol/L	(55 - 120)
CRP	73 mg/L	(< 5)
Thick blood film	No evidence of malaria parasites	
HIV 1 and 2 surface antigen/antibodies	Negative	
Hepatitis A, B, C, D and E	Negative	
Chest X-ray	No focal consolidation, masses or collapse	
quantiFERON testing	Negative	

Which of the following investigation would be the gold standard to confirm the most likely diagnosis?

A. Direct agglutination test (DAT)
B. Lumbar puncture and CSF analysis
C. Stool sample analysis
D. Blood cultures
E. Splenic aspirate

E. Splenic aspirate

Leishmaniasis is spread through sand-fly vectors from animal reservoirs and remains endemic through areas of Africa, Asia, South America and the Middle East. Visceral leishmaniasis can cause hepatosplenomegaly, spiking fevers, pancytopenia and with certain strains blackening of the skin leading to the alternative name of black fever (kala-azar). The gold standard for diagnosis would be the demonstration of amastigotes on splenic or bone marrow aspirates.

Serological testing, such as DAT, is useful in the diagnosis of leishmaniasis but it is not the gold standard due to lack of evidence demonstrating consistently higher sensitivities and specificities along with a regional variation of the parasites complicating this. They are however highly useful in endemic areas where it is a cheaper, less technically challenging and occasionally a readily available alternative.

Lumbar puncture and CSF analysis are not useful investigations in the diagnosis of leishmaniasis unless an alternative or additional pathology is suspected.

A stool sample is of no use in the diagnosis of leishmaniasis which is a vector born disease transmitted through sandfly bites.

Blood cultures can be useful in demonstrating blood-born parasites in immunocompetent hosts with sensitivity rates up to 60%. This, however, remains below that of the current gold standard.

Question 33 of 277

A 45-year-old homeless gentleman presents with a two-month history of a cough, occasional haemoptysis and weight loss. His chest X-ray shows right upper lobe consolidation. A diagnosis of tuberculosis is confirmed by microscopy and he is started empirically on rifampicin, isoniazid, pyrazinamide and ethambutol, with pyridoxine supplements. Eight weeks later, culture results show that the Mycobacterium tuberculosis is resistant to isoniazid.

What should his further treatment regime be?

A. Four months of rifampicin, isoniazid, pyrazinamide and ethambutol, with pyridoxine supplements
B. Six months of rifampicin
C. Four months of rifampicin and ethambutol, with pyridoxine supplements
D. Four months of rifampicin and ethambutol
E. Add a quinolone and aminoglycoside

D. Four months of rifampicin and ethambutol

In confirmed isoniazid resistance, ethambutol is continued for 6 months of treatment

In fully sensitive Mycobacterium tuberculosis infection, after two months, the pyrazinamide and ethambutol are stopped and rifampicin and isoniazid (with pyridoxine support) are continued for a further four months. However, in cases of confirmed isoniazid resistance, rifampicin and ethambutol are continued for the further 4 months of treatment, with discontinuation of the isoniazid (and supportive pyridoxine) and pyrazinamide.

This is not multi-drug resistant tuberculosis (does not respond to at least isoniazid and rifampicin), so it is not appropriate to add a quinolone or aminoglycoside.

Question 34 of 277

A 22 year old male attends the Genitourinary Medicine clinic which you are working in. He was contacted and asked to attend having been in direct, recent sexual contact with gonorrhoea. He is asymptomatic.

What is the best course of action?

A. No action required as he is asymptomatic
B. Treat with ceftriaxone, perform a sexual health screen and call back for a test of cure ifpositive
C. Give ceftriaxone and azithromycin, no need for a screen
D. Perform a screen and call back to treat if positive
E. Give ceftriaxone, perform a screen, and call back to give azithromycin if positive

B. Treat with ceftriaxone, perform a sexual health screen and call back for a test of cure ifpositive

The British Association of Sexual Health and HIV have clear guidelines on the investigation and management of gonorrhoea.

Recent sexual contact with person in whom gonococcal infection has been confirmed is an indication for treatment.

Treatment of uncomplicated gonorrhoea infection consists of ceftriaxone intramuscularly as a single dose. Due to increased resistance to a range of antimicrobials in recent years follow up 'test of cure' is recommended in all confirmed cases.

Question 35 of 277

A 31 year-old accountant was referred to the general medical clinic with persistent nasal stuffiness and intermittent epistaxis. He had been seen by the ear, nose and throat team who had commenced him on a course of intranasal steroids without benefit. His past medical history was unremarkable. His travel history included a gap year in South America 10 years previously. He was a non-smoker and drank 23 units of alcohol per week.

On examination, his temperature was 36.2ºC, heart rate 68 beats per minute, respiratory rate 16 breaths per minute, blood pressure 126/82 mmHg. There was some superficial ulceration of the nasal mucosa bilaterally. The chest was clear on auscultation and heart sounds were normal.

Investigations:

Haemoglobin	145 g/L
White cell count	7.0 * 10 /l9
Neutrophil count	4.0 * 10 /l9
Lymphocyte count	3.0 * 10 /l9
Eosinophil count	0.4 * 10 /l9
Platelets	300 * 10 /l9
Sodium	144 mmol/L
Potassium	4.1 mmol/L
Urea	6.1 mmol/L
Creatinine	71 mol/L
Alkaline phosphatase	56 IU/L
Alanine aminotransferase	35 IU/L
Gamma-glutyl transferase	21 IU/L
Bilirubin	13 mol/L
Albumin	39 g/L
Fasting plasma glucose	5.3 mmol/L

What is the most likely causative organism?

A. Trypanosoma cruzi
B. Plasmodium ovale
C. Leishmania braziliensis
D. Leishmania donovani
E. Chlamydia trachomatis

C. Leishmania braziliensis

The most likely diagnosis in this case is mucosal leishmaniasis. The patient probably became infected with cutaneous leishmaniasis during his visit to South America, and received no/incomplete treatment. Mucosal leishmaniasis can occur years to decades after initial infection; typical features include nasal stuffiness and epistaxis in the early stages, progressing to ulceration and destruction of the nasal mucosa. Leishmania donovani is a recognised cause of visceral rather than mucocutaneous leishmaniasis.

Question 36 of 277

A 30-year-old male with HIV and a viral load of 10^6 and CD4 dropping from 500 to 300 cells/µl since his last visit. The above mentioned results are taken while he is on his third line of therapy.

What is the most likely cause of his repeated treatment failures?

A. Non-compliance
B. Infection with multi-resistant HIV strain
C. Co-infection with a new HIV strain
D. Superinfection with a new HIV strain
E. CYP interactions

A. Non-compliance

By far the most common cause of treatment failure in HIV therapy is treatment non-compliance.

Re-infection with new HIV strain can occur via co-infection or superinfection. Co-infection is defined as infection with 2 strains either simultaneously or within a brief period of time before infection with the first strain has an established immune response. Arbitrarily, HIV coinfection would occur within the first month or so of infection. Superinfection is defined as infection with a second strain after the initial infection and the immune response to it has been established.

Question 37 of 277

A 23-year-old man presents to the emergency department with a fever and a rash having recently returned back from a back-packing trip in rural Thailand where he had been trekking. He complains of general malaise for the last few days, a frontal headache and a rash he has noticed from last night. On examination he had tender cervical lymphadenopathy and a maculopapular rash over his trunk. There was also a small painless erythematous lesion on his lower calf with a necrotic centre.

Hb	95 g/l
Platelets	60 * 10 /l9
WBC	2.5 * 10 /l9

What is the most likely diagnosis?

A. Malaria
B. Dengue fever
C. Scrub typhus
D. Leptospirosis
E. HIV conversion illness

C. Scrub typhus

The eschar makes scrub typhus the most likely diagnosis. Malaria is of course common in this region and one would expect similar laboratory results, however the rash makes this diagnosis very unlikely. Dengue fever presents with a rash and fever, but also with associated arthropathy, classically lower back pain.

Question 38 of 277

A 40-year-old-year presents to the outpatient department with three separate lesions on his hands. He reports the skin lesions developed over several months and does not remember an initial trigger or injury resulting in the nodular-like ulcers.

The patient reports he has just arrived from rural Tanzania where he has lived most of his life. He is HIV positive on treatment but has not attended any recent clinic appointments. He reports he has no other medical conditions and is not on any other medications.

Fine needle aspiration of the lesions shows the presence of protozoa particles. A picture of one of the patient's lesions is shown below.

What is the most likely cause of the patient's skin lesion?

A. African trypanosomiasis
B. Chromoblastomycosis
C. Kaposi's sarcoma
D. Leishmaniasis
E. Leprosy

D. Leishmaniasis

Leishmaniasis is caused by the protozoa parasite *Leishmania tropica* or *Leishmania mexicana* which are transmitted via sandfly mainly in the tropics and sub-tropics of Africa, Asia and the Americas. Cutaneous leishmaniasis is the commonest form of leishmaniasis, which presents an open sore at the bite sites. The lesions can develop over several months or even years leaving unpleasantlooking scars.

African trypanosomiasis is caused by the protozoa parasite *Trypanosoma bruce* which is transmitted via tsetse flies. The condition causes systemic symptoms in the form initially of fevers, headaches and joint pain, before progressing to cognitive impairment. Cutaneous lesions are not commonly associated with the condition.

Chromoblastomycosis is normally found in rural region of tropical and subtropical climates however it is a chronic fungal infection of the skin. It can be caused by a number of different fungi that are implanted under the skin, often by thorns or splinters. Analysis of skin scraping would confirm the presence of muriform cells, indicative of the fungal infection.

Kaposi's sarcoma (KS) is a type of cancer that can form nodular, blotchy-like lesions red, purple, brown, or black in colour on the skin of the lower limbs, back, face and genitals, as well as mouth and organs lesions. KS is a result of immune suppression and infection by human herpesvirus 8; it is an aids defining condition and therefore is normally seen in untreated HIV. Diagnosis is via confirming the presents of human herpesvirus 8.

Leprosy is caused by the slow-growing, acid-fast bacillus, *Mycobacterium leprae* and is transmitted by humans via respiratory droplets. Diagnosis is confirmed via a skin smear from a lesion that is stained for mycobacteria.

Question 39 of 277

An elderly gentleman presents with a three day history of bloody diarrhoea and feverishness. He has no significant travel history. His past medical history is listed as hypertension, osteoarthritis and gout. On examination his temperature is 38.0ºC, heart rate 95/min, blood pressure 120/80 mmHg and his abdomen is soft and non-tender. A stool sample has grown *Salmonella*.

What is the best treatment?

A. Metronidazole
B. Doxycycline
C. Clarithromycin
D. Ciprofloxacin
E. Amoxicillin

D. Ciprofloxacin

The BNF recommends treating invasive diarrhoea (causing bloody diarrhoea and fever) with ciprofloxacin. Most viral or bacterial gastroenteritis do not require treatment. The BNF recommends antibiotics for bacterial gastroenteritis in severe infections or in immunocompromised patients. Clarithromycin is used for traveller's diarrhoea and non-invasive diarrhoeal illnesses when treatment is necessary.

Question 40 of 277

A 40-year-old gentleman was admitted with fever, dry cough, headache, abdominal pain and diarrhoea. Around ten days previously he had been complaining of intermittent fevers and night sweats but otherwise felt well. In the last 3 days, he had developed generalised abdominal pain and watery diarrhoea, along with a dry cough and headache. Prior to this he had felt constipated only having opened his bowels once in three days which he thought was unusual as he had eaten a large amount of fruit off the market stools in South Korea where he had recently been on a business trip.

On examination, he was notably jaundiced, had a macular rash over his chest and had tender hepatomegaly. Observations revealed a temperature of 40.1ºC, heart rate 38/min, regular and a blood pressure of 130/90 mmHg. ECG showed a sinus bradycardia.

Blood tests revealed:

WBC	14.0 * 10 /l9
Neutrophils	12.0 * 10 /l9
CRP	230 mg/l
Bilirubin	52 µmol/l
ALP	80 u/l
ALT	200 u/l
Albumin	32 g/l

What investigation would you do to obtain the diagnosis?

A. Blood cultures
B. Abdominal ultrasound
C. HIV test
D. Lumbar puncture
E. ECG

A. Blood cultures

Typhoid or enteric fever is the commonest serious tropical disease requiring treatment from Asia. Incubation period 7-18 days (range: 3-60 days). The highest incidence is found in south-central Asia and south-east Asia.

Patients most commonly present with fever, headache, constipation/diarrhoea, malaise, anorexia, dry cough, abdominal pain, hepatosplenomegaly, Rose spot rash, bradycardia and potentially misleading symptoms including meningism may occur.

Transmission is usually from contaminated food or water, occasionally direct faecal-oral transmission, shellfish taken from sewage-polluted areas, ingestion of contaminated milk and milk products and flies may cause human infection through the transfer of infectious agents to foods. Around 25% of those who contract typhoid fever become chronic carriers, as bacteria persist in the biliary tract after symptoms have resolved.

Investigations may reveal raised WCC, deranged LFTS. Blood cultures have the highest yield within the first week of symptoms (sensitivity 40-80%). Diagnosis can also be made from stool and urine cultures (become positive after the first week) and bone marrow cultures.

Treatment is with quinolones most commonly ciprofloxacin. However, there has been increasing reports of quinolones resistance in patients returned from Asia and intravenous ceftriaxone may be used. If quinolone resistance is confirmed azithromycin or cefixime are suitable oral alternatives for uncomplicated disease. Treatment should be continued for 14 days to reduce the risk of relapse. The addition of steroids may be helpful in severe cases

Complications can include GI bleeding, intestinal or biliary perforation, acalculous cholecystitis, pneumonia, myocarditis, pancreatitis, UTIs, osteomyelitis, meningitis and typhoid encephalopathy,

Question 41 of 277

A 33-year-old male with a previous history of asthma and HIV presents for review to HIV clinic. He has been noticing weight gain, marks on his abdomen and his partner has noticed that his face has been looking more heavy-set over the last two months. He was diagnosed as having HIV at the age of 19 following needle sharing and use of heroin. He has had good retroviral control following starting treatment at the age of 20 with tenofovir, emtricitabine, atazanavir and ritonavir. His asthma has been well controlled with only salbutamol until six months ago when due to recurrent exacerbation due to upper respiratory tract infection his treatment was escalated to include regular fluticasone. Repeat blood tests show an undetectable viral load and a CD4 count of 900 cells/microliter.

What is the most likely cause of his symptoms?

A. Weight gain secondary to tenofovir use

B. Weight gain secondary to emtricitabine use

C. Weight gain due to reduced exercise tolerance

D. Endogenous Cushing's syndrome

E. Iatrogenic Cushing's syndrome

E. Iatrogenic Cushing's syndrome

The correct answer is iatrogenic Cushing's syndrome. HIV protease inhibitors are potent P450 inhibitors. This means that there are many possible interactions that should be checked before starting treatment. In this gentleman, hepatic enzyme inhibition has resulted in increased steroid dose from his regular inhaler for his asthma. This also explains the physical description showing standard Cushingoid features. Endogenous Cushing's syndrome is possible but is less likely, and weight gain from other causes would not explain all the physical changes described.

Question 43 of 277

A 55 year-old patient presents with a 7 day history of nausea, breathlessness and feeling generally unwell. He is an HIV positive man who was recently started on anti-retroviral therapy in South Africa. On examination his chest is clear. His investigations are:

Chest X-ray: No abnormality seen

CD4 count	380 cells / mm³
Amylase	800 units / dL
Lactate	3.8 mmol / L

What is the most likely cause?

A. Pneumocystis jirovecii pneumonia (PCP)
B. Gallstone pancreatitis
C. Epstein-Barr Virus
D. Nucleoside reverse transcriptase inhibitor (NRTI) therapy
E. Non-nucleoside reverse transcriptase inhibitor (NNRTI) therapy

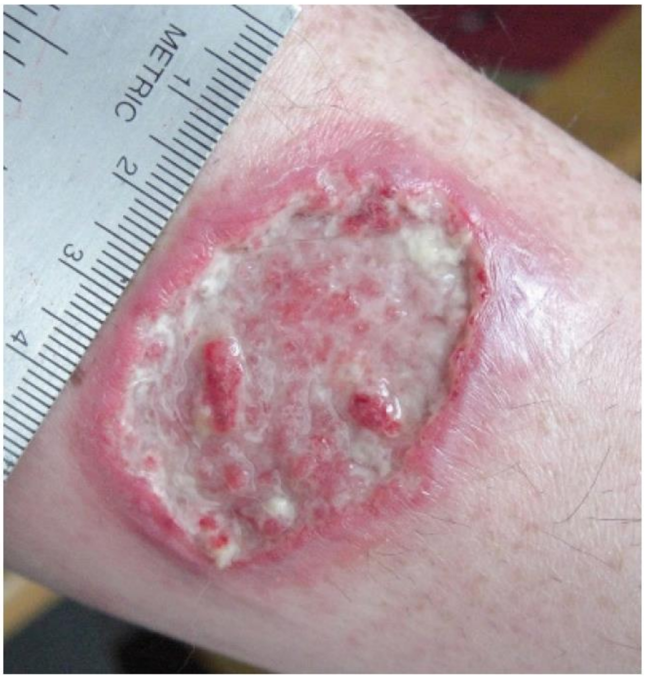
D. Nucleoside reverse transcriptase inhibitor (NRTI) therapy

NRTIs - in particular stavudine, didanosine and zidovudine - classically cause mitochondrial toxicity as an unwanted side effect. This can result in nausea, pancreatitis, lactic acidosis and lipoatrophy as demonstrated above.

Question 44 of 277

A 25-year-old woman of Caucasian origin presents to the dermatology clinic for review. She has been volunteering in India for the last 12 months and has been living with a local family. She first noticed a small lesion on her lower leg around 6 weeks ago. It has since progressed significantly, so she has returned to the UK to seek medical attention. The lesion is painless. She has no other lesions elsewhere on the body. There is no past medical history of note but her brother has ulcerative colitis.

Her skin is examined, as shown below:



What is the most likely cause of this skin lesion?

A. Buruli ulcer
B. Cutaneous leishmaniasis
C. Fish tank granuloma
D. Pyoderma gangrenosum
E. Yaws

B. Cutaneous leishmaniasis

The image shows a large shallow ulcerating lesion on the lower leg, with a moist surface. It is on an exposed area of the body and is a solitary lesion. Combined with her travel history, the most likely cause is **cutaneous leishmaniasis** . Lesions in cutaneous leishmaniasis can also be dry or covered with a crust or scab. Leishmaniasis is transmitted by bites of the sandfly and is due to a number of species of the protozoan parasite *Leishmania* . The main species causing cutaneous leishmaniasis in Asia, Africa, the Mediterranean and the Middle East are *Leishmania major*, *Leishmania tropica* and *Leishmania aethiopica*. Cutaneous leishmaniasis in Central and South America is caused mainly by *Leishmania braziliensis* and *Leishmania mexicana*.

Buruli ulcer is incorrect. This is another tropical ulcerating disease caused by *Mycobacterium ulcerans* . However, most cases occur in sub-Saharan Africa and tropical parts of Australia, and it is rare in Asia. It is also less likely in this patient because it tends to affect children under the age of 15, and affects people living in poverty in rural areas. It is not commonly seen in travellers.

Fish tank granuloma is incorrect. This condition is caused by *Mycobacterium marinum* and can be seen in people who have had exposure to fish tanks or are involved in fish or shellfish preparation. However, unlike the lesion seen in this patient, skin lesions are generally plaque-like or nodular, rather than ulcerating. Lesions can occur on the legs but are more common on the hands and arms.

Pyoderma gangrenosum is incorrect. This diagnosis is less likely in this patient because the ulcers of pyoderma gangrenosum are generally very painful, and have a blue or purple undermined edge, neither of which are present in this case. The patient also has no personal history of an underlying condition associated with pyoderma gangrenosum.

Yaws is incorrect. This condition is one caused by Treponema pallidum subspecies pertenue. It is endemic in a small number of countries in Africa, Asia and the South Pacific, but is most common in Papua New Guinea. The primary stage presents with a papule that can later ulcerate. It is most common in children between 5 and 10. It is unlikely as a diagnosis in this patient because it is extremely unusual in returning travellers as it requires close skin contact (non-sexual contact) with open skin lesions for transmission. It has also been eradicated from India.

Question 45 of 277

A 34-year-old lady presents to the emergency department.

She moved to the UK from India 10 years ago but moved to the area 3 years ago. She works as a medical coder in the hospital.

She presents with a 3-day history of severe generalised headache, a stiff and painful neck, photophobia, and fever. Her husband reports she is drowsy and has been confused since that morning.

She is generally well and takes no medications. Her only previous medical history is of groin lymphadenopathy that was investigated 5 years ago. A biopsy was taken which showed a caseating granuloma. She had no further follow-up at that time.

Investigations:

Chest x-ray lung fields clear. No obvious abnormalities Blood tests:

Haemoglobin	138 g/L
White cells	20.3x10^9/L
Platelets	310x10^9/L
CRP	>350mg/L
Glucose	6.8 mmol/L

Cerebrospinal Fluid (CSF): Appears turbid

Opening pressure	20 cmCSF
Protein	3280 mg/dL
White cells	466 cell/µL (polymorphonucleocytes 280 cell/µL and lymphocytes 206 cell/µL)
Red cells	4 cell/µL
Glucose	1.6 mmol/L
Lactate	5.6 mmol/L
CSF gram stain and PCR	pending

What is the best therapeutic regimen for this patient?

A. Start empirical ceftriaxone, vancomycin and dexamethasone
B. Await gram stain and viral PCR prior to starting a targeted therapy
C. Start aciclovir, ceftriaxone and vancomycin
D. Start isoniazid, rifampicin, pyrazinamide and ethambutol
E. Start isoniazid, rifampicin, pyrazinamide and ethambutol as well as ceftriaxone,vancomycin and dexamethasone

E. Start isoniazid, rifampicin, pyrazinamide and ethambutol as well as ceftriaxone,vancomycin and dexamethasone

This lady could have either bacterial meningitis or tuberculosis (TB) meningitis from her CSF results.

Although she has no chest signs of previous TB, she has had a previous biopsy suggesting she may have TB in her lymphatic system. This makes TB meningitis the most likely diagnosis, however, treatment should certainly be started empirically. This rules out answer 2 as the correct one. Since the gram stains and stain for acid fast bacilli would not yet be back from the lab, treatment should be started for both bacterial and TB meningitis.

Answers 1 and 3 do not include TB therapy and answer 4 does not cover for bacterial meningitis, therefore, these are incorrect answers.

Question 46 of 277

A 54-year-old man presents to the emergency department with one day of fever and a severely painful left leg. He has a past medical history of hypertension. He takes ramipril. He smokes cannabis occasionally and drinks approximately 10 units of alcohol a week. He has recently completed treatment with aciclovir for an episode of chicken-pox.

His observations are heart rate 111 beats per minute, blood pressure 86/48 mmHg, respiratory rate 21/minute, oxygen saturations 97% on room air and temperature 38.4ºC.

On examination, his left thigh is erythematous, tense and tender to touch. There is palpable crepitus.

Blood tests:

Hb	108 g/L	Male: (135-180)Female: (115 - 160)
Platelets	555 * 10 /L 9	(150 - 400)
WBC	23.1 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	191 µmol/L	(55 - 120)
CRP	351 mg/L	(< 5)

Given the likely diagnosis, what is his most significant risk factor the development of this condition?

A. Acute renal failure
B. Cannabis use
C. Chickenpox infection
D. History of hypertension
E. Weekly alcohol intake

C. Chickenpox infection

Chickenpox is a risk factor for invasive group A streptococcal soft tissue infections including necrotizing fasciitis

Chickenpox infection is correct. The patient has necrotizing fasciitis as evidenced by clinical evidence of soft tissue infection, with severe pain and crepitus. Preceding chickenpox infection is a risk factor for this condition.

Acute renal failure is incorrect. Chronic renal failure is associated with the development of necrotizing fasciitis. In this case, he has developed an acute kidney injury in the context of septic shock. Renal failure is a consequence of necrotizing fasciitis rather than a cause in this case.

Cannabis use is incorrect. Intravenous drug abuse is a risk factor for necrotizing fasciitis but not inhaled cannabis use.

History of hypertension is incorrect. Necrotizing fasciitis is associated with chronic disease. However, the conditions commonly implicated are diabetes and peripheral vascular disease rather than hypertension.

Weekly alcohol intake is incorrect. Alcohol abuse is associated withe the development of necrotizing fasciitis but he drinks within normal limits (i.e. < 14 units/week).

Question 47 of 277

A 35-year-old man presents to the emergency department with three days of headache, fever, diarrhoea and malaise. He has recently returned from Angola, where he was taking pictures of neolithic wall paintings. He has no past medical history and is on no regular medications. He works as a photo-journalist for a major international publication.

His observations are heart rate 124 beats per minute, respiratory rate 21/minute, blood pressure 85/54 mmHg, oxygen saturations 96% on room and air and temperature 39.3ºC.

Clinical examination reveals an unwell man. His capillary refill time is four seconds and his skin turgor is increased. He is oozing blood from his mucus membranes. Chest auscultation is normal. Heart sounds are normal with no murmurs. His abdomen is soft, diffusely tender but not peritonitic.

Intravenous access is obtained and intravenous fluids and empirical broad-spectrum antibiotics are administered. It is noted that he is oozing blood from his cannulae sites.

Blood tests:

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	543 * 10 /L 9	(150 - 400)
WBC	5.2 * 10 /L 9	(4.0 - 11.0)
Na +	129 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	14.1 mmol/L	(2.0 - 7.0)
Creatinine	156 µmol/L	(55 - 120)
CRP	80 mg/L	(< 5)
Bilirubin	28 µmol/L	(3 - 17)
ALP	111 u/L	(30 - 100)
ALT	143 u/L	(3 - 40)
Î³GT	99 u/L	(8 - 60)
Albumin	28 g/L	(35 - 50)

Based on the probable diagnosis, to which zoonotic vector has he likely been exposed?

A. Bats
B. Birds
C. Cattle
D. Pigs
E. Rats

A. Bats

Exposure to bats/caves is a risk factor for Marburg virus, which results in a viral haemorrhagic fever

Bats are the correct answer. This man has evidence of viral haemorrhagic fever (VHF) with hypotension and multi-organ dysfunction. He has returned from a region where Marburg virus has previously been found. Additionally, he has been taking photos of neolithic wall paintings, which are typically found in caves. Exposure to bats and caves are risk factors for Marburg virus.

Birds are not the correct answer. While there is some suggestion that birds can carry infected ticks from continent to continent and thus spread viruses causing (VHF), this is not a common vector for the animal to human transmission of these diseases.

Cattle is incorrect. While people can occasionally contract Crimean-Congo haemorrhagic fever from exposure to infected cattle, there has never been an outbreak of this condition in Angola and he has not been exposed to slaughtered animals.

Pigs are incorrect. This is not a common zoonotic vector for transmission of viral haemorrhagic fever.

Rats are incorrect. While exposure to rats can result in hantavirus and haemorrhagic fever and renal dysfunction, this is more common in Asia, the Americas and Europe, rather than Africa.

Question 48 of 277

A 43 year old man attends for follow up at the Infectious Diseases clinic. He is an HIV-positive patient who has been well while on treatment for the last 13 years. His current treatment regimen is emtricitabine, atazanavir and tenofovir. He has however begun to notice altered taste and a difficulty in swallowing over the last couple of months. In the last few days he has even noticed a white coating in his mouth that is not removed by vigorous scrubbing with his toothbrush. He describes being compliant with his medications and not taking any illicit drugs. He no longer has unprotected sexual intercourse. The only change that is identified is that he recently visited his GP with non-specific symptoms and was started on a new medication.

CD4 count in clinic 4 months ago 526

CD4 count currently 210

What medication is the GP likely to have started?

A. Lansoprazole
B. Aspirin
C. Amitriptyline
D. Paracetamol
E. Simvastatin

A. Lansoprazole

Interactions between anti-reteroviral drugs and other more common medications are many and varied. It is a complex area but is one that is becoming more prominent given the larger prevalance of HIV. HIV is no longer a death sentence and with current treatments patients can expect to have an almost normal life expectancy. Full knowledge of all the possible interactions is unrealistic but some of the main ones should be kept in mind when prescribing any new medication. There is an excellent resource kept by the University of Liverpool that can be found at https://www.hiv-druginteractions.org/

In the case detailed above the patient is likely to have been started on a PPI such as Lansoprazole. Lansoprazole is known to dangerously lower the efficacy of atazanavir and this is exhibited by the dramatic fall in CD4 count. This patient also seems to have developed oesophageal candidiasis and so urgent management to manage his HIV is required to avoid potentially deadly opportunistic infections.

Question 49 of 277

A 48-year-old woman originally from South Africa has lived in the UK for 17 years and works as a librarian. She was diagnosed with HIV 18 months ago after she discovered her husband had been having an affair. Her lowest CD4 count was 211 /mm3. She was commenced on Anti-Retroviral Therapy (ART) on diagnosis with Tenofovir, Emtricitabine and Kaletra (Lopinavir/Ritonavir) and Cotrimoxazole.

Her past medical history prior to diagnosis was unremarkable. She has been well on her ART until 3 weeks ago when she was seen in HIV clinic with a 4-week history of a cough and weight loss of 3 kilogrammes.

She had a chest x-ray showing new right apical nodular opacities and had scanty Acid Fast Bacilli on sputum smear microscopy. Her CD4 count was 312 /mm3 with and she was commenced on standard TB therapy with Rifampicin, Isoniazid, Ethambutol and Pyrazinamide, as well as switching Kaletra to Efavirenz.

Today she has been brought into hospital by the Police, she was found naked wandering in her street, accosting passers-by and asking them to help her remove a device planted under her skin by the CIA to monitor her thoughts.

Her observations are within normal limits. She is moderately difficult to examine but there is no focal neurology detectable. She has mildly reduced air entry in her right upper lobe and her examination is otherwise normal.

Results:

Hb	8.1 g/dl
MCV	84 fl
Platelets	86 * 10 /l9
WBC	4.5 * 10 /l9
CRP	27 mg/l
ESR	41 mm/hr

Urea & electrolytes, liver function tests and thyroid function tests were normal. A CT head and lumbar puncture were also unremarkable.

What is the cause of her admission?

A. TB meningitis
B. HIV encephalopathy
C. Ethambutol toxicity
D. Efavirenz toxicity
E. Immune thrombocytopaenic purpura

D. Efavirenz toxicity

This is Efavirenz toxicity.

Rifampicin causes potent enzyme induction and therefore dramatically reduced the level of Protease Inhibitors. Efavirenz is less susceptible to inducing effects Rifampicin, therefore the switch to Efavirenz was logical.

Efavirenz however can cause neuropsychiatric toxicity (due to variable metabolism which is genetically determined) which is the cause of psychosis here. Normal LP excludes TB meningitis. Ethambutol causes optic neuritis, so monitoring of visual acuity during treatment is essential. HIV encephalopathy is possible but unlikely to present so acutely and the temporal relation to Efavirenz introduction, in this case, is the key.

Question 50 of 277

A 26-year-old woman presents to the emergency department with right upper quadrant pain which is worse when she takes a deep breath in. Her symptoms started three days earlier and have been progressively getting worse. She has no past medical history and takes no medications apart from the oral contraceptive pill and paracetamol to help control the pain. She has also noticed an increase in vaginal discharge over the last two weeks and has noticed an unpleasant smell with it. She works in an investment bank. On examination, she has right upper quadrant tenderness, but the abdomen is soft and no organomegaly is noticed. Abdominal ultrasound demonstrates the presence of gallstones in the gallbladder but is otherwise normal.

What treatment is most likely to resolve the cause of her underlying problem?

A. Cholecystectomy
B. Trimethoprim
C. Antiviral treatment
D. Antiretroviral treatment
E. Ceftriaxone

E. Ceftriaxone

Intramuscular ceftriaxone is the treatment of choice for *Gonorrhoea*

The correct answer is ceftriaxone. This woman has unfortunately developed Fitz-Hugh-Curtis syndrome following pelvic inflammatory diseases. The key aspects are RUQ pain worse with breathing; symptomatic of peri-hepatic adhesions. This combined with vaginal discharge are highly suggestive of Fitz-Hugh-Curtis syndrome, which can be treated with antibiotics. Cholecystectomy would be appropriate management if the US had found evidence of cholecystitis. Trimethoprim would be appropriate if there was evidence of urinary symptoms, whilst there is no evidence to suggest that this is an AIDS-defining illness needing antiretroviral treatment. Antiviral treatment would imply viral hepatitis, but there is no clear evidence of hepatitis.

Question 51 of 277

A 28-year-old female presents with a 4-day history of fevers and joint pain. She has recently returned from a 3 month gap year trip to the South-East Asia three days ago and reports no ill health during her travels. She has no past medical history, does not smoke, drinks minimal alcohol and denies the use of illicit drugs. During her travels, she reports two episodes of unprotected sexual contact with a non-regular partner. Although she knew she would be entering a malaria area and was indeed bitten by mosquitoes on a number of occasions, she did not take any malaria prophylaxis.

On examination, heart sounds and chest examination are both normal. A maculopapular rash is noted on her left thigh and right upper arm, with bilateral conjunctival injection. Abdominal examination reveals a soft abdomen with no masses. She has a significantly joint and muscle pains, limiting your neurological examination. She is alert and orientated to time and place, scoring 10/10 on abbreviated mental testing. Her blood tests are as follows:

Hb	109 g/l
Platelets	45 * 10 /l9
WBC	3.5 * 10 /l9
Na +	137 mmol/l
K +	3.8 mmol/l
Urea	7.1 mmol/l
Creatinine	100 µmol/l
CRP	70 mg/l
Bilirubin	7 µmol/l
ALP	30 u/l
ALT	162 u/l

Her first malaria film is negative and a chest radiograph is unremarkable.

What is the most likely diagnosis?

A. Gonorrhoea with reactive arthritis
B. HIV seroconversion
C. Dengue fever
D. Malaria falciparum
E. Typhoid

C. Dengue fever

Retro-orbital headache, fever, facial flushing, rash, thrombocytopenia in returning traveller → ?dengue

The context of this patient should alert you to that of fever in a returning traveller. This is a patient who presents with a combination of fever, myalgia and arthralgia, skin rash, conjunctival injection, raised ALT, thrombocytopaenia and leucopenia, strongly suggestive of dengue fever. The key differential for a returning traveller from South East Asia, where ingestion of contaminated water is possible, is to consider is also typhoid fever, which also presents with a skin rash (classically a rose spot) with diarrhoea and vomiting much more prominent. Although she had unprotected sex during her travel, gonorrhoea presents more typically with a migratory arthritis and tenosynovitis with discharge. Leucopenia is classical of dengue fever and does not necessarily suggest immunodeficiency, possibly secondary to HIV.

Question 52 of 277

A 39-year-old pet shop owner is referred to the dermatology clinic due to lesions on his right hand. He describes noticing a lump over his 2nd metacarpophalangeal joint 2 months ago, this has since increased in size and crusted over, and further similar lesions have appeared. He denies pain or itching and has tried a number of topical emollients without improvement. He has no past medical history of note and no allergies.

On examination, there are multiple crusted lesions measuring 1-2cm in diameter on his knuckles and the dorsum of his hand. There are no other skin or mucosal changes.

A biopsy is taken for analysis:

Skin biopsy	Granulomatous dermatitis with inflammatory infiltrate

What is the most likely causative organism?

A. Human papilloma virus
B. Mycobacterium leprae
C. Mycobacterium marinum
D. Mycobacterium tuberculosis
E. Pseudomonas aeruginosa

C. Mycobacterium marinum

Fish tank granuloma is caused by *Mycobacterium marinum*

This patient has an infection with the bacterium ***Mycobacterium marinum***, a species of mycobacteria commonly contracted through exposure to swimming pool water or contact with fish e.g. through fish tanks. This patient is a pet shop owner and has likely contracted the illness through occupational exposure. Notably, in such patients, the dominant hand is most frequently affected. After a 3-4 week incubation period, a single lump or pustule appears that breaks down to form a crusted lesion. The knuckles are commonly affected and a biopsy of the lesion demonstrates granulomatous dermatitis and inflammatory infiltrate within the dermis. Treatment is with antibiotics e.g. doxycycline.

Human papilloma virus (HPV) is a common cause of viral warts that are commonly located on the cutaneous surface (e.g. hands, knees and feet) or genitalia. Common warts found on the hands (also known as verruca vulgaris) are hyperkeratotic, rough and papillomatous lesions. However, on dermoscopy, multiple papillary capillaries can be visualised rather than granulomatous dermatitis with inflammatory infiltrate.

Mycobacterium leprae causes leprosy. Symptoms of leprosy include hypopigmented patches of skin associated with sensory loss. The areas of skin affected by the disease are not limited by exposure, in contrast to this patient's presentation.

Mycobacterium tuberculosis can cause cutaneous symptoms such as tuberculous gumma from the haematogenous spread of disease, lupus vulgaris and miliary tuberculosis where there are multiple millet-sized red skin lesions. These lesions are not seen in this patient and there is no other history to suggest underlying tuberculosis.

Pseudomonas aeruginosa is implicated in skin infections such as external otitis or hot tub folliculitis (acquired from chlorinated hot tubs). Infection is particularly more common in the immunocompromised and is unlikely to be the causative pathogen in this case.

Question 53 of 277

A 65-year-old man has just returned from a trip to India one week ago. He has had bloody diarrhoea and fevers for the last two weeks and noted rose coloured spots on his abdomen yesterday. Apart from a prosthetic aortic valve, he has no significant past medical history. His blood tests indicate raised inflammatory markers and stool microbiology has found a gramnegative bacillus identified as a non-typhoidal *Salmonella*. Sensitivities are pending.

Which one of the following options is best initial empiric management?

A. Amoxicillin + clavulanic acid
B. Gentamicin
C. Ciprofloxacin
D. Clindamycin
E. Not for antibiotics

C. Ciprofloxacin

According to the NICE guidelines, anyone above the age of 50, immunocompromised or has cardiac valve disease/endovascular abnormalities should be treating empirically with ciprofloxacin 500mg BD when they have been diagnosed with non-typhoidal *Salmonella* gastroenteritis.

Question 54 of 277

An 80-year-old lady presents from a nursing home with a one-day history of fevers, drowsiness and vomiting. She has been unwell, not eating for the past 3 days according to her carer. Recently she has been exhibiting behavioural changes, crying and agitation when lights are turned on in the room, and holding her neck. She has a back ground of Alzheimer's dementia, hypertension, congestive cardiac failure(CCF) and chronic kidney disease.

On examination, she is febrile with a temperature of 38.1oC. Heart rate 112bpm, respiratory rate 20breaths per minute and oxygen saturations of 94% on air. On auscultation, there are bibasal crepitations and cardiovascular examination is consistent with mild CCF. There is neck stiffness and photophobia on cranial nerve examination, pupils equal and reactive to light. Kernig's sign is positive.

Investigations:

Na+	129mmol/l
K+	4.8 mmol/l
Urea	10.9 mmol/l
Creatinine	123 µmol/l
Serum glucose	5.9mmol/l
C Reactive protein	95mg/l
Haemoglobin	126 g/l
White cell count	16.4 x 10^9/L
INR	1.2

Cerebro-spinal fluid (CSF) analysis:

Opening pressure	25 cmH20
Protein	1.8 g/L
Glucose	2.6 mmol/l
White cell count	>1000 per mm³
Gram Stain	Gram-positive rods seen
Colour	Cloudy, turbid

What is the likely causative organism?

A. Streptococcus pneumoniae
B. Listeria monocytogenes
C. Staphylococcus aureus
D. Neisseria meningitidis
E. Haemophilus influenzae

B. Listeria monocytogenes

This lady has bacterial meningitis as evidenced from her LP results. There is only one gram-positive bacilli in the list and that is *Listeria monocytogenes*, a common causative organism of meningitis in the extremes of age.

Gram-positive bacilli (or rods): ABCDL

- Actinomyces
- Bacillus anthracis
- Clostridium,
- Corynebacterium
- Diphtheria
- Listeria monocytogenes

Gram positive cocci:

- Streptococci
- Staphylococci

Gram-negative cocci: NNM

- Neisseria (Neisseria meningitides, Neisseria gonorrhoea)
- Moraxella

Gram negative bacilli (or rods): almost every other pathogenic gram negative bacteria.

- Salmonella spp.
- Escherichia spp.
- Pseudomonas
- Bacteroides

Question 55 of 277

A 24-year-old male patient is referred to HIV clinic following positive testing on screening in a local GUM clinic. His CD4 count is 1020 cells/microlitre and viral load is 10,123 copies/ml. He is offered to start antiretroviral treatment or monitoring. He has a past medical history of depression and has emigrated from Nigeria three years ago. He is planning to return abroad in two years.

What benefit has been established from starting early antiretroviral treatment as opposed to deferring treatment?

A. Increased efficacy
B. Reduced risk of AIDS and mortality
C. Reduced drug resistance
D. Reduced toxicity
E. Reduced anxiety

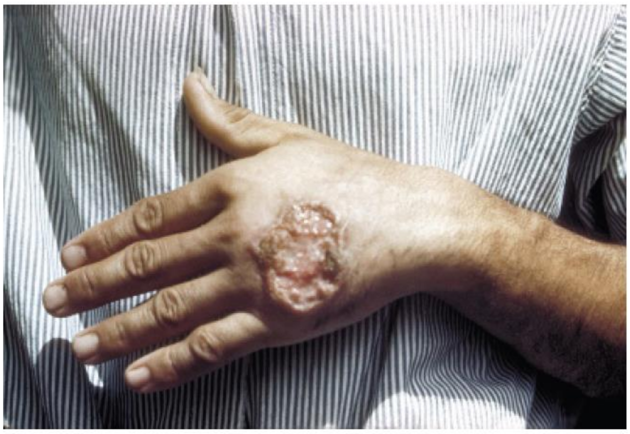
B. Reduced risk of AIDS and mortality

The correct answer is the reduced the risk of AIDS and mortality. BHIVA has made the recommendation to offer antiviral therapy regardless of the CD4 count. This is partly due to results of the SMART study which demonstrated reduced chance of AIDS, a serious non-AIDS event or death by 57% with similar results in high, middle and low-income countries. Data on virological efficacy, drug resistance and toxicity is not yet established. Reduced anxiety may also be a benefit but has not been as definitively established.

Question 56 of 277

A 42-year-old man attends the GP with a lesion on his left hand. He says it first appeared as a red spot 2-3 weeks ago when he returned from Iraq. However, since then the lesion has been progressively enlarging. There is no history of pain or itch and he otherwise feels well. He is normally fit and well and takes no regular medications.

On examination, his observations are all within the normal range. His hand appears as shown below. On further inspection, there is sparing of the mucous membranes and no further lesions are found on his body.



What is the most likely diagnosis?

A. Anthrax
B. Chagas disease
C. Leishmaniasis
D. Leprosy
E. Lyme disease

C. Leishmaniasis

This patient has a superficial cutaneous lesion on his left hand with central ulceration. The surrounding skin is not affected. Given the history of rapid growth from a small red papule and a recent tour in Iraq, it is likely that this patient has leishmaniasis, a parasitic disease spread by sandflies. There are different species of leishmania that are responsible for different manifestations of the disease, with cutaneous leishmaniasis being the most common. Initially, a small red papule appears at the site of the sandfly bite which gradually enlarges followed by central ulceration before spontaneously resolving. The time to resolution varies between 2 months and 1 year. The Middle East, North Africa, and Asia are more common areas for contracting the disease.

Anthrax is a bacterial disease caused by *Bacillus anthracis*. Infection is associated with exposure to infected carcasses and the introduction of the organism into the body through a superficial wound. An initial pustule appears at the site of infection which progresses to a black eschar (a necrotic-looking ulcer with a black scab). The infection usually resolves spontaneously, but in some can lead to death. The lesion shown in this question is not that of a black eschar but rather a crusted ulcer from a sandfly bite. This makes leishmaniasis the correct diagnosis.

Chagas disease is a parasitic disease spread by triatomine or 'kissing' bugs. The disease is prevalent in Latin America and consists of an initial acute phase and chronic phase. In the earlier stages of the disease, symptoms include generalised malaise, fever, headaches, and myalgia along with anorexia, nausea, and vomiting. In others, a chagoma (an indurated, oedematous skin lesion) may be seen. In contrast, the patient in this question has returned from the Middle East with a cutaneous ulcerated lesion, making Chagas disease unlikely.

Leprosy is a granulomatous disease caused by *Mycobacterium leprae* that affects the peripheral nerves and skin. Initial symptoms include numbness, typically with loss of temperature followed by light touch, pain, and finally deep pressure. Cutaneous lesions follow later in the disease and appear as hypopigmented patches of skin with associated sensory loss. This patient has a painless, crusted ulcer with no other lesions or neurology making leprosy an unlikely diagnosis.

Ticks are well-known to spread Lyme disease, a bacterial infection caused by Borrelia *burgdorferi* . The most common dermatological manifestation of Lyme disease is a bulls-eye rash that appears at the site of the tick bite. Other symptoms include fever, lethargy, and arthralgia that are not described in this question.

Question 57 of 277

A 63 year old man, originally from Ukraine is admitted to hospital with a right sided pleural effusion. On admission he is febrile at 37.8 C. He reports 6kg of weight loss, and night sweats over the previous 4 months.

His pleural effusion is exudative with a pH of 7.4.

A CT chest/abdo/pelvis reveals a right sided pleural effusion, multiple enlarged lymph nodes in his abdomen and mediastinum. A pleural biopsy reveals scanty Acid Fast Bacilli and he is commenced on treatment for tuberculosis with Rifampicin, Isoniazid, Ethambutol, Pyrizinamide. PCR confirms this to be Mycobacterial Tuberculosis complex with wild type rpoB, katG, inhA genes. His HIV serology is positive and his CD4 count is 47 cells/mm3

One week following admission he is commenced on anti-retroviral treatment with Emtricitabine, Lamivudine and Efavirenz with Co-trimoxazole.

Three weeks later he becomes more unwell. He has daily fevers up to 39°C.

On examination he is febrile 38.1 with an associated tachycardia of 119 beats/min, his blood pressure is 112/67 mmHg and respiratory rate is 22 breaths/min. His oxygen saturations are 93%. He has reduced air entry at the right base, but no other abnormality on examinations.

His results are as following:

Hb	10.1 g/dl
MCV	82 fl
Platelets	97 * 10 /l9
WBC	7.8 * 10 /l9
Neutrophils	6.3 * 10 /l9
Lypmphocytes	1.2 * 10 /l9
Eosinophils	0.02 * 10 /l9
ESR	62 mm/hr
Bilirubin	9 µmol/l
ALP	312 u/l
ALT	153 u/l

γGT	456 u/l
Albumin	22 g/l
CRP	67 mg/l
Lactate	1.1 mmol/l

Other results were as follows;

Urea and electrolytes: normal.
Clotting screen: normal
Blood cultures: negative (x3)
Urinalysis: normal
ECHO: normal
CXR: right pleural effusion
USS abdo: several abdominal nodes visible, nil else.
Toxoplasmosis serology: negative
CMV: IgG negative IgM: negative
EBV: IgG positive IgM: negative
Cryptococcal antigen: Negative
Leishmania serology: negative

What is the most likely diagnosis?

A. Pneumococcal pneumonia
B. Drug resistant tuberculosis
C. Infectious mononucleosis
D. Immune reconstitution inflammatory syndrome
E. Burkitts Lymplhoma

D. Immune reconstitution inflammatory syndrome

This is a classic history of Immune Reconstitution Inflammatory syndrome (IRIS). IRIS is a paradoxical worsening of symptoms, due to increasing inflammatory activity with a recovering immune system. It is seen in the context of anti-retroviral therapy.

In this case we are reassured of a correct diagnosis to TB with the PCR result, and the initial PCR results suggest a fully susceptible organism (although this will need to be confirmed by culture and sensitivity testing.) You may not have a luxury of a confident diagnosis of TB, and patients with HIV may have many different opportunistic infections. Therefore IRIS is a diagnosis of exclusion. In this case an extensive screen has revealed no alternative cause for his symptoms.

The diagnosis of IRIS depends on all three of :

1. Antecedants:

- Diagnosis of TB fulfilling WHO clinical criteria
- Initial response to anti-retroviral treatment

2. Clinical (1 major criteria or 2 minor)

- Major: New or worsening cold abscess lymph nodes, radiological features of TB, CNS TB or TB serositis
- Minor: New or worsening constitutional symptoms, respiratory symptoms or abdominal pain.

3. Alternative explanations for clinical deterioration must be excluded.

Question 58 of 277

A 17 year old girl presents to A&E accompanied by her anxious mother. She was born in England, but both her parents were born in a rice growing community in rural China. She has recently returned from a holiday where she was visiting her family in China. They live on a farm where she had close contact with dogs, sheep and pigs.

She arrived home one week ago. She was taking Mefloquine for malaria prophylaxis.

She was complaining of fever and a headache yesterday. Today she has been confused and disorientated.

She is previously fit and well, she has had all her immunisations according to the UK immunisation schedule, with normal growth and development. She does well at college and is a keen member of her college canoe club. She has no allergies.

On examination she is febrile at 38.9°C but haemodynamically stable. She appears confused and has an obvious difficultly walking. Examination of her cranial nerves is difficult but unremarkable. She has normal power and increased tone in her arms, which is more pronounced on the left side, with hyperreflexia bilaterally. She has several writhing involuntary movements of her upper limbs during the consultation.

A CT scan shows hypodensity in the thalami and basal ganglia bilaterally, more pronounced on the left side.

A lumbar puncture reveals a lymphocytic CSF with a raised protein.

What is the most likely diagnosis?

A. Herpes Simplex Encephalitis
B. Japanese Encephalitis
C. Alcohol consumption
D. Rabies
E. Mefloquine toxicity

B. Japanese Encephalitis

The most likely diagnosis in this case is **Japanese Encephalitis**. The patient's history of travel to a rural area in China, where she had close contact with animals, combined with her presenting symptoms of fever, headache, confusion, and difficulty walking, as well as the CT scan findings of hypodensity in the thalami and basal ganglia bilaterally are all consistent with Japanese Encephalitis. This disease is a mosquito-borne flavivirus infection that predominantly affects people living or travelling to Asia.

Herpes Simplex Encephalitis is less likely due to the patient's travel history and exposure to animals. Although Herpes Simplex Encephalitis can also present with fever, headache, and confusion, it typically has a more acute onset and would show different findings on imaging studies (such as temporal lobe involvement on CT or MRI).

Alcohol consumption is an unlikely cause for this patient's presentation. While excessive alcohol intake can lead to neurological symptoms such as ataxia and confusion, there is no indication from the patient's history that she has been consuming large amounts of alcohol. Furthermore, her CT scan findings and lumbar puncture results do not support this diagnosis.

Rabies could be considered given the patient's close contact with animals during her trip; however, her clinical presentation does not fit the classic signs of rabies. Rabies usually presents with hydrophobia (fear of water), hypersalivation, and progressive paralysis. Additionally, while rabies can affect the central nervous system leading to encephalitis-like symptoms, it would not produce the specific CT scan findings seen in this case.

Finally, **Mefloquine toxicity** is an unlikely diagnosis because although mefloquine can cause neuropsychiatric side effects like dizziness or insomnia in some individuals, the patient's symptoms and investigation results are much more consistent with Japanese Encephalitis. Mefloquine toxicity would not typically cause the neurological findings observed in this case, nor would it explain the CT scan and lumbar puncture results.

Question 59 of 277

A 45-year-old male from Afghanistan presents with a rash all over his body. He describes the rash and suggests that it was initially multiple specks of light skin that were not raised or roughened. they have now progressed to plaques, some of which have become nodular.

He is otherwise well and his past medical history is significant only for the successful treatment of visceral leishmaniasis in his home country some 5 years ago.

What is the most likely underlying diagnosis?

A. Leprosy
B. HIV
C. Post kala azar dermal leishmaniasis (PKDL)
D. Histoplasmosis
E. Pityriasis versicolor

C. Post kala azar dermal leishmaniasis (PKDL)

This is a classic description of post kala azar dermal leishmaniasis (PKDL) from an area where the disease is endemic. Leishmaniasis can manifest as cutaneous, muco-cutaneous and visceral disease. PKDL is a chronic skin condition that arises after the treatment of visceral disease. The skin condition can arise months or years after successful treatment and often presents with erythematous or hypo-pigmented macules that may progress to become nodular. Clinically the lesions look very similar to pityriasis versicolour, however this has a predilection for the chest and back and is likely to have a scaly appearance rather than nodular. Perhaps the most important differential is leprosy and lesions should be tested for anaesthesia which would be strongly indicative for leprosy over PKDL.

Although HIV can cause a myriad of skin pathology there is nothing given in the question to make this a likely diagnosis and the best answer is therefore PKDL.

Question 60 of 277

A 40-year-old male presented to the Emergency Department with a decreasing level of consciousness. He had just returned from the Hajj pilgrimage in Saudi Arabia. He was completely healthy during his travels, but he started to develop a fever two days after his return. The fever was associated with a severe frontal headache and photophobia. These symptoms persisted for the last two days and he started to become sleepier.

On examination: blood pressure 100/80 mmHg, pulse rate 120/min, temperature 39.2ºC, respiratory rate 27/min. He had evidence of neck stiffness. Blood investigations showed:

Hb	123 g/l
Platelets	130* 10 /l9
WBC	13* 10 /l9

What is the most likely diagnosis?

A. Meningococcal meningits type A
B. Meningococcal meningits type B
C. Meningococcal meningits type C
D. Malaria
E. Hemorrhagic fever

A. Meningococcal meningits type A

The candidate should have no difficulty in recognising that this patient has meningitis. However, good knowledge of the epidemiology of meningitis is required to answer the question completely.

The most common cause of meningitis in Saudi Arabia during Hajj is meningococcal meningitis type A. It is also the leading cause of epidemics of what is known as the meningitis belt in Africa along the equator line including Sudan, Ethiopia and Nigeria.

Type B and Type C are mainly responsible for sporadic cases of meningitis in Europe and South America.

Question 61 of 277

A 54-year-old intravenous drug user is newly diagnosed with HIV, after presenting with progressive shortness of breath. He was diagnosed with pneumocystis pneumonia and commenced on appropriate treatment.

His CD4 count is 54 cells/mm3 and his viral load is 1.7 x10^7 copies per ml.

As part of his routine workup, it is also revealed that he has co-infection with hepatitis C. A test for HIV viral tropism is reported as dual tropism virus.

Which drug is unlikely to be effective in this man's treatment?

A. Maraviroc
B. Raltegravir
C. Tenofovir
D. Ribavirin
E. Abacavir

A. Maraviroc

HIV binds to the CD4 cell via the CD4 receptor. This interaction also depends on viral interaction with the CD4 co-receptor. There are two forms of CD4 co-receptor CCR5 and CXCR4.

The test for viral tropism determines which of these co-receptors HIV will bind to. Maraviroc blocks HIV binding to the CCR5 receptor, and therefore is an effective drug in a 'CCR5 tropic' virus. However, it is not effective if the virus is 'CXCR4 tropic' or 'dual tropic'. The tropism of HIV will not affect the use of any of the other drugs listed.

It is routine to test HIV viral tropism on diagnosis, or on virological failure to assess if maraviroc is a therapeutic option.

Question 62 of 277

A 45-year-old man attends with a skin rash after returning to the UK following a 5-month stay in Sudan. He explained that he sustained multiple fly bites during his travels and that some of the bites became raised red bumps that became scabby and painful, the majority of these have not healed.

On examination, there is a handful of atrophic scars over his cheeks, arms, and ankles. There are also raised scaly lesions with interspersed erythematous ulcerated papules, some of which are oozing pus in the same distribution.

What diagnostic tool would typically be used to confirm the likely diagnosis?

A. Blood cultures
B. Bone marrow aspiration
C. Punch biopsy of a lesion
D. Skin scraping of a lesion
E. Splenic aspirate

C. Punch biopsy of a lesion

Cutaneous leishmaniasis is typically diagnosed using a punch biopsy

The most likely diagnosis here is cutaneous leishmaniasis. This should be suspected in any patient with non-healing, scaling skin lesions, particularly if they have been in an endemic area.

Punch biopsy is correct. This is the typical method of diagnosing cutaneous leishmaniasis.

Blood cultures is incorrect. Leishmaniasis is a parasitic disease, blood culture is therefore not the typical diagnostic tool. In some cases, evidence of leishmaniasis can be seen on blood film.

Bone marrow aspiration is incorrect. This would be a diagnostic tool if we were concerned about visceral leishmaniasis. Fevers, substantial hepatomegaly, and blackening of the skin would raise suspicion of visceral leishmaniasis. None of these features are mentioned in the stem for this patient.

Skin scraping of a lesion is incorrect. Generally, leishmaniasis is diagnosed with PCR testing of a punch biopsy. This can also be performed on a sample obtained through skin scraping, but the diagnostic sensitivity is much poorer.

Splenic aspirate is incorrect. This would be a diagnostic tool if we were concerned about visceral leishmaniasis. Fevers, substantial hepatomegaly, and blackening of the skin would raise suspicion of visceral leishmaniasis. None of these features are mentioned in the stem for this patient.

Question 63 of 277

A 60-year-old man presented with history of excessive urination especially during night which disturbs his sleep, excessive thirst and tiredness for the past 2 months. He was a known HIV positive patient for which he was on highly active anti-retroviral therapy (HAART) since 6 months. Clinical examination was within normal limits. HIV related diabetes mellitus was suspected by the treating physician. His blood investigations are as follows

Hb	150 g/l
Platelets	150 * 10 /l9
WBC	7 * 10 /l9
Fasting blood glucose	10 mmol/l
Post prandial blood glucose	13.9 mmol/l
Serum creatinine	130 umol/L

He was planned to be started on metformin therapy.

Which of the following investigations is important to be checked before starting metformin in this patient?.

A. Liver enzymes
B. Venous lactate
C. Serum triglycerides
D. Serum albumin
E. Serum ammonia

B. Venous lactate

Patients with HIV are at increased risk of lactic acidosis and hence it is prudent to check lactate levels before starting metformin in such patients.Lactic acidaemia with no or mild symptoms was detected in 8% to 21% of patients receiving at least 1 nucleoside reverse transcriptase inhibitor, versus 0% to 1% of patients receiving no antiretroviral therapy. Symptomatic lactic acidaemia is less common (occurring in about 1.5%2.5%).Monitoring for lactic acidosis is recommended in the initial few months of metformin therapy. Patients with impaired renal function(serum creatinine>1.5 mg/dl) or with a venous lactate level more than twice the normal level prior to treatment should not be started on metformin.

This patient has an elevated serum creatinine but not >1.5mg/dl. So, he should get a venous lactate estimation before being started on metformin therapy considering the evidences so far.

Question 64 of 277

A 25-year-old man reports feeling unwell with fever, generalised muscle aches, headache and widespread rash 1 week after returning from Thailand. On admission his chest X-ray is unremarkable. His urine dip showed 1+ protein only and viral swabs are negative. Bloods are also normal aside from low platelet count. On day 2 of admission his blood pressure drops and repeat bloods show a further fall in platelets and reduction in haemoglobin count.

What is the most likely diagnosis?

A. Measles
B. Malaria
C. Dengue fever
D. Gonococcal septicaemia
E. Herpes simplex encephalitis

C. Dengue fever

Retro-orbital headache, fever, facial flushing, rash, thrombocytopenia in returning traveller → ?dengue

All plausible options and further history including prior vaccination, sexual history and malaria prophylaxis would be helpful. The history and deterioration are most likely due to dengue fever and subsequent 'dengue shock syndrome'. Measles would be unlikely at his age, malaria does not classically cause a widespread rash and herpes simplex would not cause a drop in the platelets. Gonorrhoea fits quite well and has a similar incubation period (4-7 days) . The patient would have normally have reported an isolated septic joint by this stage in the disease.

Question 65 of 277

A 68-year-old lady presents with lower abdominal pain, dysuria, and urinary frequency. A urine dip was positive for nitrites and leukocytes. She has a past medical history of recurrent C.difficile infection which has been treated with two tapering courses of vancomycin.

Microbiology results are as follows:

Urine culture	Vancomycin Resistant Enterococcus (VRE

How will you manage this patient?

A. Amoxicillin
B. Linzolide
C. Gentamicin
D. Penicillin
E. Erythromycin

B. Linzolide

Vancomycin Resistant Enterococcus (VRE) can be treated with linezolid, daptomycin and tigecycline

Enterococci are gram positive gamma-haemolytic Streptococci. Most important are E. faecalis and E. faecium. They are part of the normal flora of the human intestine, the female genital tract, and urinary tract. They are intrinsically of low pathogenicity however have a natural high resistance to antibiotics.

Vancomycin Resistant Enterococcus (VRE) are important nosocomial pathogens for which there are limited treatment options. Predisposing factors for VREs include previous treatment with antimicrobials (especially vancomycin, cephalosporins and broad-spectrum antibiotics).

Most VRE have high-level resistance to β-lactams and aminoglycosides.

Management of VRE may include removal of catheters and drainage of abscesses

If after clinical assessment and primary management, antimicrobial treatment of VRE is considered necessary, a drug should be selected based upon susceptibility testing of the organism involved. Nearly all strains of E. faecalis, including VRE strains, are susceptible to ampicillin. VREs also often remain sensitive to chloramphenicol, rifampicin and tetracyclines. A number of newer agents include linezolid, daptomycin and tigecycline.

Gentamicin can be used synergistically with another antibiotic, however it should not be used alone.

Question 66 of 277

A 26-year-old woman presents to the Emergency Department with a one week history of cough, fever and headache. She returned from Indonesia one week ago.

On examination she appears drowsy and a little muddled. She has no photophobia or focal neurological deficit. She has mild hepatosplenomegaly but no palpable lymphadenopathy. Her chest is clear and heart sounds are normal. She has a macular rash on both legs with a greyishblack scab-like lesion on her left shin.

Investigations results:

Chest x-ray: Bilateral patchy consolidation

Blood culture: Pending

Hb	120 g/l
Platelets	130 * 10 /l9
WBC	18 * 10 /l9
Blood film	Left shifted neutrophils in large numbers
Na +	142 mmol/l
K +	4.1 mmol/l
Urea	6 mmol/l
Creatinine	90 µmol/l
Bilirubin	23 µmol/l
ALP	170 u/l
ALT	50 u/l
Albumin	35 g/l

What is the most appropriate first line treatment?

A. Azithromycin
B. Chloroquine
C. Doxycycline
D. Mefloquine
E. Supportive medications

C. Doxycycline

Doxycycline is typically used in the management of typhus

This lady has a triad of fever, hepatosplenomegaly and encephalitis, which in a returning traveller could point towards a number of diseases including malaria and dengue fever. However, the lesion on her shin is an eschar, which points towards a diagnosis of rickettsia. Given her clinical signs and that she has been to Indonesia, this is likely to be scrub typhus (infection with Orienta Tsutsugamushi). Low platelets, raised LFTs and bilateral infiltrates on chest x-ray support this diagnosis.

First line treatment is with doxycycline for seven days, although a single dose of azithromycin may work in those for whom it is not possible to give doxycycline.

Mefloquine and Chloroquine are used in malaria. Supportive therapy is the recommended treatment in dengue fever.

Question 67 of 277

You are asked to review a patient on the ward who the nurse feels is looking very flushed. The nurse noticed the change in the patient whilst they were receiving their first dose of vancomycin. On examination the patient has no symptoms or signs of cardiorespiratory distress. Observations are as follows:

- Temperature 37.2 ºc
- Respiratory rate 18 breaths/min
- Saturations on air 97%
- Heart rate 70 beats/min
- Blood Pressure 136/72 mmHg

A blanching macular rash is evident on the patient's upper arms and upper thighs. No signs of urticaria or excoriations. The patient is penicillin allergic.

What is your next step?

A. Measure mast cell tryptase levels
B. Stop the infusion, give the patient piriton and hydrocortisone
C. Stop the infusion and give the patient piriton, hydrocortisone, adrenaline
D. Continue the infusion but slow it down and give the patient piriton
E. Stop the infusion, do not give any further treatment but discuss an alternative antibioticwith microbiology

D. Continue the infusion but slow it down and give the patient piriton

The most likely explanation for the patient's condition is a drug reaction called red man syndrome secondary to vancomycin infusion. This is not an allergic reaction as demonstrated by the lack of cardiorespiratory distress, subcutaneous oedema, wheals or urticaria. The reaction is more of a rate dependent infusion reaction. Treatment involves slowing down the infusion of vancomycin and administration of anti-histamines.

Question 68 of 277

A 75-year-old male with a long history of intravenous drug use is admitted with fevers, rigors and back pain. Three sets of blood cultures taken at admission grow positive for gram positive cocci in clusters. He is suspected of having *Staphylococcus aureus* bacteraemia and is commenced on intravenous vancomycin.

Half an hour after the infusion is commenced, he is noted by the nurse to be flushed. On examination, he is noted to have erythema over his neck, face and trunk but denies any significant distress or discomfort.

His observations are as follow: blood pressure 125/70 mmHg, heart rate 85/min, temperature of 36.8ºC, respiratory rate of 18/min and oxygen saturation of 98% on room air.

Which of the following is the most appropriate management?

A. Stopping the vancomycin infusion, administering 200mg of IV hydrocortisone and informing the patient that he is allergic to the medication
B. Stopping the vancomycin infusion and administering a single dose of 0.5mcgintramuscular adrenaline
C. Stopping the vancomycin infusion until symptoms resolve and then re-starting a slowerrate
D. Stopping the vancomycin infusion and prescribing topical 1% hydrocortisone cream toaffected areas
E. Continuing the vancomycin infusion and administering 1000 ml of 0.9% saline solutionover 1 hour

C. Stopping the vancomycin infusion until symptoms resolve and then re-starting a slowerrate

Red man syndrome is associated with rapid intravenous infusion vancomycin. It is a common adverse reaction of intravenous vancomycin use and is a distinct entity from anaphylaxis due to vancomycin use. Typical symptoms include redness, pruritus and a burning sensation, predominantly in the upper body (face, neck and upper chest). Severe cases can be associated with hypotension and chest pain.

The pathophysiology of red man syndrome is attributed to vancomycin-related activation of mast cells with release of histamine.

The management of red man syndrome involves cessation of the infusion, and when symptoms have resolved, recommencement at a slower rate. In patients who are more symptomatic antihistamines can be administered, and may require intravenous fluids if the syndrome is associated with hypotension.

Question 69 of 277

You are the medical basic specialist trainee on call and have been asked to see a gentleman who has just been admitted for a bad chest infection. According to the ward nurse, he has developed an allergic reaction after five minutes of vancomycin i.v infusion.

On arrival you proceed to examine this young man who is febrile, obviously unwell and receiving oxygen via nasal prongs. He claims he had not developed any new symptoms since admission but felt sudden warmth and flushing few minutes into his vancomycin drip. On examination he has crepitations in his left base.

Apart from generalised erythema he appears to be stable and there is no immediate danger to his airways. His blood pressure was 105/67mmHg, pulse was 99b/min and oxygen saturation on 4L oxygen was 95% (all observations are similar to previous readings). He has never taken vancomycin but states he is allergic to penicillin and ciprofloxacin.

Given the likely diagnosis, what is the next step in your management?

A. Immediately stop vancomycin
B. Continue vancomycin but at a slower rate
C. Continue vancomycin rate unchanged
D. Administer i.v chlorphenamine maleate and stop vancomycin
E. Urgent i.m adrenaline

B. Continue vancomycin but at a slower rate

Answer: continue vancomycin but at a slower rate.

This is typical red man syndrome caused by rapid infusion of vancomycin i.v. Vancomycin should be administered diluted and at a rate of 10mg/minutes for doses over 500mg i.v.

It is an IgE independent mast cell degranulation reaction that occurs up to 10 minutes into receiving vancomycin i.v at a fast rate. It is not a true allergic reaction thus vancomycin should be continued but at a lower rate of infusion.

Antihistamine prophylaxis, lower but frequent dosing and 2 hour infusion rate have been found to reduce the incidence of red man syndrome.

This gentleman is obviously unwell but his vitals and chest findings are more in keeping with his chest infection and possible sepsis.

Red-man syndrome after vancomycin: potential cross-reactivity with teicoplanin C Khurana, M A de Belder http://pmj.bmj.com/content/75/879/41.long

Question 70 of 277

A 36-year-old man is admitted with a painful right arm. On examination, there is mild erythema overlying the forearm but extreme tenderness to palpate. The arm is also tender beyond the area of erythema. Observations are as follows.

- Respiratory rate 32/min
- Oxygen saturation 94% on air
- Heart rate 134/min
- Blood pressure 72/44mmHg
- Temperature 38.4ºC

Over the next few hours, he deteriorates rapidly despite antibiotic therapy. The arm develops bullae and necrotic areas and ultimately requires amputation. His family arrive and ask how he could have developed this illness.

What recent infection could increase the risk of his current condition?

A. Chickenpox
B. Herpes simplex virus encephalitis
C. Influenza
D. Mumps
E. SARS-CoV2

A. Chickenpox

Chickenpox is a risk factor for invasive group A streptococcal soft tissue infections including necrotizing fasciitis

The correct answer is **chickenpox**. This patient has developed necrotising soft tissue infection, most commonly due to infection with group A streptococcus. Recent chickenpox is a recognised risk factor for invasive group A streptococcal (iGAS) infections such as this.

Herpes simplex virus encephalitis is incorrect. This is a severe central nervous system infection which does have complications including stroke and epilepsy. It is not known to increase the risk of iGAS.

Influenza is incorrect. The main bacterial infection seen in the aftermath of influenza is *Staphylococcus aureus* pneumonia.

Mumps is incorrect. It does have a range of complications including encephalitis and pancreatitis, but an increased risk of iGAS is not recognised.

SARS-CoV2 is incorrect. Infection with this virus can increase the risk of secondary bacterial respiratory tract infections. Some treatments also increase the risk of infections - for example, some areas saw increased rates of invasive fungal infections like mucormycosis related to highdose corticosteroid use. An association with iGAS, however, has not been described.

Question 71 of 277

A 27 week pregnant woman attends her GP with a 12 hour history of a rash. On examination, she has lesions consistent with a diagnosis of chickenpox. Her clinical observations are stable and she is otherwise well.

What would be the recommended management?

A. No treatment needed
B. Symptomatic treatment only (antihistamine & calamine lotion)
C. Oral aciclovir
D. Varicella-zoster immunoglobulin (VZIG)
E. Oral aciclovir & VZIG

C. Oral aciclovir

Pregnant women ≥ 20 weeks who develop chickenpox are generally treated with oral aciclovir if they present within 24 hours of the rash

The development of chickenpox in a pregnant woman is associated with increased morbidity, including pneumonia, hepatitis and encephalitis. Therefore, pregnant women who develop a chickenpox rash should see their GP immediately.

Oral aciclovir should be prescribed in pregnant women with chickenpox, if they present within 24 hours of the onset of the rash and are 20 weeks gestation or beyond. (Use before 20 weeks can be considered).

Aciclovir reduces the duration of fever and symptomatology of varicella, if commenced within 24 hours of developing the rash. Symptomatic treatment can be used alongside aciclovir.

Pregnant women with severe chickenpox should be referred to hospital for intravenous aciclovir. In addition, a referral to fetal medicine would be necessary (in the above scenario), due to the small risk of fetal varicella syndrome in the first 28 weeks of pregnancy.

It is important to advise anyone with chickenpox to avoid contact with other potentially susceptible people, such a pregnant women and neonates until the last lesions have crusted over (usually 5 days after the onset of the rash).

VZIG has no therapeutic benefit once the rash has started. RCOG Greentop guidelines, Chickepox in pregnancy.

Question 72 of 277

A 20-year-old law student had been backpacking around India for 2 months over her summer holiday. She spent time in a number of rural and coastal areas and volunteered at a wildlife conservation project for 2 weeks. She took malaria prophylaxis throughout.

A few days before her return to the UK she noticed a small nodule on her left forearm. The nodule has gradually enlarged and ulcerated over the last 4 weeks to form a 4cm painless ulcer.

What is the most appropriate investigation to confirm the diagnosis?

A. Biopsy of a draining lymph node
B. Montenegro skin test
C. Punch biopsy of the lesion for histology
D. Serology
E. Serum PCR

C. Punch biopsy of the lesion for histology

Cutaneous leishmaniasis is typically diagnosed using a punch biopsy

This patient has cutaneous leishmaniasis. This is a protozoal infection mainly caused by *Leishmania major*, *Leishmania tropica* and *Leishmania aethiopica* in Asia, Africa, the Middle East and the Mediterranean, and by *Leishmania braziliensis* and *Leishmania mexicana* in Central and South America. It presents classically with a slowly developing painless ulcer at the site of a sandfly bite.

The most appropriate investigation to confirm the diagnosis is **punch biopsy of the lesion for histology**. The biopsy should be taken from the outer border of the ulcer and should be full thickness. The specimen can be examined using Wright or Giemsa stains to look for amastigotes in the tissue. Culture or PCR can also be performed on the tissue sample.

Biopsy of a draining lymph node is incorrect. You are unlikely to see parasites in tissue samples outside of the ulcer itself in cutaneous leishmaniasis, as the infection is limited to the ulcer only.

Montenegro skin test is incorrect. This is a test in which killed promastigotes are injected under the skin, and the degree of induration at the site is read 48-72 hours later. It is used in some South American countries but is not recommended as the sensitivity is low and it cannot differentiate between past and current infections.

Serology is incorrect. This is not used in diagnosing cutaneous leishmaniasis because antibody levels are generally low, meaning that the sensitivity of the test is low. The specificity is also variable and there may be cross-reactivity with other infections.

Serum PCR is incorrect. PCR can be carried out on tissue samples from the lesion but is not carried out on serum as there would be minimal or no protozoal DNA in the circulating blood, so the sensitivity would be too low.

Question 73 of 277

A 43-year-old man presents to the emergency department with a fever, rash, and headache. He has recently returned from travelling around the Solomon Islands. He has no past medical history of note.

On examination, he has a diffuse morbilliform rash and a dark, scab-like lesion is noted on his leg. His temperature is 38.4ºC.

Given the likely diagnosis, what is the most appropriate management?

A. Atovaquone-proguanil
B. Ceftriaxone
C. Ciprofloxacin
D. Doxycycline
E. Supportive management

D. Doxycycline

Doxycycline is typically used in the management of typhus

Doxycycline is correct. The patient presents with a fever, headache, and rash. These are common features of many illnesses in the returning traveller. However, the dark scab-like lesion is more discriminating and in the context of a patient returning from the Solomon Islands, this likely represents the black eschar associated with scrub typhus infection. The Solomon Islands from the southern tip of the 'Tsutsugamushi Triangle' where scrub typhus is endemic. The treatment is with doxycycline.

Atovaquone-proguanil is incorrect. Also known as Malarone, this is an accepted oral treatment for uncomplicated malaria. Malaria is present in the Solomon Islands but a rash is actually uncommon in malaria and a black eschar is not a feature.

Ceftriaxone is incorrect. This would be an appropriate treatment for typhoid, which is a common cause of fever in returning travellers. A black eschar is not a feature of typhoid infection.

Ciprofloxacin is incorrect. This would be an appropriate treatment if we suspected anthrax. This is another cause of eschar. However, while a patient with anthrax may be systemically unwell, a diffuse morbilliform rash is not typical. Additionally, the eschar of anthrax may be associated with some perilesional oedema and blister which are not mentioned here.

Supportive management is incorrect. The mortality rate of scrub typhus is 6% untreated. Management is with doxycycline.

Question 74 of 277

A 46-year-old man telephones his GP for advice. Five days ago, he was in contact with his nephew, who was unwell and had a rash at the time. It has since been confirmed that his nephew has measles. The patient is concerned as he was not immunised against measles as a child. Furthermore, he takes methotrexate for rheumatoid arthritis.

He has no symptoms currently.

What is the most appropriate treatment?

A. Immunoglobulin
B. Measles, mumps and rubella (MMR) vaccine
C. Measles, mumps and rubella (MMR) vaccine and immunoglobulin
D. Measles-only vaccine
E. No treatment

A. Immunoglobulin

Those exposed to measles can be given immunoglobulin to reduce the risk of infection

The most appropriate course of action, for a patient who is immunosuppressed and does not have adequate immunity to measles, is to administer **immunoglobulin** following exposure. Ideally, this should be done within 72 hours, but can be done up until 6 days post-exposure.

For patients with normal immunity, who have not been fully immunised against measles, the **MMR vaccine** should be administered within 72 hours of exposure.

Administering both the **MMR vaccine and immunoglobulin** is inappropriate. This can invalidate the effect of the vaccine.

Giving the **measles-only vaccine** would also be inappropriate. This patient should be given immunoglobulin. For a patient with normal immunity, who is not fully immunised, the MMR vaccine should be given rather than a measles-only vaccine.

No treatment is incorrect. Given this patient's clear exposure and history of both immunosuppression and lack of immunisation against measles, immunoglobulin should be given.

Question 75 of 277

A 35-year-old man is referred to a tuberculosis (TB) clinic after his wife is confirmed to have fully sensitive pulmonary TB. There is no history of cough, fevers or weight loss. He has no medical problems, does not take any medication regularly and does not smoke or drink alcohol. His blood tests show:

HIV antibody test	negative
Hepatitis B surface antigen test	negative
Hepatitis B surface antibody test	positive
Hepatitis C antibody test	negative
Interferon-gamma release antibody	positive

What is the most appropriate treatment to offer initially?

A. 2 months of rifampicin, isoniazid, pyrazinamide, ethambutol and pyridoxine
B. 2 months of tenofovir
C. 3 months of rifampicin, isoniazid and pyridoxine
D. 48 weeks of peginterferon alfa-2a
E. 6 months of rifampicin only

C. 3 months of rifampicin, isoniazid and pyridoxine

Latent tuberculosis treatment options:

- 3 months of isoniazid (with pyridoxine) and rifampicin, or
- 6 months of isoniazid (with pyridoxine)

This patient has latent TB as evidenced by a positive interferon-gamma release antibody (IGRA) test and no other symptoms consistent with active TB. NICE advises that treatment for latent TB should be with either **3 months of rifampicin, isoniazid and pyridoxine** or 6 months of isoniazid and pyridoxine.

This patient has either been immunised against Hepatitis B or previously infected and therefore has a positive Hepatitis B surface antibody test but a negative antigen test. If they had chronic hepatitis B they would have a positive antigen test. Treatment of chronic hepatitis B includes onceweekly injections of **peginterferon alfa-2a, a recombinant interferon, for 48 weeks** or antivirals such as **tenofovir** or entecavir.

If this patient had a positive IGRA test and symptoms consistent with active TB, they would require treatment for active TB with **2 months of rifampicin, isoniazid, pyrazinamide, ethambutol and pyridoxine** followed by 4 months of rifampicin, isoniazid and pyridoxine.

6 months of rifampicin only can be used to treat patients with latent TB but is not recommended by NICE guidelines. It could also be used if this patient's wife had isoniazid-resistant pulmonary TB.

Question 76 of 277

A 38-year-old man presents to the emergency department with fever and shivering, occurring approximately every two days. He has returned from India three weeks ago, having spent four months travelling. While he was in India, he was treated for malaria with chloroquine. He has no other past medical history and does not take any regular medications.

Observations:

- Heart rate 88 beats/min
- Blood pressure 120/77 mmHg
- Respiratory rate 18 breaths/min
- Oxygen saturations 98% on room air T
- emperature 38.6ºC

On examination, the patient is diaphoretic. There is palpable splenomegaly. A thick and thin blood film confirms malaria.

What organism is most likely to be responsible?

A. Plasmodium falciparum
B. Plasmodium knowlesi
C. Plasmodium malariae
D. Plasmodium ovale
E. Plasmodium vivax

E. Plasmodium vivax

P. vivax and *ovale* have hypnozoite forms, which can cause clinical disease long after patients

leave the endemic area or may cause relapsing disease following treatment

Plasmodium vivax is the correct answer. The patient has a confirmed diagnosis of malaria, having previously been treated for malaria within the last six months. This suggests a relapse of disease. The two forms of malaria that cause relapsing disease are Plasmodium vivax and Plasmodium ovale. Plasmodium vivax is more common in India while Plasmodium ovale is more common in Africa. Chloroquine is the typical treatment in most countries. This medication acts on blood-stage parasites only and does not act on hypnozoites. The only available drug that can kill the hypnozoites is primaquine.

Plasmodium falciparum is incorrect. This type of malaria does not cause relapsing disease.

Plasmodium knowlesi is incorrect. This form of malaria, which is common in South-East Asia does not cause relapsing disease.

Plasmodium malariae is incorrect. This does not cause relapsing disease and is a less common form of malaria. Additionally, it causes fever every three days rather than every two days as in other forms of malaria.

Plasmodium ovale is incorrect. This can also cause relapsing disease. However, it does so far less commonly than *vivax* malaria and is more common in Africa rather than Asia.

Question 77 of 277

A 42-year-old woman visits the emergency department with a 4-day history of high fevers and myalgia. She has just landed in the UK from the Democratic Republic of the Congo. Her past medical history includes uterine fibroids and iron deficiency anaemia for which she takes regular ferrous sulfate.

Her observations are as follows:

- Temperature 39.1ºC
- Heart rate 122bpm
- Blood pressure 105/80mmHg
- Respiratory rate 15 breaths/min
- Oxygen saturations 99% on air

On examination, she is clammy to touch and complains of a headache. Her chest sounds are clear and her heart sounds are normal. She has a soft and non-tender abdomen. On closer examination, there are multiple enlarged and tender lymph nodes in her axillae and groin.

What is the most likely causative organism?

A. Burkholderia pseudomallei
B. Mycobacterium leprae
C. Treponema pallidum pertenue
D. Yersinia pestis
E. Zaire ebolavirus

D. Yersinia pestis

The plague is caused by the gram-negative bacterium *Yersinia pestis*. Three clinical presentations can occur: bubonic (most common), pneumonic and septicaemic

This patient has a diagnosis of the bubonic plague, caused by the gram-negative bacterium ***Yersinia pestis***. It is transmitted by fleas and is endemic to the Democratic Republic of the Congo, Madagascar, and Peru. Symptoms typically include flu-like symptoms from 3-7 days post-exposure followed by the eruption of inflamed, tense and painful lymph nodes. The disease carries a significantly high mortality rate if not treated and prompt recognition and antibiotic administration (i.e. Streptomycin) can reduce the mortality from 60% to 15%.

Melioidosis is a bacterial illness caused by ***Burkholderia pseudomallei***. It is a tropical disease seen in South-East Asia, Africa, the Middle East and the South Pacific. Some may present with a localised skin infection from exposure to the bacterium as it enters the skin (e.g. nodule or ulcer formation) whereas other patient's progress to septicaemia and abscess formation. Melioidosis is not associated with inflamed and painful lymph nodes making it an unlikely diagnosis.

Leprosy is a granulomatous disease caused by ***Mycobacterium leprae*** which affects the peripheral nerves and skin causing symptoms such as loss of temperature and light touch followed by loss of pain sensation. Associated cutaneous lesions follow later in the disease and appear as hypopigmented patches of skin. These symptoms are not seen in the above patient and leprosy is not associated with painful lymphadenopathy.

Yaws is a chronic skin infection caused by the bacterium ***Treponema pallidum pertenue***. There are several stages of illness with the disease initially presenting as a papule from the site of infection that later ulcerates. As the disease progresses, more widespread papules appear over the rest of the body. These lesions are not seen with this patient, making Yaws incorrect.

Ebola virus disease is an extremely deadly disease caused by multiple different viruses including **Zaire ebolavirus**. The disease causes flu-like symptoms including fever, myalgia and sore throat along with gastrointestinal symptoms such as abdominal pain and vomiting. Zaire ebolavirus causes a haemorrhagic illness and as the disease progresses, patients develop unexplained bleeding and bruising. Although this patient has flown from a high-risk area for the Ebola virus, she has no gastrointestinal symptoms or haemorrhagic symptoms.

Question 78 of 277

A 38 year-old woman presented to the medical outpatient clinic with an 8 month history of deteriorating vision. She also complained of a pruritic rash intermittently affecting her forearms and neck. She had recently migrated to the UK from Guinea, where she had lived since birth. She had suffered from malaria as a child but had been fit and well since. She did not smoke and drank 6-10 units of alcohol per week.

On examination, her temperature was 36.7ºC, pulse was 68 beats per minute and blood pressure was 124/80 mmHg. Her chest was clear on auscultation and heart sounds were normal. Fundoscopy was not possible due to clouding of both corneas. There was evidence of a mottled rash over the forearms and neck with a leopard print appearance.

Investigations:

Haemoglobin	141 g/L (130-180)
White cell count	6.7 x /L (4.0-11.0)$_{9}$
Neutrophil count	3.0 x /L (2.0-7.5)$_{9}$
Lymphocyte count	1.7 x /L (1.3-3.5)$_{9}$
Eosinophil count	0.6 X /L (0.1-0.4)$_{9}$
Platelets	260 x /L (150-400)$_{9}$
Sodium	138 mmol/L (135-145)
Potassium	4.3 mmol/L (3.5-5.0)
Urea	7.2 mmol/L (2.5-7.5)
Creatinine	61 mol/L (25-95)
Fasting plasma glucose	5.0 mmol/L (3.0-6.0)
Giemsa-stained blood film	No abnormality detected

Given the likely diagnosis, what is the most appropriate treatment?

A. Diethylcarbamazine (DEC)
B. Ivermectin
C. Benzinidazole
D. Albendazole
E. Praziquantel

B. Ivermectin

This patient has presented with features of onchocerciasis, a disease caused by the filarial nematode Onchocerca volvulus. The parasite is transmitted by blackflies of the genus Simulium, which deposit the parasites larva onto the skin when biting to extract blood. The adult worm lives in subcutaneous nodules and produces larvae, which become deposited in the skin and eyes. Disease manifests when the parasite dies in tissues and releases Wolbachia endosymbiotic bacteria into tissues, provoking a host immune response. This above patients disease has manifested as river blindness, where the worms die in the cornea and provoke chronic inflammation, eventually leading to clouding of the cornea. Inflammation in subcutaneous tissues leads to a pruritic rash and formation of a leopard-skin appearance over time. The worms can be visualised by microscopy of skin snip biopsy. The treatment of choice is ivermectin; DEC should not be used because rapid death of the worms can exacerbate damage to surround tissues and even cause complete blindness.

Question 79 of 277

A 29-year-old lady comes to see you for advice having seen news of the recent Zika virus outbreak. She and her husband are planning on starting a family, but she has only arrived back from Brazil last week after a business trip. She has not experienced any fever or worrying symptoms, either during travel or since arrival back in the UK.

What would be the most appropriate advice to give her?

A. Start 5mg folic acid daily
B. If no fever can become pregnant
C. Need to check Zika virus serology before becoming pregnant
D. Should avoid becoming pregnant for at least 2 weeks after travel
E. Should avoid becoming pregnant for at least 8 weeks after travel

E. Should avoid becoming pregnant for at least 8 weeks after travel

The latest advice as per Public Health England is that women who are considering becoming pregnant should avoid becoming pregnant while travelling in an area with active Zika virus transmission, and for 8 weeks after their return.

Whilst folic acid is recommended to women trying for pregnancy, the usual dose is 400 micrograms daily and there is currently no recommendation to increase this after Zika exposure. The test for Zika serology is only recommended for patients with a relevant travel history and current symptoms.

Question 80 of 277

A 27-year-old man who recently immigrated to the UK from Ethiopia complains of a chronic cough with night sweats for five weeks. On direct questioning, he also admits coughing up small volumes of bright red blood a few times. This has made him especially concerned as he his father died from lung related problems following chronic coughs.

Following a chest X-ray and blood tests he is diagnosed with TB and contact tracing is started. His 25-year-old male partner lives with him and is identified as being at high risk of contracting TB. The partner undergoes Mantoux testing and has a 2mm area of induration. He has never had BCG vaccination as far as he is aware and has no vaccination scar.

What is the most appropriate management that should be offered to the partner?

A. BCG vaccination
B. HIV testing and if negative then BCG vaccination
C. Prophylactic anti-TB treatment
D. Repeat TB screening in six weeks
E. No further management needed

B. HIV testing and if negative then BCG vaccination

The correct answer is HIV testing and if negative then BCG vaccination. The low area of response to the Mantoux testing indicates that he is unlikely to have TB and has not been vaccinated. However, the test can be a false negative result in an immunosuppressed patient. As the partner is at increased risk of HIV, NICE advises that an HIV test should be done prior to vaccination. BCG vaccination is a live vaccination and therefore is contraindicated in an immunosuppressed patient. Of note, previous vaccination can lead to a false positive result.

NICE advises that once a diagnosis of pulmonary TB has been made then close contacts should be managed as follow:

- If asymptomatic and younger than 65 years then test for latent TB. If Mantoux-negative and unvaccinated then offer vaccination. If at risk of HIV then test for HIV first.
- If asymptomatic and older than 65 years then assess with a chest X-ray.

Treatment for TB should be considered if TB is confirmed and not used prophylactically. Repeat screening is generally not used.

Question 81 of 277

A 35-year-old man is referred to the medical assessment unit by his general practitioner. He reports two months of episodic swellings of the soft tissue near various joints that are hot and occasionally pruritic. He has no past medical history and is not on any regular medications. He has recently returned from spending six months in Equatorial Guinea.

On examination, there is a large, 2 x 3cm non-pitting swelling of his dorsal forearm that is hot but not erythematous.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	14.2 * 10 /L 9	(4.0 - 11.0)
Neuts	6.5 * 10 /L 9	(2.0 - 7.0)
Lymphs	2.2 * 10 /L 9	(1.0 - 3.5)
Mono	0.3 * 10 /L 9	(0.2 - 0.8)
Eosin	5.2 * 10 /L 9	(0.0 - 0.4)

What is the likely diagnosis?

A. Cutaneous larva migrans
B. Cutaneous leishmaniasis
C. Loiasis
D. Schistosomiasis
E. Syphilis

C. Loiasis

Calabar swellings: transient, non-erythematous, hot swelling of soft-tissue around joints → loiasis

Loiasis is the correct answer. The patient presents with transient, non-erythematous, hot swellings of the soft tissues around joints. This is a description of so-called Calabar swellings, which are associated with loiasis. This condition is a filarial infection caused by the nematode Loa Loa. The Calabar swellings are caused by an immune reaction to the worms. Eosinophilia is common in this condition and it is endemic to Equatorial Guinea.

Cutaneous larva migrans is incorrect. This can cause skin lesions and eosinophilia. However, the lesions in this condition (which is caused by a hookworm infection) are classically serpiginous in outline and therefore a 2x3cm lesion would not be characteristic.

Cutaneous leishmaniasis is incorrect. This condition is transmitted by sandflies. It characteristically causes an ulcerative lesion, which is not present in this case as there is no mention of skin erosion. Additionally, the lesions tend not to be transient and persist without treatment.

Schistosomiasis is incorrect. An acute schistosomiasis infection is typically characterized by fever, blotchy rash, myalgia, arthralgia and diarrhoea. So while it is endemic in Equatorial Guinea and associated with blood eosinophilia, the presentation is not characteristic of the disease.

Syphilis is incorrect. This can cause a skin lesion called a chancre, which is a painless ulcer. However, this typically occurs on the genitals and occurs once rather than episodically. Additionally, eosinophilia is not typical of this condition.

Question 82 of 277

A 25-year-old man is seen in the walk-in travellers clinic. He returned from a holiday in Brazil 5 days ago and has a 1 day history of fever, headache and myalgia. He is usually fit and well. He tells you he took regular malaria prophylaxis while away.

On examination he has a heart rate of 110 beats per minute and a blood pressure of 102/72 mmHg. His temperature is 38.1 ºC and he has dry mucous membranes. Examination of cardiovascular, respiratory and gastrointestinal systems is unremarkable but he has multiple mosquito bites over his arms and legs.

His blood tests are as follows:

Hb	132 g/l	Na +	144 mmol/l	Bilirubin	8 µmol/l
Platelets	91 * 10 /l 9	K +	3.5 mmol/l	ALP	98 u/l
WBC	13 * 10 /l 9	Urea	9.7 mmol/l	ALT	22 u/l
Neuts	11 * 10 /l 9	Creatinine	111 µmol/l	γGT	14 u/l
Lymphs	0.6 * 10 /l 9	CRP	78 mg/l	Albumin	40 g/l

He is admitted for broad spectrum antibiotics, fluids and analgesia but his fever continues. His malaria films are negative but he has a positive PCR for dengue virus. Antibiotics are stopped but fluids are continued. His fever and headache settle though he does developed some mild ankle oedema.

Which of the following is true regarding his discharge?

A. Dengue shock is unlikely to occur after 24 hours post-fever
B. Dengue shock is unlikely to occur once platelets improving
C. Dengue shock is unlikely to occur once renal function improving
D. Platelets above 20 * 109/l are considered safe for discharge
E. Stable haematocrit is essential for discharge

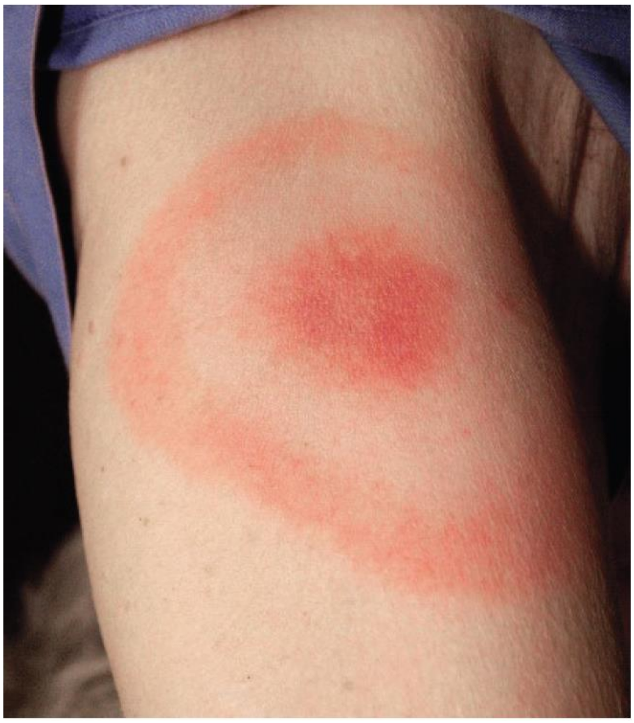
E. Stable haematocrit is essential for discharge

This gentleman is admitted in the febrile phase of his dengue infection. The plasma leak phase may occur anytime within the first 48 hours after the fever has broken and manifests with leakage into pleural and peritoneal spaces. It may be accompanied by shock and in some cases haemorrhage. Platelets and renal function may be falsely reassuring as they tend to improve after the febrile phase but rising haematocrit is a sensitive sign of plasma leak. It is therefore essential to monitor patients for a full 48 hours after the febrile phase and ensure haematocrit is stable prior to discharge. Platelets should be at least 50 * 109/l and rising prior to discharge.

Question 83 of 277

A 28-year-old woman presents to the dermatology clinic with a rash on her right upper arm. She says it has been enlarging over the past 2 weeks. There is no history of pain or itch. Her past medical history includes mild gastritis and she is 14-weeks pregnant. She has no known allergies.

On examination, her observations are within normal limits. Her rash is examined, as shown below:



What is the recommended management for this patient?

A. Amoxicillin
B. Clotrimazole
C. Doxycycline
D. Phenoxymethylpenicillin
E. Prednisolone

A. Amoxicillin

This patient's rash is typical of erythema migrans given the 'bulls-eye' appearance of a circular erythematous centre with a clear border and outer erythematous border. Erythema migrans is typically associated with Lyme disease, a zoonotic infection secondary to the spirochete *Borellia burgdorferi*. It is spread by the bites of infected ticks. Associated symptoms include fever, myalgia and fatigue. The rash can appear 1-2 weeks following a tick bite and can enlarge in size over time with central clearing. The lesions are not typically painful or itchy.

Amoxicillin is correct. The typical first-line treatment for Lyme disease is doxycycline. However, as this patient is pregnant, doxycycline is contraindicated and amoxicillin is the next best treatment of choice.

Clotrimazole is incorrect. This is used in the treatment of fungal infections including tinea corporis. Tinea corporis can present similarly with a circular lesion and an erythematous outer border.

However, the lesions with ringworm are usually itchy with a scaly outer edge which is not seen here.

Doxycycline is incorrect. This is the first-line management for lyme disease. However, doxycycline is contraindicated in pregnancy due to the risk of bone and teeth deformity. Therefore, the most appropriate option would be amoxicillin.

Phenoxymethylpenicillin is incorrect. This is typically used in the management of infections caused secondary to Streptococcal species (e.g. *Streptococcus pyogenes*). Group A Streptococci such as *Streptococcus pyogenes* have the potential to cause infections such as tonsillitis and rheumatic fever. Rheumatic fever is associated with erythema marginatum, an annular erythematous rash that appears on the trunk, upper arms and legs that spread outwards in a circular shape with central clearing. However, this is very rare in adults and in developed countries.

Prednisolone is incorrect. Corticosteroids can be used for several inflammatory skin conditions including eczema and psoriasis. However, these lesions are often multiple, exfoliative, scaly and itchy which is not seen in this patient's presentation. Therefore, an alternative diagnosis should be considered.

Question 84 of 277

A 45-year-old female presents with a rash. She states that she initially felt feverish and had a runny nose. This progressed to a rash over her arms, trunk and legs. She recently immigrated to the UK from Poland. She lived in a travellers community in Poland and is not aware of any childhood vaccinations. She has a past medical history of asthma and hereditary spherocytosis. On examination you note a erythematous maculopapular rash over the the upper limbs, thorax and lower limbs.

The following investigations were performed:

Hb	95 g/l	Na +	138 mmol/l
Platelets	110 * 10 /l 9	K +	3.8 mmol/l
WBC	3.8 * 10 /l 9	Urea	6.5 mmol/l
Neuts	1.8 * 10 /l 9	Creatinine	58 µmol/l
Lymphs	1.6 * 10 /l 9	CRP	48 mg/l

What is the most likely diagnosis?

A. Measles
B. Mumps
C. Rubella
D. Parvovirus B19
E. Scabies

D. Parvovirus B19

Parvovirus B19 can cause fever, rash and patients with predisposing haematological conditions, pancytopenia

The patient has presented with a febrile rash. The differential is wide. The immunisation history should alert you to possible measles or rubella. However the presence of pancytopenia favours a diagnosis of parvovirus B19 infection which is associated with an aplastic crisis.

Although most patients have a decrease of hematopoiesis during parvovirus infection, it is most dangerous in patients with pre-existing bone marrow stress (e.g. sickle cell anaemia or hereditary spherocytosis) as these disorders are heavily dependent on erythropoiesis due to the reduced lifespan of the red cells.

Question 85 of 277

A 42-year-old man presents with a fever and shortness of breath. Of note, he is a cattle farmer. Observations are as follows: heart rate 82 beats per minute, blood pressure 130/85 mmHg, temperature 38.2ºC, respiratory rate 20 breaths per minute, and SpO2 95% on air.

Blood results are as follows:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	162 * 10 /L 9	(150 - 400)
WBC	14.4 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)
CRP	44 mg/L	(< 5)
Bilirubin	16 µmol/L	(3 - 17)
ALP	104 u/L	(30 - 100)
ALT	146 u/L	(3 - 40)
Î³GT	68 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

A chest x-ray is as follows:

Chest x-ray	Perihilar patchy reticulonodular opacities

What treatment is indicated?

A. Amoxicillin
B. Clarithromycin
C. Co-amoxiclav
D. Doxycycline
E. Levofloxacin

D. Doxycycline

Doxycycline should be used to treat Q fever

Doxycycline is correct. The chest x-ray appearances are suggestive of atypical pneumonia. Atypical pneumonia associated with fever, hepatitis, and exposure to cattle is highly suggestive of Q fever. Doxycycline is the antibiotic of choice for Q fever.

Amoxicillin is incorrect. Penicillins are ineffective against Q fever since the bacteria is intracellular.

Clarithromycin is incorrect. Whilst macrolides have activity against some intracellular bacteria, they are not considered the first-line treatment choice for Q fever due to a limited evidence base.

Co-amoxiclav is incorrect. Penicillins are ineffective against Q fever since the bacteria is intracellular.

Levofloxacin is incorrect. Q fever can be treated with fluoroquinolones however these agents are not first-line since they have a much broader spectrum.

Question 86 of 277

A 55-year-old man was admitted with a fever, pain, and erythema across his abdomen. He had been discharged 8 days prior following an elective repair of an umbilical hernia. He has a background of type 2 diabetes mellitus and a raised body mass index of 32kg/m² (normal range 18.5 - 24.9kg/m²).

He had been recovering from his operation at home and had felt well up until that morning. He had noticed a small area of erythema and tenderness around the incision site near his umbilicus. This area of erythema seemed to grow and become more painful throughout the day, therefore, he was brought to the Emergency Department by his wife.

On examination, he looked unwell. His observations were as follows:

- temperature 38.6ºC
- respiratory rate 23 breaths/min
- oxygen saturation 97% on air
- heart rate 125bpm
- blood pressure 88/61mmHg

He felt nauseous and had vomited once, complaining of severe abdominal pain. There was a large area of erythema across the lower half of his abdomen which was extremely tender to palpation. Examination of the erythematous area also revealed impaired sensation to light touch.

His blood results:

WBC	17 * 10 /L 9	(4.0 - 11.0)
CRP	460 mg/L	(< 5)

What is the most likely cause of this patient's infection?

A. Polymicrobial
B. Streptococcus pyogenes
C. Aeromonas hydrophila
D. Staphylococcus epidermidis
E. Bacillus anthracis

A. Polymicrobial

Type 1, or polymicrobial, necrotising fasciitis is the most common

This patient is systemically unwell with a rapidly progressive soft tissue infection. Diabetes mellitus is a risk factor for necrotising fasciitis and his recent operation served as a cutaneous portal of entry for causative organisms. A rapidly expanding area of cellulitis in a systemically unwell patient should alert you to the possible diagnosis of necrotising fasciitis. Furthermore, the presence of anaesthesia of the area and pain out of keeping with the visible skin changes is also characteristic of this condition. Whilst necrotising fasciitis is often seen in the extremities, it can also occur in the perineum, head, neck, and trunk.

The most common cause of necrotising fasciitis is type 1, caused by polymicrobial infection of subcutaneous tissue (organisms present include *Bacteroides*, *Peptostreptococcus*, *E. coli*, *Enterobacter*, etc). Bacteria are introduced into the skin via minor skin trauma or surgery and track along fascial planes, extending beyond the area of overlying cellulitis.

Type 2 necrotising fasciitis is a monomicrobial infection most commonly caused by *Streptococcus pyogenes*.

Aeromonas hydrophila is a less common cause of necrotising fasciitis, typically associated with freshwater exposure.

Staphylococcus epidermidis is a commensal organism present on the skin and the most common cause of infections from indwelling medical devices.

Bacillus anthracis, a gram-positive bacteria, causes cutaneous anthrax. There is typically a history of exposure to animals/animal products or IV drug use. A papule forms following exposure which develops into a black eschar with surrounding oedema.

Question 87 of 277

A 48-year-old man presented to the emergency department with a headache, confusion, and slurred speech. His past medical history, family history, and medication history were unremarkable. He had returned to the UK three weeks ago from Germany where he had been camping in a forest with his family. On the last day of his trip, he noticed a tick on his right leg which he carefully removed with tweezers. One week later, he began to develop fevers, muscle aches, and fatigue so was prescribed doxycycline by his GP. After about 7 days these symptoms resolved but over the past 24 hours, he began to feel worse. His family is in good health and he denied any unwell contacts.

On examination, he was confused with a score of 14/15 on the Glasgow Coma Scale and a noticeable tremor. He was globally weak and looked lethargic. His observations were as follows:

- temperature 38.5ºC
- respiratory rate 19/min
- heart rate 92bpm
- blood pressure 128/84mmHg
- oxygen saturations 98% on room air

Examination of his chest and abdomen was unremarkable and no rashes could be seen. A CT head scan was unremarkable.

A lumbar puncture was performed and the patient was started on empirical treatment with IV aciclovir and ceftriaxone. The CSF results were as follows:

Polynuclear WBCs	3 cells/µL	(0-5 cells/µL)
Mononuclear WBCs	71 cells/µL	(0-5 cells/µL)
Red blood cells	8 cells/µL	(0-10 cells)
Glucose	4.5 mmol/L	(>70% serum glucose)
Protein	0.89 g/L	(0.15-0.45 g/L)
Cytomegalovirus CSF PCR	negative	
Enterovirus CSF PCR	negative	
Epstein-barr virus CSF PCR	negative	
Herpes simplex virus 1 and 2 CSF PCR	negative	
Varicella zoster virus CSF PCR	negative	

Blood test results were as follows:

Serum glucose	5.1 mmol/L	(4 - 11.1 mmol/L)

Borrelia burgdorferi IgG	negative
Borrelia burgdorferi IgM	negative
Treponema pallidum screening serology	negative
Tuberculosis IGRA	negative
HIV screening serology	negative

What is the most appropriate management of this patient given the likely diagnosis?

A. A further course of doxycycline
B. Continue aciclovir
C. Supportive management
D. IV immunoglobulin
E. Praziquantel

C. Supportive management

investigations for HSV-1 and HSV-2 and

Treatment for tick-borne encephalitis is supportive

This patient presents with a history typical of tick-borne encephalitis. Tick-borne encephalitis (TBE) presents as meningoencephalitis, caused by a flavivirus infection of the central nervous system. This virus is transmitted by the *Ixodes* tick, the activity of which is usually highest in the summer months. The disease is endemic in Central and Eastern Europe and the Far East (Russia, China, northern Japan). The disease starts 4-28 days after being bitten by the infected tick and presents in a biphasic fashion. After a few days of fever, fatigue, and myalgia, the patient will have a symptomfree interval before progressing to central nervous system dysfunction (meningitis/encephalitis/cranial nerve palsies).

Diagnosis is generally by CSF/serum serology for TBE-specific antibody and management is supportive - aciclovir is given initially as an empirical treatment but can be stopped when HSV/VZV is ruled out.

In this case, whilst the specific serology confirming the infection is not given, the other investigations and history of a tick bite point towards this diagnosis. He has a predominantly lymphocytic pleocytosis with a raised CSF protein which is typical for viral CNS infections.

Whilst doxycycline appeared to help this patient initially, this coincided with the symptom-free interval commonly seen in the biphasic illness of TBE. Negative serology for *Borrelia burgdorferi* makes a diagnosis of Lyme disease very unlikely. Therefore, another course of doxycycline is not appropriate.

Continuing aciclovir is not necessary given that the CSF VZV are negative.

IV immunoglobulin can be used for autoimmune/paraneoplastic encephalitis but there is nothing in the stem to suggest that this is the underlying pathological process.

Praziquantel is a drug used in the treatment of parasitic infections such as schistosomiasis.

The management of TBE is supportive. Whilst it would be important to identify the cause by performing further serological testing, this is not an option.

Question 88 of 277

A 55-year-old woman is referred for an urgent assessment by the infectious diseases team after presenting to her local out of hours GP. The patient stated that she was concerned about having caught Lyme disease during a recent day out in the New Forest in Hampshire, UK. The patient was particularly concerned about this diagnosis as she had a close friend who had been forced to give up work after suffering from neuroborreliosis.

On closer questioning, the patient reported that 2 days previously she had gone on a walk in the New Forest. When she had arrived home that evening she had found two engorged ticks attached to her right lower leg. Her husband had removed the ticks by applying nail polish to them and then pulling them off with tweezers.

The patient denied suffering from any symptoms at the time of presentation though admitted she was very anxious. In particular, the patient had not experienced any neurological or cardiovascular symptoms and had not observed any skin rashes.

The patient was receiving treatment from her GP for hypercholesterolaemia and mild asthma. The patient had no known drug allergies and was employed as a legal secretary at a local firm.

A full examination of the patient's skin was performed and no abnormal rashes or other skin changes were identified. No focal neurology was identified on examination of the peripheral and central nervous systems. The assessment did not identify any signs of meningism. The patient was afebrile.

What is the appropriate management of this patient's tick bites?

A. Treat with amoxicillin for 14 days
B. Immediate serological testing for pathogenic Borrelia species
C. Serological testing for pathogenic Borrelia species in 4 weeks (to allow for seroconversion)
D. No investigation or treatment indicated at present time, carefully observe for onset ofsymptoms
E. Treat with doxycycline for 14 days

D. No investigation or treatment indicated at present time, carefully observe for onset ofsymptoms

There is no need for prophylactic antibiotics for Lyme disease in asymptomatic patients bitten by a tick

This patient has a convincing history for the attachment of ticks from a region of the UK at high risk of Lyme borreliosis. When assessing the risk of tick bites it is important to clarify for how long the tick was attached and if it became engorged. Transmission of pathogenic *Borrelia* species is unlikely if ticks are attached for less than 24 hours or do not become engorged. Ticks should be removed gently using tweezers to minimise irritation to the skin and the risk of rupturing the tick which can increase the risk of infection.

Asymptomatic patients who report a tick bite should not undergo serological testing or receive treatment. Testing can lead to false positives secondary to previous infection or cross-reactive antibodies. Prophylactic treatment of tick bites may be required if the patient is immunosuppressed or in certain regions of the USA where the prevalence of infected ticks is particularly high.

When serological testing is indicated paired blood samples should be taken at four week intervals to allow seroconversion to take place. Treatment with doxycycline or amoxicillin for 14 days is the appropriate treatment for a patient presenting with erythema migrans after a tick bite.

Question 89 of 277

A 14-year-old, unvaccinated child is brought into the emergency department after possible exposure to measles. The child has juvenile arthritis well controlled on methotrexate but is otherwise well with no other medical issues. His mother explains that the child attended a large party 3 days previously and she received a call this morning informing them that another child who attended the party has just been diagnosed with measles. She has no further information regarding the other child or as to whether they were symptomatic etc.

The 14-year-old reports no symptoms currently and appears well in the emergency department. His examination is unremarkable and observations are as follows:

- Heart rate 100 beats per minute
- Blood pressure 120/80 mmHg
- Respiratory rate 20 breaths per minute
- Oxygen saturations 98%
- Temperature 36.2 ºC

What is the most appropriate management option?

A. No treatment is indicated
B. Provide aciclovir immediately
C. Provide immunoglobulin immediately
D. Test for IgM antibodies and if present start aciclovir
E. Test for serum measles DNA and if present provide immunoglobulin

C. Provide immunoglobulin immediately

Those exposed to measles can be given immunoglobulin to reduce the risk of infection

Providing immunoglobulin (Ig) is correct as the child is unvaccinated, immunocompromised due to methotrexate and has had exposure to measles. The MMR vaccination can also be offered to patients who are unvaccinated and have exposure as vaccine-induced measles antibody develops more rapidly than that following natural infection.

No treatment is incorrect. The child is unvaccinated, immunocompromised and most likely had significant measles exposure therefore immunoglobulin should be provided as a minimum.

Aciclovir is incorrect as it does not play a role in post-exposure prophylaxis or the treatment of active measles.

Testing for serum measles DNA is incorrect as measles is an RNA paramyxovirus and also this will have no impact on management.

IgM antibodies can be tested for, and are normally present within a few days of rash onset however aciclovir is not indicated in measle post-exposure prophylaxis.

Question 90 of 277

A 30-year-old homeless, intravenous drug user is brought into the emergency department by his concerned friends. The patient has difficulty speaking clearly but his friends report he had been complaining of progressive weakness, especially of his face with difficulty swallowing and some double vision.

On examination, the patient has a broad gait, with flaccid weakness globally. Cranial nerve examination relieves ptosis, ocular and facial muscle weakness. The patient exam is otherwise normal including a normal GCS.

On further questioning, the group who brought the patient in reports another one of their friends was admitted with similar symptoms a few days ago. On review of the hospital computer system, it is noted that this friend's blood cultures grew a gram-positive, anaerobic bacillus.

What should be provided to the patient urgently?

A. Intubation and ventilation
B. Broad spectrum antibiotics
C. Plasma exchange
D. Antitoxin
E. Specific vaccination

D. Antitoxin

The treatment of botulism - supportive care and botulism antitoxin

This patient is suffering from botulism which, although rare, normally presents following consumption of contaminated food (e.g. tinned) or as in this case IV drug use. The patient has the typical presentation of flaccid paralysis with bulbar and ocular involvement, whilst maintaining full consciousness and no sensory disturbance. The mainstay of treatment is supportive with early antitoxin use which can neutralise non-bound, circulating botulinum toxin.

This patient has most likely a diagnosis of botulism. Although this can progress to cause respiratory issues the patient does not currently have evidence of respiratory failure. Antitoxin should be given as a priority and respiratory function monitored.

Broad-spectrum antibiotics can be considered if there is evidence of wound infection with *Clostridium botulinum* otherwise there use is non-beneficial and specific botulism antitoxin with supportive care are the only management that will affect the course of the disease.

Plasma exchange is incorrect as this has no evidence for its use in botulism.

To date, no effective vaccination to assist in the management of botulism has been approved for use.

Question 91 of 277

A 23-year-old woman attends with fever, myalgia, rash, and headache 4 days after returning from Sao Paulo. She noted that fevers and generalised abdominal pain started the day before she boarded her flight home and that the rash had come up in the last 24 hours.

On examination, the woman has petechiae and a maculopapular rash over her wrists, ankles, and palms as well as a single itchy, erythematous raised papule with a central punctum on her right calf.

Given the likely diagnosis, what is the most appropriate treatment?

A. Albendazole
B. Artemether with lumefantrine
C. Doxycycline
D. Metronidazole
E. Praziquantel

C. Doxycycline

Doxycycline is typically used in the management of typhus

The most likely diagnosis here is Rocky Mountain spotted fever, one of the Rickettsial diseases. Rocky Mountain spotted fever is transmitted via tick bites in endemic areas such as South America - the single, itchy, erythematous, raised papule is descriptive of a tick bite. It presents initially with general symptoms of malaise, fever, and abdominal pain. The classic vasculitic rash then develops after 3-5 days.

Doxycycline is the treatment of choice for Rocky Mountain spotted fever.

Albendazole is incorrect. This would be more appropriate for helminth infections such as roundworm and hookworm.

Artemether with lumefantrine is incorrect. This would be the appropriate treatment for uncomplicated *P. falciparum* malaria. *P. falciparum* malaria is most prevalent in Africa rather than in South America. It can present with similar general symptoms to Rocky Mountain spotted fever

with fevers, headache, and myalgias but is also often associated with hepatomegaly and splenomegaly. It is not typically associated with the vasculitic rash seen in this patient.

Metronidazole is incorrect. It has good action against anaerobic bacteria and protozoa but would not be the choice for Rickettsial infections.

Praziquantel is incorrect. This is used to treat parasitic worm infections such as schistosomiasis. It would not be the choice for Rickettsial infections.

Question 92 of 277

A 25-year-old gentleman was referred to the outpatient infectious diseases clinic by his GP. He had recently immigrated from Pakistan a few months ago with his extended family. A couple of weeks ago his mother who lived in the same house as him was diagnosed with respiratory tuberculosis and he was accordingly advised to get 'checked up' by his GP. He felt well in himself, stating that he recovered from a cold a few weeks ago having had symptoms of nasal congestion, sore throat and a cough lasting a few days. He has since felt well, denying the presence of any further symptoms. Of note he has not lost weight, not had a fever, and did not suffer from a cough or night sweats. He was unsure what immunisations he had whilst in Pakistan. As a precautionary measure, the GP referred him to the infectious diseases clinic given the close proximity with his mother.

Examination revealed a well looking 25-year-old gentleman. His temperature was 36.6ºC, heart rate 78 bpm, respiratory rate 16/min and oxygen saturations 99% on air. He had a BCG scar on his left arm. Examination of his cardiovascular, respiratory, gastrointestinal and neurological systems were all entirely unremarkable.

Initial investigations revealed the following:

Blood film:negative; including negative malaria screen

Blood culture: negative culture; awaiting prolonged acid-fast bacilli culture result

Quantaferon blood test: positive Mantoux test: positive

Chest x-ray: normal appearances of heart and lung fields, no abnormality was seen

Based upon the above information, what is the next best management step?

A. Commence treatment with isoniazid, pyridoxine, ethambutol, rifampicin and pyrazinamide for 2 months
B. Discharge from clinic with no further action to take
C. Refer for diagnostic bronchoscopy alveolar lavage
D. Commence isoniazid and pyridoxine for 6 months
E. Repeat Quantaferon blood test weekly for the next month - treat if remains positive

D. Commence isoniazid and pyridoxine for 6 months

Latent tuberculosis treatment options:

3 months of isoniazid (with pyridoxine) and rifampicin, or

6 months of isoniazid (with pyridoxine)

This gentleman has latent TB. He has had close (and presumably prolonged) contact with an active TB carrier but other than the presence of transient symptoms of an upper respiratory tract infection has been asymptomatic. He has had a positive Mantoux test, which can be positive with both active and latent TB but can also by a previous BCG vaccination. Quantiferon testing, on the other hand, is not influenced by BCG vaccination status but cannot distinguish between active and latent TB. However in the absence of significant symptoms and with normal investigations including a normal CXR the most likely diagnosis is latent TB and therefore he requires monotherapy with isoniazid (and pyridoxine) for 6 months.

Question 93 of 277

A 28-year-old man presents to the Emergency Department with a four-day history of recurrent headaches. He reports no significant medical history but mentions a recent trip to Bolivia, where he recalls sustaining a tick bite. He also describes a rash that started on his extremities.

On examination, you observe a maculopapular rash involving his extremities, face, and trunk. His vital signs are as follows: blood pressure 110/80 mmHg, pulse rate 78 beats per minute, and temperature 39.6 ºC.

The following laboratory results are available:

Hb	140 g/L	Male: (135-180)
Platelets	105 * 10 /L 9	(150 - 400)
WBC	3.1 * 10 /L 9	(4.0 - 11.0)
ALT	68 u/L	(3 - 40)

What is the most likely diagnosis?

A. Babesiosis
B. Dengue Fever
C. Lyme disease
D. Rocky Mountain Spotted Fever
E. Tularemia

D. Rocky Mountain Spotted Fever

Headache, fever, rash on the peripheries before spreading centrally, tick bite → Rocky Mountain spotted fever (*Rickettsia ricketsii*)

Rocky Mountain Spotted Fever is the correct diagnosis. The clinical presentation of fever, headache, and a rash that started on the extremities and subsequently spread to the face and trunk, coupled with a travel history to South America (specifically Bolivia) and a tick bite, should prompt consideration of Rocky Mountain spotted fever. This disease involves the proliferation of intracellular bacteria *Rickettsia rickettsii* at the site of the tick bite, predominantly affecting the endothelium of small vessels. Laboratory findings such as thrombocytopenia, leukopenia, and raised liver enzymes further support this diagnosis.

Babesiosis represents a tick-borne disease caused by protozoan parasites of the Babesia genus. Transmission is primarily through Ixode ticks. While it shares common features with Rocky Mountain spotted fever, including fever, headache, thrombocytopenia, and increased liver enzyme levels, Babesiosis characteristically does not present with a rash and mainly infects erythrocytes.

Dengue Fever is an arboviral infection endemic in the Americas transmitted by mosquitoes carrying dengue virus. Clinical manifestations typically include fever, retro-orbital pain, severe myalgia, and a distinctive rash which commences with facial flushing before progressing to a second maculopapular rash on the back of hands and feet extending to the torso. However, this type of rash differs from that described in the scenario provided.

Lyme disease, another tick-borne illness caused by spirochetes of *Borrelia burgdorferi*, is transmitted via hard ticks. It typically presents with an expanding area of localised erythema with central clearing (erythema migrans), often resembling a bull's-eye pattern at the tick bite location. The rash does not match Lyme disease but suggests Rocky Mountain spotted fever.

Tularemia is an uncommon zoonotic infection caused by Francisella tularensis bacteria and transmitted by ticks. It can cause symptoms such as fever, painful ulcerative lesions at inoculation sites with associated regional lymphadenopathy, hepatosplenomegaly, and potentially community-acquired pneumonia. The patient's clinical features do not correspond with those commonly associated with tularemia.

Question 94 of 277

A 32 year old man presents with left lower limb weakness for the past three weeks. Over the past week his condition has got much worse. He has lost his appetite and about six kilograms in the last two months. In the same period he reported recurrent bleeding from the nose.

With the help of three months of nicotine transdermal patches and vareniciline he is now no longer actively smoking. He is married and works as a salesman in a pharmaceutical company. For the last year he has been to many destinations around the world as part of his job.

On examination he appeared ill. He was oriented in time, place, and person, but was mentally slow in understanding commands during examination. The power in the left leg was grade 2 for all muscle groups. Tone, sensation, coordination and reflexes were all normal. The right leg was normal. No abnormality detected in other systems. The following investigation were ordered:

Hb	10g/dl
Platelets	10 * 10^9/l

WBC	4* 10^9/l
Neutrophils	60%
Lymphocytes	34%
Na+	135 mmol/l
K+	4 mmol/l
Creatinine	95 µmol/l
Urea	4 mmol/l

Urine analysis: Clear

MRI brain showed bilateral multiple hyperintense demyelinating lesions involving sub cortical areas without any mass effect.

What is the most appropriate thing to do?

A. CSF analysis for oligoclonal bands
B. Brain biopsy
C. CSF analysis for herpes simplex virus (HSV)
D. HIV test
E. Stop vareniciline

D. HIV test

HIV, neuro symptoms, widespread demyelination - progressive multifocal leukoencephalopathy

The progressive neurological symptoms with demyelination on MRI points to progressive multifocal leukoencephalopathy (PML).

PML is a demyelinating disease of the CNS due to the JC virus. It occurs almost exclusively in immunosuppressed individuals with the majority of cases being secondary to HIV infection. Patients typically experience insidious onset of focal symptoms that include mainly behavior, cognitive, speech, and motor functions. Polymerase chain reaction (PCR) of the CSF has a high sensitivity and specificity for the detection of JC virus in patients with PML.

Neither the symptoms nor the signs are compatible with either multiple sclerosis or HSV.

Vareniciline could cause low platelets and appetite changes with psychiatric manifestation. But it would not explain the motor deterioration nor the cognitive decline for this patient.

Question 95 of 277

A 21-year-old man presents to the emergency department with five days of feeling tired, cough, fevers and general lethargy. He becomes quite tearful during the consultation as he has never felt like this.

On examination, he has tenderness over both trapezium muscles, his temperature is 38.6 ºC and his throat is red without any collections of pus.

A rapid point of care test shows that he is influenza positive. \

What is your next management step?

A. Oseltamivir
B. Zanamivir
C. Admit for observation
D. Discharge with reassurance
E. Oral amoxicillin

D. Discharge with reassurance

Low-risk patients with influenza who present 48 hours after symptoms are recommended for supportive treatment

This is a simple case of influenza of which most people who are low risk will recover with supportive treatment. In high risk groups e.g. immunosuppression or pregnancy, oseltamivir or zanamivir can be considered. The duration of symptoms is important as those who present within 48 hours of symptoms are more likely to derive benefit. Oral antibiotics are not usually recommended though bacterial superinfection can occur in influenza.

Question 96 of 277

A 27 year-old Lithuanian male presents to the Emergency Department with a short history productive cough, fever and breathlessness. The chest X-Ray shows left upper zone consolidation. His white cell count and CRP are elevated and IV antibiotics are commenced for a community acquired pneumonia. He makes some improvement after 48 hours but remains on 4L of oxygen to maintain adequate saturations. An interferon gamma release assay for mycobacterium is positive.

What would be the correct course of action?

A. Send three morning sputum samples for acid fast bacilli
B. Arrange a bronchoscopy and washings for acid fast bacilli
C. No action, continue antibiotics, repeat CXR in 6 weeks time
D. Treat for latent pulmonary tuberculosis with two agents
E. Treat for active pulmonary tuberculosis with quadruple therapy

A. Send three morning sputum samples for acid fast bacilli

This young gentleman's positive interferon release assay shows he has been exposed to tuberculosis in the past. It however does not give any information regarding this active infection which could represent pulmonary tuberculosis or bacterial pneumonia. A wise course of action would include isolating the patient and sending three morning sputum samples to look for acid fast bacilli. He is not currently fit for bronchoscopy given his oxygen requirements.

Question 97 of 277

A 24-year-old lady presents 16 weeks pregnant. She complains of myalgia, sore throat and coryza and is noted to have a pyrexia of 38.1. She works in a nursing home which is currently closed due to an influenza A outbreak. On further questioning, you note that she has been vomiting every morning for the past 8 weeks and is no longer able to take oral medication. On examination her chest is clear but she is obviously coryzal with an erythematous oropharynx (no exudate). Chest Xray is clear.

Apart from informing the obstetrics team, how would you manage this patient?

A. Admit, isolate and commence oseltamivir
B. Admit and observe
C. Oral antibiotics
D. Admit, isolate and commence zanamivir
E. Admit, isolate and await nose and throat swabs before commencing antiviral therapy

D. Admit, isolate and commence zanamivir

This patient has had known exposure to influenza A. She should be admitted for observation and immediately commenced on empirical treatment. NICE recommends oseltamivir treatment as first line for suspected or confirmed influenza A in pregnancy. However, given that this patient has been vomiting, zanamivir (intranasal/intravenous) should be used in preference to oral Tamiflu (oseltamivir). Empirical treatment should be commenced immediately and not withheld until the results of swabs are available.

There may be a role for antibiotics if there is a co-existing infection or evidence of pneumonia on chest X-ray.

Question 98 of 277

A 35 year-old Brazilian accountant presented to the medical outpatient clinic with progressive leg swelling over the last 18 months. His mobility had become increasingly restricted due to both the swelling and shortness of breath on exertion. His father and paternal grandfather had both died from ischaemic heart disease in their 60s. His past medical history was unremarkable. He had smoked 15 cigarettes a day for 15 years and drank 15 units of alcohol per week.

On examination, his temperature was 36.5ºC, blood pressure was 95/50 mmHg and heart rate was 75 beats per minute. His JVP was elevated to the angle of the jaw. His chest was clear on auscultation, but a third heart sound and pan-systolic murmur were audible on auscultation of the precordium. Bilateral pitting oedema to mid-thigh level was present.

Investigations:

Haemoglobin	131 g/L (130-180)
White cell count	6.9 x 10 /L (4.0-11.0)9
Neutrophil count	3.1 x 10 /L (2.0-7.5)9
Lymphocyte count	1.9 x 10 /L (1.3-3.5)9
Eosinophil count	1.1 X 10 /L (0.1-0.4)9
Platelets	260 x 10 /L (150-400)9

Sodium	132 mmol/L (135-145)
Potassium	3.6 mmol/L (3.5-5.0)
Urea	8.0 mmol/L (2.5-7.5)
Creatinine	101 mol/L (20-90)
Fasting plasma glucose	7.2 mmol/L (3.0-6.0)

Echocardiogram	Moderately impaired left ventricular systolic function Dilated left ventricle with moderate mitral regurgitation

What is the most appropriate treatment for the underlying condition?

A. Sulfadiazine and pyrimethamine
B. Doxycycline
C. Artesunate
D. Benznidazole
E. Mebendazole

D. Benznidazole :

This patient has developed chronic infection with tropical trypanosomiasis (Chagas disease). The parasite is endemic in South America, and is transmitted by the triatomine bug. Initial infection may present with transient fever and/or a swelling around the site of inoculation. In this case, chronic infection has developed; this may consist of dilated cardiomyopathy, arrhythmias or oesophageal dysmotility mimicking achalasia. Though this patient has some risk factors for ischaemic heart disease, the chances of this affecting him at this age are relatively small. The current treatment of choice for tropical trypanosomiasis is benznidazole.

Question 99 of 277

A 65-year-old man is undergoing treatment in the intensive care unit. He had presented 8 days previously after suffering a seizure at home. He had been unable to give a coherent history at the time of presentation but his family had reported he had been unwell for about two weeks. Initial symptoms included a fever, myalgia, anorexia and an intense itching of his left arm. Subsequently, the patient had developed progressive confusion and agitation and was incoherent by the time of presentation to hospital. The patient was a long-term resident of the UK, but had made a trip back to his native India around 6 months previously. During that trip, his wife recalled the patient being bitten by a dog in his family village, although the wound had been minor and healed without incident after basic first aid. Medical history was otherwise fairly unremarkable, including hypertension, tablet-controlled type 2 diabetes and gout.

At presentation, the patient had been noted to been highly agitated and disorientated. Hypersalivation was noted and patient had been refusing to eat or drink. Examination had been limited by the patient's agitation but no overt focal neurological symptoms were noted in the cranial nerve or peripheral nervous examination. After the patient had been sedated, it was noted that striking a large muscle group with a tendon hammer led to few seconds of mounding of the muscle.

CSF protein	457 g / dL
CSF Microscopy	NAD
CSF rabies virus neutralising antibodies	Not detected
Serum rabies virus neutralising antibodies	Detected

At the present time, the patient is receiving end-of-life care. He is sedated and appears comfortable secondary to midazolam delivered by a syringe driver. His family wish to be present at his bedside.

What is the appropriate personal protection for healthcare workers and family members to use while in contact with the patient?

A. High isolation
B. Standard precautions
C. Respiratory isolation
D. Reverse isolation
E. Biocontainment precautions

B. Standard precautions

The patient is unfortunately suffering from rabies. His presentation is consistent with the classical form of 'furious rabies', with fever, agitation, confusion and seizures. The response of the patient's muscles to being struck with a tendon hammer described in the question is called myoedema and is suggestive of rabies. Neutralising serum antibodies may be detected 7-8 days after the onset of symptoms but are only occasionally found in CSF. An alternative form of the disease ('paralytic rabies') is also known, featuring an ascending paralysis or symmetric quadriparesis.

The patient presumably contracted the disease on his previous trip to India when he was bitten by a dog. An incubation period of 6 months is not uncommon (mean incubation time 274 days in one study) with cases reported with incubation time up to 10 years. By the time neurological symptoms have taken hold, death is inevitable in unimmunised patients. This highlights the need for appropriate vaccination for individuals travelling to high-risk areas, as well as post-exposure vaccination and immunoglobulin administration.

Lyssaviruses such as rabies cannot cross intact skin and humans are regarded as an end-host (outside of transplantation-associated transmission). Therefore, only standard infection-prevention precautions such as gloves and gowns are required.

High isolation refers to the extreme precautions taken with high-transmissible and dangerous infections such as Ebola. Respiratory isolation requires the use of a mask to prevent droplet transmission by the respiratory route. Reverse isolation refers to techniques required to prevent external pathogens causing harm to an immunosuppressed patient. Biocontainment refers to laboratory biosafety techniques required when handling highly pathogenic organisms.

Question 100 of 277

A 65 year-old gentleman with type 2 diabetes mellitus and alcoholism presents with fever, headache and neck stiffness. He has a history of previous anaphylactic reaction to penicillin.

On examination the temperature is 37.9ºC, respiratory rate is 20 breaths/min and heart rate is 105 beats per minute. Nutritional state and dental hygiene is poor. The chest is clear to auscultation. The abdomen is soft and non-tender. The Glasgow coma scale score is 15, the patient is uncomfortable during pen-torch pupillary examination and neck flexion is limited by pain.

CSF examination reveals:

White Cells	560 per mm³ (85% polymorphs)
Red cells	8 per mm³
Protein	0.9g/L
Glucose	3.3mmol/L (serum glucose 9.2mmol/L
Gram stain	Gram-negative coccobacilli

Which antimicrobial agent should be initiated?

A. Vancomycin
B. Ceftriaxone
C. Chloramphenicol
D. Rifampicin
E. Gentamicin

C. Chloramphenicol

This patient has meningitis caused by Haemophilus influenzae. Immunocompromised patients including those with alcoholism or diabetes are at risk.

Other gram -ve coccobacilli include Gardnerella vaginalis, Chlamydia trachomatis, Bordetella pertussis, Coxiella burnetti and Haemophilus ducreyi however these would not classically cause meningitis.

Cefotaxime or ceftriaxone would be the first-line treatment for haemophilus meningitis however for those with a history of anaphylaxis to penicillin, chloramphenicol is the most appropriate choice.

Chloramphenicol would also be the appropriate choice in meningococcal meningitis in a penicillinallergic patient.

The area of induration described in the vignette constitutes a positive Mantoux test. The area of surrounding erythema is not taken into account.

Question 101 of 277

A 54-year-old oil businessman who frequently visits the Gambia and is usually careful with his malaria prophylaxis has been admitted with general malaise and relapsing/remitting fevers which seem to occur every third day. He returned from the Gambia about one week ago and on this occasion, he did not take his malaria prophylaxis as he has never caught it before. He has no past medical history of note and no regular medication. Malarial parasites are seen on the thick and thin films and it is confirmed as *Plasmodium vivax* by the Malaria Reference Laboratory.

What is the most appropriate management according to current UK guidelines?

A. Chloroquine
B. Atovaquone-proguanil
C. Chloroquine and primaquine
D. Artemether with lumefantrine
E. Intravenous artesunate + primaquine

C. Chloroquine and primaquine

Plasmodium vivax is the second most commonly seen cause of malaria by UK statistics after *Plasmodium falciparum* malaria. It is characteristically a cause of benign tertian malaria where fevers occur every three days. Current UK guidelines (Health Protection Association(are that nonfalciparum malaria should be treated with chloroquine but *P. vivax* and *P. ovale* are unusual in that dormant parasites (or hypnozoites) can exist within the liver.

The only currently available treatment for hypnozoites is primaquine and vivax malaria is more effectively treated with a higher dose than ovale (30mg). Therefore the correct answer is chloroquine and high-dose primaquine. Anyone commencing treatment with primaquine should have their glucose-6-phosphate dehydrogenase status tested as primaquine could precipitate severe haemolysis in deficient patients.

Artesunate, atovaquone-proguanil and artemether with lumefantrine are treatments for falciparum malaria.

Question 102 of 277

A 35-year-old man presents to the genitourinary medicine clinic with a 1-week history of an ulcer on his penis. It is painless and he feels it might be increasing in size, though there are no other ulcers. He has never had any ulcers before.

He is HIV positive and remains sexually active with one regular male partner. They do not usually use condoms as he strictly adheres to his antiretroviral medication schedule and has an undetectable viral load.

He had gonorrhoea aged 18 which was treated with antibiotics at the time and he has no history of any other sexually transmitted infections.

He has no other past medical history and no drug allergies. He takes no medications other than his antiretrovirals.

On examination, he has a single shallow ulcer 1 x 2 cm on the dorsal surface of the penis with a small rim of surrounding erythema. He has no other rashes or lymphadenopathy. The systemic examination is otherwise unremarkable with no focal neurology.

Swabs from the ulcer are negative for herpes simplex virus 1 and 2. Penile swabs are negative for chlamydia and gonorrhoea.

Syphilis serology result: Enzyme immunoassay (EIA) +

Treponema Pallidum particle agglutination assay (TPPA) + Rapid plasma reagin (RPR) -

What is the best immediate management option?

A. Intramuscular penicillin G and check repeat syphilis serology
B. Intramuscular penicillin G and check syphilis PCR
C. Check syphilis PCR
D. Oral doxycycline and check repeat syphilis serology
E. Oral doxycycline and check syphilis PCR

B. Intramuscular penicillin G and check syphilis PCR

This gentleman has a painless single penile ulcer which given negative testing for HSV, should be investigated for syphilis.

His syphilis serology shows a positive screening EIA and follow up TPPA (both treponemalspecific). However, his RPR titre is undetectable. This could indicate either past infection only or early acute infection without seroconversion on the RPR.

This gentleman is having unprotected intercourse and is HIV positive, so high risk for syphilis even if he gives a history of a single long-term partner. He also gives no history of past infection and so he should be treated for syphilis with antibiotics. Given he has no allergies, the first choice should penicillin G.

However, for clarification regarding diagnosis, he requires further testing, the gold standard being syphilis PCR.

Question 103 of 277

A 35-year-old female returned from Tanzania 2 weeks ago. She had consulted her GP after feeling unwell over the previous 3 days with intermittent symptoms of fever, headache and generalised arthralgia. She had taken doxycycline as an antimalarial and denies missing any of the prescribed doses and had been fully vaccinated prior to her travel.

She is referred to the medical take where you retake the history. She admits to getting mosquito bites regularly whilst away, one of them she seemed to react severely to and this has left a mark on her shoulder.

On examination she appears drowsy, she has mild heptosplenomegally and there is a well circumscribed, rubbery, painful, red lesion approximately 5cm in diameter above her left shoulder.

What is the likely diagnosis?

A. Plasmodium falciparum
B. Trypanosomiasis brucei rhodesiensi
C. Trypanosomiasis brucei cruzi
D. Trypanosomiasis brucei gambiensi
E. Toxoplasmosis

B. Trypanosomiasis brucei rhodesiensi

Human African trypanosomiasis (HAT), also known as sleeping sickness, is caused by protozoan parasites. There are two forms of the disease, an acute form occurring mainly in East Africa caused by *Trypanosoma brucei rhodesiense*, and a more chronic form occurring in West and Central Africa, caused by *Trypanosoma brucei gambiense*. *Trypanosomiasis brucei cruzi* is endemic in south america where it causes Chagas disease.

Trypanosomiasis rhodesiense is transmitted by the tsetse fly which are classically found on safari in Tanzania. *T. rhodesiense* will often form a chancre at the site of inoculation and can often be the first and only sign of disease where it is rapidly progressive.

Given the story we are immediately highlighted to the potential of malaria. However given that she has taken adequate prophylaxis we should keep an open mind to other potential diagnoses. Furthermore her illness started 3 days prior to her admission to hospital making *P.falciparum* less likely as this would have resulted in her being very unwell by this point.

As explained *T.Cruzi* is endemic in south america and can therefore be discounted early on. *T.gambiense* is likely to present with a much more chronic picture. Toxoplasmosis is very unlikely in an immunocompetant host and her travel to Tanzania would not necessarily increase her risk of acquiring the condition. As a result the most likely diagnosis is *T.rhodesiense*. Diagnosis can be made by demonstration of the parasite in the blood, lymph node/chancre aspirate or on CSF examination. The condition is fatal in the absence of treatment.

Question 104 of 277

A 59 year-old man attends his general practitioner with a 10 day history of watery diarrhoea. His stools are unformed, sometimes associated with fresh red blood. He also has associated abdominal cramps for which he has been taking paracetamol. He estimates a 5kg weight loss during this period, and has struggled to tolerate food or fluids due to significant pain on swallowing. He also has an intermittent sensation of needing to defecate, but being unable to.

He has been diagnosed with HIV 8 years ago, and admits that he has not been attending follow up, or taking his medications. He is unsure what his last CD4 cell count was. He has had 5 episodes of pneumonia over the last 12 months, the last one was 4 months ago.

On examination, he has dry mucous membranes with reduced skin turgor. He has generalised abdominal tenderness, but no features of peritonism, or organomegaly.

Observations

- Respiratory rate- 18 breaths per minute
- Heart rate- 110 beats per minute
- Blood pressure- 104/60 mmHg
- Temperature 37.7ºC

What is the most likely pathogen causing his symptoms?

A. Cryptosporidiosis
B. Clostridium difficile
C. Giardia
D. E Coli 0157
E. Cytomegalovirus colitis

E. Cytomegalovirus colitis

Cytomegalovirus (CMV) colitis is usually seen in patients who are immunocompromised. It is a member of the herpes virus, for which around 50-80% of the general population are seropositive. The virus lays dormant until the patient is sufficiently immunocompromised.

Approximately 30% of all patients with AIDS will develop a gastrointestinal CMV infection. This usually occurs when the CD4+ counts drop to below 100 mm3.

CMV can affect the gastrointestinal tract from the oesophagus to the rectum, and symptoms depend on the site of infection. CMV oesophagitis causes odynophagia and retrosternal chest pain. CMV enterocolitis commonly presents with diarrhoea, fever, weight loss and per rectal bleeding. Tenesmus can occur if there is rectal involvement.

Cryptosporidiosis is a protozoal infection caused by cryptosporidium parvum. Immunocompromised individuals are particularly susceptible. The incubation period is between 2- 10 days (average 7) and symptoms usually last about 1 to 2 weeks, although can occur for longer. The most common symptom is watery diarrhoea. Other symptoms include stomach cramps, dehydration, nausea and vomiting and fever.

E Coli 0157 is a relatively rare cause of infective diarrhoea in England. Symptoms range from mild gastroenteritis through to severe bloody diarrhoea. It can be associated with haemolytic uraemic syndrome and thrombotic thrombocytopaenic purpura.

Giardia is causes by the protozoon parasite Giardia lamblia. Symptoms include diarrhoea, foul smelling flatulence and abdominal cramps. Symptoms typically last between 2-4 weeks, but chronic diarrhoea and malabsorption can occur.

The patient has likely got a very low CD4+ count, due to his non-compliance with medication and follow up and history of recurrent pneumonia. CMV colitis with rectal and oesophageal involvement would explain the tenesmus, odynophagia, along with the bloody diarrhoea, abdominal cramps and weight loss.

Cryptosporidiosis and giardia do not tend to cause bloody diarrhoea. Clostridium difficile is an important cause of diarrhoea in immunocompromised patients. However, neither clostridium difficule nor E Coli 0157 this would not explain the odynophagia or tenesmus.

Question 105 of 277

A 47-year-old man presented with a headache to the emergency department a few days ago. His partner accompanied him and reported that he has been more confused over the last few days. He had also been febrile and complained of swollen glands in his neck. He had a self-terminating seizure whilst awaiting transfer to the medical ward.

His past medical history is significant for HIV. His partner reported he is not compliant with his anti-retroviral treatment and last year was hospitalised for severe pneumonia.

A CT head showed multiple ring-enhancing lesions. The infectious diseases team reviewed him and suggested additional blood tests, results of which are shown below:

Hb	140 g/L	(135-180)
Platelets	167 * 10 /L 9	(150 - 400)
WBC	3.8 * 10 /L 9	(4.0 - 11.0)
Na^{+}	137 mmol/L	(135 - 145)
K^{+}	4.5 mmol/L	(3.5 - 5.0)
Urea	8.5 mmol/L	(2.0 - 7.0)
Creatinine	137 µmol/L	(55 - 120)
CRP	50 mg/L	(< 5)
Toxoplasmosis serology	positive	
Cryptococcal serology	negative	
β-d-Glucan	normal	
Galactomannan	normal	

What is the most appropriate treatment to give this patient?

A. Co-trimoxazole and prednisolone
B. Fluconazole
C. Pyrimethamine and sulphadiazine
D. Amphotericin B
E. Pentamidine and prednisolone

C. Pyrimethamine and sulphadiazine

Immunocompromised patients with toxoplasmosis are treated with pyrimethamine plus sulphadiazine

This man has a background of HIV and is not compliant with treatment, therefore is immunocompromised and at risk of opportunistic infections. Toxoplasmosis serology is positive and the multiple ring-enhancing lesions on CT support this diagnosis. Management of toxoplasmosis in immunocompromised patients is with pyrimethamine and sulphadiazine.

Co-trimoxazole and prednisolone is used in the management of *Pneumocystis jirovecii* pneumonia. There are no chest symptoms to suggest this is the cause of this patient's presentation.

Fluconazole can be used to treat fungal infections such as candidiasis.

Amphotericin B is used in the management of cryptococcal infection. Cryptococcus serology is negative, and the CT head would show cerebral oedema and meningeal enhancement if this was the diagnosis.

Pentamidine and prednisolone is an alternative treatment regimen for *Pneumocystis jirovecii* pneumonia.

Question 6 of 277

A 28-year-old man presents to the clinic with a rash on his foot. He states that he first noticed it two weeks after returning from Thailand. The rash is very itchy and has been keeping him awake at night. He has no past medical history and takes no regular medicines. On examination he has a erythematous, oedematous, serpiginous track on the superior aspect of his right foot.

What is the treatment of choice for this condition?

A. Clotrimazole
B. Terbinafine
C. Albendazole
D. Flucloxacillin
E. Doxycycline

C. Albendazole

Albendazole is the treatment of choice for cutaneous larva migrans

The clinical history is suggestive of cutaneous larva migrans which is caused by infection of the dog hookworm Ancylostoma braziliense. Management is with albendazole or ivermectin.

Flucloxacillin and doxycycline are indicated for cellulitis.

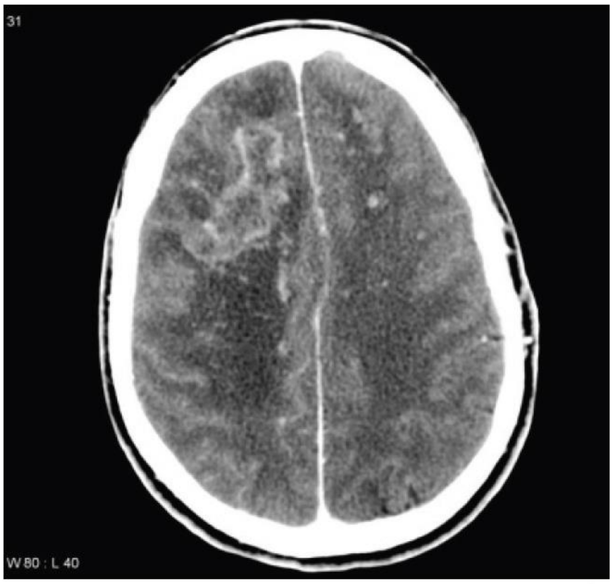
Clotrimazole and terbinafine are used in the treatment of fungal infections such as ringworm.

Question 107 of 277

A 33-year-old man who is HIV positive is admitted to the Emergency Department with confusion and drowsiness. He has been complaining of headaches for a number of days. On examination heart rate is 90/min, blood pressure 104/78 mmHg and temperature is 37.2ºC. He is confused giving a Glasgow Coma Scale (GCS) score of 14. There is no photophobia or neck stiffness.

His infectious diseases consultant reports that he is prescribed highly active antiretroviral treatment (HAART) but his compliance is poor and he often misses clinic appointments.

A CT scan is requested: .



What is the most likely diagnosis?

A. Cerebral toxoplasmosis
B. Tuberculosis
C. CMV encephalitis
D. Progressive multifocal leukoencephalopathy
E. Cryptococcal infection

A. Cerebral toxoplasmosis

HIV, neuro symptoms, multiple brain lesions with ring enhancement - toxoplasmosis

The CT scan shows multiple ring enhancing lesions consistent with cerebral toxoplasmosis. He is at risk of this due to his poor compliance with medication.

Cerebral toxoplasmosis is the most common neurological infection seen in HIV, occurring in up to 10% of patients.

Question 108 of 277

A 25-year-old man presents to the genitourinary medicine clinic with a penile lesion which has been present for the last three weeks but is now starting to reduce in size. He has had two sexual partners in the last 2 months, who were both men. There is no history of travel outside of the UK in the last 3 years.

The lesion is a shallow ulcer with well-defined margins, which is not tender to palpation. He has some non-tender enlarged lymph nodes on both sides in the inguinal region.

What is the most likely diagnosis?

A. Chancroid
B. Donovanosis
C. Lymphogranuloma venereum
D. M-pox
E. Primary syphilis

E. Primary syphilis

Primary syphilis is associated with **painless** ulceration

The correct answer is **primary syphilis** , which is caused by *Treponema pallidum*. This classically presents with a chancre at the site of entry of infection. This usually starts as a painless papule, which evolves into a painless ulcer. The lesion is usually single but multiple lesions can occur. It generally heals over a few weeks.

Chancroid is incorrect. This is a sexually transmitted disease caused by *Haemophilus ducreyi*. However, unlike in this patient, the ulcers are commonly multiple and very painful. The inguinal lymphadenopathy in chancroid is also generally painful. Chancroid is rare in the UK, and most cases are acquired abroad in Africa or South East Asia.

Donovanosis is incorrect. This condition is also called granuloma inguinale and is caused by *Klebsiella granulomatis*. The genital ulcers in this condition are painless with a classically 'beefy red' base. This diagnosis is less likely in this patient because the ulcers would not start to heal without treatment but would continue to enlarge, and because it is rarely seen in the UK. It is most commonly seen in tropical regions.

Lymphogranuloma venereum is incorrect. This is caused by serovars L1, L2 and L3 of *Chlamydia trachomatis* . It is more common in tropical areas but does occur in the UK, mainly in men who have sex with men. It can cause painless ulceration in the primary stage, but unlike in this scenario, the ulcers are small and heal within 1-3 days so this stage is generally not noticed by patients. The secondary stage is characterised by painful swollen inguinal lymph nodes or anal symptoms in patients who have acquired an anal/rectal infection.

M-pox is incorrect. The M-pox virus classically causes painful vesicular lesions, which usually start at the site of inoculation and are generally multiple. The lesions may then spread to involve other areas of the body.

Question 109 of 277

A 35-year-old man presents to his general practitioner with two months of dysphagia and odynophagia. He has a past medical history of HIV. He is not compliant with anti-retroviral treatment.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 120/72 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 98% on room air
- Temperature 37ºC

On examination, there are white patches on the gums, tongue and extending past the pharynx. The examination is otherwise unremarkable.

What is the most appropriate treatment?

A. Amphotericin
B. Fluconazole
C. Lansoprazole
D. Nystatin
E. Surgical excision

B. Fluconazole

Candidiasis in immunocompromised patients should be treated using high dose fluconazole

Fluconazole is the correct answer. The description of the lesions is typical of candidiasis. Given the patient has oesophageal symptoms in the form of dysphagia and odynophagia, we can assume that the oesophagus is involved, in addition to the oro-pharynx. The patient is not compliant with treatment for HIV and is therefore at risk of developing AIDS. Oesophageal candidiasis is an AIDSdefining illness. In immunocompromised patients, the treatment of candidiasis is with high dose fluconazole.

Amphotericin is incorrect. This is an intravenous treatment associated with significant toxicity. It is reserved for life-threatening, disseminated fungal infections.

Lansoprazole is incorrect. The dysphagia and odynophagia are not likely a result of gastrooesophageal reflux.

Nystatin is incorrect. This would be suitable to treat oral thrush in an immunocompetent patient but would not be sufficient in this case.

Surgical excision is incorrect. A differential for a single white patch in the mouth or tongue might be oral leucoplakia, which is a pre-malignant condition and which could be surgically excised. However, in this context, multiple white patches in multiple locations is more likely to reflect candida.

Question 110 of 277

A 65-year-old man presents to the emergency department complaining of a 1 day history of fever, new rash and severe pain in his leg. His past medical history includes type 2 diabetes and peripheral vascular disease. His medications include metformin and clopidogrel. He smokes twenty cigarettes daily and lives alone.

His observations are heart rate 110 beats per minute, blood pressure 88/51 mmHg, respiratory rate 21/minute, oxygen saturations 96% on room air and temperature 38.4ºC.

On examination, he appears unwell. He is clammy and diaphoretic. There is an area of erythema extending from his right calf to his right thigh. It is warm to touch and in the region of the thigh, is diffusely tender. The degree of tenderness seems out of proportion to the severity of the rash. Cardiovascular, respiratory and abdominal examinations are unremarkable.

Blood tests:

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	444 * 10 /L 9	(150 - 400)
WBC	14.4 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	9.8 mmol/L	(2.0 - 7.0)
Creatinine	180 µmol/L	(55 - 120)
CRP	176 mg/L	(< 5)
Lactate	3.4 mmol/L	(0.5 - 2.2)
Creatine kinase	1200 U/L	(40-320)

Despite antibiotics and aggressive fluid resuscitation with 3 litres of normal saline, he remains hypotensive with a blood pressure of 85/52 mmHg.

Given the likely diagnosis, what combination of organisms is likely to be responsible?

A. Bacteroides fragilis and Clostridium perfringens
B. Pseudomonas aeruginosa and Escherichia coli
C. Staphylococcus aureus , Streptococcus pyogenes and Enterococcus faecalis
D. Streptococcus pyogenes , Escherichia coli and Clostridium perfringens
E. Vibrio vulnificus and Pseudomonas aeruginosa

D. Streptococcus pyogenes , Escherichia coli and Clostridium perfringens

Type 1, or polymicrobial, necrotising fasciitis is the most common

Streptococcus pyogenes , *Escherichia coli* and *Clostridium perfringens* is the correct answer. The diagnosis is necrotizing fasciitis, as evidenced by a severe soft tissue infection with pain and tenderness out of proportion to the clinical signs. Further supportive of evidence of necrotizing fasciitis versus a simple skin and soft tissue infection is the associated evidence of septic shock and organ dysfunction (acute kidney injury and raised lactate) with a raised creatine kinase. The most common type of necrotizing fasciitis is 'Type 1', which is caused by a combination of gram positive, gram negative and anaerobic bacteria. Furthermore, this type is more common in an older population with type 2 diabetes and peripheral vascular disease. It is the only option listed that is polymicrobial. Management is with antibiotics and aggressive surgical debridement.

Pseudomonas aeruginosa and *Escherichia coli* is the wrong answer. While both of these organisms can cause necrotizing fasciitis, they are both gram negative rods. They are less likely to cause necrotizing fasciitis either alone or in combination when compared to a polymicrobial combination.

Staphylococcus aureus , *Streptococcus pyogenes* and *Enterococcus faecalis* is incorrect. All of these organisms can cause necrotizing fasciitis. However, they are a less likely combination than the polymicrobial subtype and are all gram positive cocci. Type 2 necrotizing fasciitis tends to be caused by *Streptococcus pyogenes* alone and is more common in a younger population.

Bacteroides fragilis and *Clostridium perfringens* is the wrong answer. These are anaerobic bacteria that can cause necrotizing fasciitis but they are less likely to cause necrotizing fasciitis either alone or in combination than the polymicrobial subtype.

Vibrio vulnificus and *Pseudomonas aeruginosa* is the wrong answer. These are both gram negative rods rather than a polymicrobial combination. *Vibrio vulnificus* has been implicated in the development of necrotizing fasciitis and is a bacterium found in saltwater but this is a rare cause.

Question 111 of 277

A 33-year-old woman is brought to the emergency department by ambulance. She was found by her sister at home, confused and complaining of headache and fever. She has no past medical history and is on no regular medications. She had returned seven days previously from a trip on the Trans-Siberian Railway where she had stopped at a number of locations to do some hiking with friends. She had a brief flu-like illness towards the end of the holiday, which had resolved.

Her observations are heart rate 93 beats per minute, blood pressure 128/84 mmHg, respiratory rate 19/minute, oxygen saturations 96% on room air and temperature 38.4ºC.

On examination, her Glasgow coma scale is 12/15 (eyes 3 verbal 4 motor 5). There is evidence of nuchal rigidity and when she opens her eyes she is photophobic. Examination is otherwise unremarkable and there is no evidence of rash.

Urinalysis is normal.

An ECG demonstrates sinus rhythm.

Plain radiography of the chest demonstrates clear lung fields. Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	149 * 10 /L 9	(150 - 400)
WBC	11.8 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.4 mmol/L	(2.0 - 7.0)
Creatinine	101 µmol/L	(55 - 120)
Glucose	4 mmol/L	(4-11)
CRP	38 mg/L	(< 5)

She is treated empirically with ceftriaxone and aciclovir for presumed meningo-encephalitis and a lumbar puncture is performed.

Results:

Appearance	clear	
WCC	80 cells/µL	(<5)
Cell type	lymphocytes	92%
Glucose	3.6 mmol/L	(2.8-4.2)
Protein	.65 g/L	(0.15 -0.45)

Subsequent testing reveals specific IgM antibodies in the CSF against a flavivirus.

What is the appropriate next step in management?

A. Continue aciclovir and ceftriaxone
B. Continue aciclovir and stop ceftriaxone
C. Continue ceftriaxone and stop aciclovir
D. Stop ceftriaxone and aciclovir and manage supportively
E. Stop ceftriaxone and aciclovir and start ganciclovir

D. Stop ceftriaxone and aciclovir and manage supportively

Treatment for tick-borne encephalitis is supportive

Stop ceftriaxone and aciclovir and manage supportively is the correct answer. The patient has tickborne encephalitis. This is evidenced by the fact that she has returned from a region where the disease is endemic (Siberia) and has presented with a biphasic illness characterized by flu-like symptoms in the first stage and neurological dysfunction in the form of meningoencephalitis in the second stage. Her lumbar puncture results suggest a viral meningitis and her CSF testing reveal specific antibodies against a flavivirus, which is the cause of tick-borne encephalitis. There is no specific antiviral treatment for tick-borne encephalitis. Patients need admission to hospital if neurological symptoms are present and require supportive care in the form of analgesia, antipyretics, fluid and electrolyte management and intensive care input if appropriate.

Continue aciclovir and ceftriaxone is an incorrect answer. We have confirmed a diagnosis of tickborne encephalitis. Ceftriaxone can be stopped as the CSF results do not indicate a bacterial infection and aciclovir can be stopped as we have a confirmed diagnosis that does not benefit from specific anti-viral treatment. Aciclovir is indicated in cases of meningo-encephalitis caused by herpes zoster and herpes simplex.

Continue aciclovir and stop ceftriaxone is incorrect. Aciclovir has no benefit in the management of tick-borne encephalitis.

Continue ceftriaxone and stop aciclovir is incorrect. The CSF results demonstrate a lymphocytic pleocytosis with a normal glucose, indicating a viral meningitis. Ceftriaxone has no role in the management of viral infections.

Stop ceftriaxone and aciclovir and start ganciclovir is incorrect. Ganciclovir is predominantly used in the treatment of severe cytomegalovirus infection in immunocompromised patients. It has no role in the treatment of tick-borne encephalitis.

Question 112 of 277

A 65-year-old man presents to the emergency department with three days of fever, leg pain and rash. He has a past medical history of type 2 diabetes, peripheral vascular disease and hypertension. He is on regular clopidogrel, amlodipine, metformin, gliclazide and insulin. He is independent and a retired shoe-maker.

His observations are, heart rate 121 beats per minute, blood pressure 84/56 mmHg, respiratory rate 24/minute, oxygen saturation 95% on room air and temperature 39.1ºC.

On examination, he appears diaphoretic and unwell. His capillary refill time is four seconds and he is cool to touch. His pulse is regular and thready. Chest auscultation is normal. His abdomen is soft and non-tender. Heart sounds are normal and there are no murmurs. His left thigh is erythematous and painful to touch. The pain appears out of proportion to the clinical signs and the leg feels wooden and hard.

Blood tests:

Hb	108 g/L	Male: (135-180)Female: (115 - 160)
Platelets	555 * 10 /L 9	(150 - 400)
WBC	21.1 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	181 µmol/L	(55 - 120)
CRP	321 mg/L	(< 5)

What is the appropriate initial pharmacological management?

A. Benzyl-penicillin and Flucloxacillin
B. Flucloxacillin
C. Intravenous immunoglobulin
D. Tazocin and Clindamycin
E. Vancomycin and Metronidazole

D. Tazocin and Clindamycin

Type 1, or polymicrobial, necrotising fasciitis is the most common

Tazocin and clindamycin is the correct answer. This man has necrotizing fasciitis as evidenced by an erythematous rash with pain out of proportion to the clinical signs, fever, a tense thigh and shock with organ dysfunction (acute kidney injury). The most common type of necrotizing fasciitis is type 1, which is polymicrobial. We, therefore, need an antibiotic combination that provides adequate coverage against gram-positive, gram-negative and anaerobic bacteria. Tazocin and clindamycin is the only option listed that fulfils these criteria. Clindamycin has the additional benefit of theoretically inhibiting toxin production in severe streptococcal infections. The polymicrobial type is in particular, more common in diabetic patients.

Benzyl-penicillin and Flucloxacillin are not correct. This will only provide adequate coverage for streptococcal and staphylococcal skin and soft tissue infections (gram-positive) but will not adequately treat gram-negative and anaerobic infections.

Flucloxacillin is incorrect. Again, this has activity predominantly against gram-positive bacteria.

Intravenous immunoglobulin is incorrect. This treatment can be used as an adjunct in severe skin and soft tissue infections but it does not replace antibiotic treatment.

Vancomycin and metronidazole are incorrect. Vancomycin provides coverage for gram-positive organisms and metronidazole for anaerobic bacteria but there is not sufficient gram-negative coverage in this combination.

Question 113 of 277

A 32-year-old man presents with his left eyelid closing and dribbling from the side of his mouth. This arose three weeks ago and he has also felt tired and fatigued. He denies any fevers and has no weakness in any other parts of his body. He has a dry cough which comes and goes and he put down to hay fever. His left ear has reduced hearing and has been sore.

In addition, there is a red rash on his legs which has now faded. He has no past medical history, has not travelled abroad and is regularly sexually active with a single male partner. He has had shingles three months ago.

On examination, he has a clear left sided facial droop with normal sensation and no sparing of the forehead. He has normal power in all four limbs with no sensory loss. There is a faint red circle on the right leg surrounding a central red area within. Scattered crepitations are present in the lungs. He has pain in his left ear with an effusion behind the tympanic membrane.

Hb	156 g/l	Na +	135 mmol/l
Platelets	345 * 10 /l 9	K +	4.5 mmol/l
WBC	12 * 10 /l 9	Urea	4.2 mmol/l
Neuts	9 * 10 /l 9	Creatinine	94 µmol/l
Lymphs	1 * 10 /l 9	CRP	34 mg/l
Eosin	0.2 * 10 /l9		
Corrected Calcium	2.2mmol/l		

ECG	sinus, PR interval 202ms
Chest x-ray	no abnormalities seen

What is the likely diagnosis?

A. Ramsay hunt syndrome
B. Lyme disease
C. Sarcoidosis
D. Bell's palsy
E. Syphilis

B. Lyme disease

Lyme's disease can present with a facial nerve palsy

This gentleman has a facial nerve palsy without sparing of the forehead. Ramsay hunt syndrome occurs following shingles in the facial nerve and has vesicles in the ear canal but this is visible and it does not cause an effusion. Sarcoidosis is possible but the calcium is normal and there is no hilar lymphadenopathy. Bell's palsy is idiopathic or even possibly viral and should be diagnosed once all other causes are excluded. Syphilis is possible and can have a rash however the rash here is described as a red circle with a central part which should prompt thoughts of erythema migrans in Lyme disease.

Question 114 of 277

You are working in the liver clinic. A 28-year-old pregnant lady attends the clinic. She has been diagnosed with hepatitis C. She has no other co-morbidities and is not taking any regular medications. Hepatitis B and HIV have been excluded. She asks you about the risk to her baby.

What is the risk of vertical transmission?

A. 30%
B. 6%
C. 80%
D. 50%
E. No risk

B. 6%

Risk of vertical transmission for hepatitis C is 6%

Risk of vertical transmission with hepatitis C is generally low and up to 6%. The risk of transmission appears to be high in women with HIV co-infection or high viral load.

Question 115 of 277

A 55-year-old patient is admitted to the acute medical unit with a 10-day history of a dry cough and progressive shortness of breath, particularly on exertion. He also complains of intermittent fevers and a general loss of appetite. His past medical history includes HIV and he is noncompliant with his regular medications.

His observations are as follows:

- Temperature 38.3ºC
- Heart rate 112 beats/min
- Blood pressure 123/84mmHg
- Respiratory rate 25 breaths/min
- Oxygen saturations 94% on air, 83% on exertion

On examination, he appears pale and cachectic. There are audible crackles bilaterally. His heart rate is regular and heart sounds are normal. He has a soft and non-tender abdomen.

Laboratory tests:

CD4 count	< 200/mm³

Which of the following complications is most commonly associated with the likely underlying diagnosis?

A. Encephalitis
B. Hepatitis
C. Pancreatitis
D. Pleural effusion
E. Pneumothorax

E. Pneumothorax

Pneumocystis jiroveci pneumonia - pneumothorax is a common complication

This patient has a diagnosis of pneumocystis jirovecii pneumonia (or PCP), a fungal pneumonia that is most commonly seen in immunocompromised individuals, particularly those with HIV. Symptoms of infection include fever, dry cough and shortness of breath (especially on exertion) as

seen in this patient. Given his lack of compliance with his medications, most importantly the highly active antiretroviral therapy, combined with the CD4 count < 200/mm³, this patient is at high risk of developing PCP. The most common complication associated with PCP is a pneumothorax secondary to rupture of pulmonary cysts.

Extrapulmonary manifestations of PCP include hepatosplenomegaly and lymphadenopathy. However, these are rare and less likely. Encephalitis is a complication of several viral infections including measles, herpes simplex and varicella-zoster virus. It is not a complication of PCP.

Hepatitis has multiple causes such as inflammatory, ischaemic and infective (e.g. hepatitis A,B,C,D and E). PCP is not a cause of hepatitis.

Pancreatitis is a complication of mumps and coxsackie B virus, but not PCP.

Along with pneumothorax, other respiratory complications of PCP include acute respiratory distress syndrome. However, a pleural effusion is a less likely complication compared to a pneumothorax, making it incorrect.

Question 116 of 277

A 28-year-old man presents with cough and fevers. He states that the cough has been going on for approximately 6 months. He states that there is occasional blood in the sputum. He has also lost approximately 10 kg over the past 2 months. He immigrated to the UK from India approximately 1 year ago. He is not aware of being in contact with anyone with tuberculosis.

You suspect a diagnosis of tuberculosis and isolate him into a negative pressure room.

What investigation is most likely to yield a positive diagnosis?

A. Bronchoalveolar lavage (BAL) with staining, culture and sensitivity
B. Induced sputum with staining, culture and sensitivity
C. Interferon-Gamma Release Assays
D. Mantoux test
E. Chest x-ray

A. Bronchoalveolar lavage (BAL) with staining, culture and sensitivity

In order to confirm the diagnosis of TB, it is necessary to culture *Mycobacterium tuberculosis* from a respiratory specimen. Bronchoscopy will produce the best respiratory specimen for acid-fast staining and mycobacterial culture

Patients who are suspected to have pulmonary tuberculosis should have multiple respiratory samples (3 deep cough sputum samples, preferably including 1 early morning sample) for TB microscopy and culture. Patients that are unable to produce sputum spontaneously or have smear-negative sputum present a diagnostic challenge. NICE recommend that clinicians should perform induction of sputum or bronchoscopy and lavage in adults in this situation.

The investigation with the greatest diagnostic yield is bronchoscopy with lavage making this the best answer.

The Mantoux and Interferon-Gamma Release Assays tests are useful for diagnosing latent TB infection.

Question 117 of 277

A 38 year-old intravenous drug user presented to accident and emergency with a 10-day history of severe watery diarrhoea and abdominal cramps. Her past medical history included treatment for a groin abscess 3 years previously. She could not remember ingesting any possible causative food and had not travelled abroad. She smoked 15 cigarettes per day and drank 30-40 units of alcohol per week.

On examination, her temperature was 36.8ºC, heart rate 100 beats per minute, blood pressure 92/58 mmHg, respiratory rate 18 breaths per minute and oxygen saturations 100% on room air. Her tongue appeared dry with white patches evident on the hard palate and throat. The JVP was not visible. Her chest was clear on auscultation and heart sounds were normal. The abdomen was soft on palpation with some mild central abdominal tenderness.

Investigations:

Haemoglobin	170 g/L
White cell count	4.5 * 10 /l9
Neutrophil count	3.0 * 10 /l9
Lymphocyte count	0.1 * 10 /l9
Eosinophil count	0.4 * 10 /l9
Platelets	423 * 10 /l9

Sodium	132 mmol/l
Potassium	3.0 mmol/L
Urea	13.0 mmol/L
Creatinine	110 mol/L
Alkaline phosphatase	57 IU/L
Alanine aminotransferase	60 IU/L
Gamma-glutyl transferase	67 IU/L
Bilirubin	19 mol/L
Albumin	29 g/L

Abdominal x-ray: No abnormality detected Stool culture: No growth at 48 hours

What additional staining technique should be used for analysing the stool sample?

A. Ziehl-Neelson
B. Romanowsky
C. Periodic acid-Schiff
D. Sudan
E. Silver

A. Ziehl-Neelson

This patient is likely to have *Cryptosporidium parvum* infection. In the immunocompetent, the protozoan causes a self-limiting diarrhoeal illness lasting 7-10 days or may even be asymptomatic. However, in this case there is likely to be co-existing immunosuppression from human immunodeficiency virus infection, which can result in a severe cholera-like diarrhoea syndrome. The most appropriate staining technique in this case is a modified acid-fast stain such as ZiehlNeelson, which will stain *C. parvum* oocysts red. Periodic acid-schiff is used on jejunal biopsy specimens to diagnose Whipples disease. Silver staining can pick up *Pneumocystis jiroveci* on sputum samples. Sudan stain is used to diagnose steatorrhoea, and Romanowsky is a blood staining method which preceded Giemsa staining.

Question 118 of 277

A 23-year-old man attends the emergency department after arriving back in the UK from a oneyear trip travelling in South America. He denies any acute medical problems but reports that he is concerned about a dog bite he had received in Brazil about three months previously. The patient had been on a rain-forest expedition when a dog from the village he was staying in became aggressive and bit him on the left hand, leaving a open wound. The local inhabitants of the village had then chased the dog away. The patient had received first aid from his tour guide and been provided with a course of oral antibiotics. The wound had then healed over the following two weeks. It was only when the patient had been speaking with fellow travellers shortly before he returned to the UK did he realise the possible risk for rabies exposure.

The patient was well in himself and denied any neurological or other symptoms. He had no significant past medical history and took no regular medications. He admitted that he had no adequately researched his travel health needs before leaving the UK and so had not had any vaccinations prior to his trip.

Examination of the patients wound demonstrated fully healed scars consistent with a bite marks across the palm and dorsal surface of the wrist. The limb had normal neurological and vascular examination and the patient reported normal function of the hand.

What is the correct statement regarding rabies post-exposure prophylaxis for this patient?

A. The patient should receive rabies vaccination but not rabies immunoglobulin as his wound has now healed
B. The patient does not require post-exposure prophylaxis as he remains free of symptomsfollowing the incubation period of rabies
C. The patient should receive rabies immunoglobulin and full rabies vaccination schedule
D. The patient does not require rabies post-exposure prophylaxis as he did not receive hisinjury in a high-risk region
E. The patient should receive rabies immunoglobulin but not rabies vaccination as this isonly of benefit if given pre-exposure

C. The patient should receive rabies immunoglobulin and full rabies vaccination schedule

The patient requires immediate (if belated) rabies post-exposure prophylaxis. Penetrating wounds are considered high risk-exposures, especially those to highly innervated areas such as the hands. The history of an unprovoked animal biting is also of concern.

Rabies immunoglobulin should be given no matter how long has elapsed since the exposure. As much as possible of the immunoglobulin dose should be infiltrated around the wound, with the remainder given as an IM gluteal injection. This should be combined with a full course of rabies vaccination (typically a 5-dose schedule with doses at day 0, 3, 7, 14 and 28). Such post-exposure prophylaxis is highly effective in preventing the rabies virus reaching the nervous system.

Large parts of South America and Central America (including Brazil) are considered high-risk rabies regions. The virus is also endemic in Africa, the Middle East, Eastern Europe and most of Asia.

The incubation period of rabies can be prolonged and the patient is certainly still at risk of contracting the disease. One study found a mean incubation time of 274 days (range 12 days to 10 years).

Question 119 of 277

A 35-year-old woman attends gastroenterology clinic following a referral from her general practitioner. The patient is suffering from ongoing gastrointestinal symptoms following a recent diagnosis of giardiasis, despite receiving appropriate first line treatment. The patient reports a 3- month history of variable bowel habit, consisting of periods of normal motions interspersed with episodes of frequent diarrhoea. During the course of her illness, the patient reports having lost approximately 7 kg in weight. The patient denied every experiencing fever or bloody diarrhoea, but did report unusual episodes of burping with an unpleasant taste, described by the patient as tasting like 'rotten eggs'.

After her initial symptoms, the patient attended her GP, with a subsequent stool microscopy test demonstrating evidence of infection with *Giardia lamblia*. The patient had not undertaken any recent overseas travel but was employed as a nursery nurse, which was suspected of being the source of her infection. Her employer had moved the patient to a different job role, not including direct contact with children after the patient disclosed her condition.

After the diagnosis of giardiasis, the patient was treated with a 5-day course of metronidazole consistent with British National Formulary guidelines. Following treatment, the patient reported some improvement but had not gained full resolution of her symptoms.

The patient was normally fit and well and her only significant past medical history was a salpingectomy performed 5 years previously due to an ectopic pregnancy. She had never previously experienced problematic gastrointestinal symptoms. The patient took no regular medications and had no known drug allergies.

Examination of the patient's abdomen was unremarkable and she appeared to be in generally good physical condition. A urinary pregnancy test was negative.

Following her review in the clinic, a decision was made to prescribe the patient a single dose of tinidazole as a second-line treatment for giardiasis.

What advice should be given to the patient alongside this treatment?

A. Avoid consuming legumes for 2-6 weeks
B. Avoid consuming dairy products for 2-6 weeks
C. Avoid consuming eggs for 2-6 weeks
D. Her ongoing symptoms are likely secondary to irritable bowel syndrome not giardiasis
E. Avoid consuming gluten for 2-6 weeks

B. Avoid consuming dairy products for 2-6 weeks

The patient has typical symptoms of giardiasis. While giardiasis is the most common protozoal infection in returning travellers, research suggests that the majority of cases in the UK are acquired through domestic exposure such as child-care, sexual contact or consumption of unprocessed foods.

Following unsuccessful first line treatment, a repeat course of antibiotic therapy (either metronidazole or tinidazole) should be given. The patient has already taken steps to avoid reinfection by temporarily changing her job role away from direct contact with children. Giardiasis can cause temporary lactose intolerance, which can lead to ongoing gastrointestinal symptoms after the infection has been eradicated. To exclude this possibility, patients should be advised to avoid dairy products for 2-6 weeks.

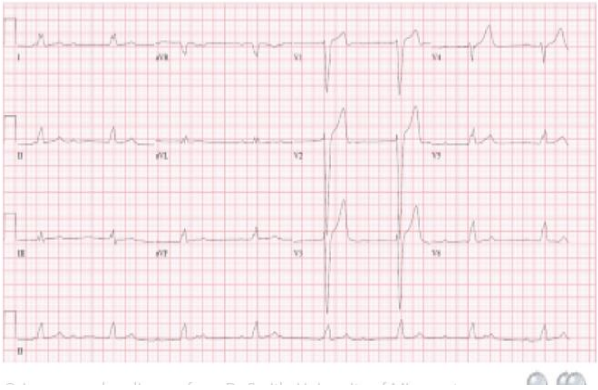
There is an overlap between the symptoms of irritable bowel syndrome and giardiasis. Therefore, in an individual with symptoms suggestive of irritable bowel syndrome but with risk factors for *Giardia* infection, faecal testing for ova and parasites should be considered to exclude giardiasis. However, in this patient, the absence of gastrointestinal symptoms prior to the current episode would make a diagnosis of irritable bowel syndrome unlikely.

Question 120 of 277

A 31-year-old man presents to the emergency department with an episode of collapse. He reports that for the past week, he has been having fevers, headaches, and generally feels faint. He has recently returned from a two-month holiday to the North-Eastern coast of the United States of America (USA). He has no past medical history.

Blood results are as follows:

Hb	141 g/L	135-180
Platelets	231 * 10 /L ^{9}	(150 - 400)
WBC	19.3 * 10 /L ^{9}	(4.0 - 11.0)
Na $^{+}$	138 mmol/L	(135 - 145)
K $^{+}$	4.1 mmol/L	(3.5 - 5.0)
Urea	5.1 mmol/L	(2.0 - 7.0)
Creatinine	91 µmol/L	(55 - 120)
CRP	74 mg/L	(< 5)



Which infectious cause is most likely to be responsible?

A. American trypanosomiasis
B. Coxsackie A
C. Coxsackie B
D. Group A streptococcus
E. Lyme disease

E. Lyme disease

This man's ECG shows a complete heart block with complete dissociation of the QRS complexes from the p waves. The most common infectious cause for this is Lyme disease which is the correct answer here. Ticks that transmit Lyme disease can be found in the United Kingdom as well as the USA.

American trypanosomiasis causes Chagas' disease which can manifest as myocarditis and, ultimately, arrhythmias including complete atrioventricular block. Despite the name, this disease is mainly found in Southern and Central America, whereas the main source of transmission throughout the USA is via immigration and blood transfusions.

Coxsackie A is not associated with ECG changes and therefore this answer is incorrect.

Coxsackie B can cause viral myocarditis for which the most common ECG change is sinus tachycardia. Fulminant Coxsackie myocarditis can result in complete heart block however this would likely present with gastrointestinal symptoms and more severe signs of cardiogenic shock.

Group A streptococci can cause rheumatic fever which in turn can cause first-degree heart block however complete heart block is a far rarer observation.

Question 121 of 277

A 28 year-old man presents to his doctor with a rash and bone pain. Radiographs of the limbs revealed numerous osteolytic lesions. He was successfully treated for secondary syphilis.

Which of the following tests is likely to remain positive in this patient despite treatment?

A. Blood culture
B. Treponema pallidum particle agglutination (TPPA)
C. Venereal disease reference laboratory (VDRL)
D. Rapid plasmin reagin (RPR)
E. Wasserman test

B. Treponema pallidum particle agglutination (TPPA)

Syphilis is a disease caused by infection with the spirochete Treponema pallidum. The infection is systemic and the disease is characterized by periods of latency. These features, together with the fact that Treponema pallidum cannot be isolated in culture, mean that serologic techniques play a major role in the diagnosis and follow-up of treatment for syphilis.

The Treponema pallidum particle agglutination assay (also called TPPA test) is an indirect agglutination assay used for detection and titration of antibodies against Treponema pallidum.

IgG antibodies to syphilis can remain elevated despite appropriate antimicrobial treatment and a reactive result does not distinguish between recent or past infection.

Question 122 of 277

A 20-year-old woman who is 16 weeks pregnant presents with pain passing urine and an irritating rash. On examination, she has a tender, red, vesicular rash on her vulva. A urine dipstick shows both blood and white cells.

What is the best treatment?

A. Clotrimazole
B. Cefalexin
C. Oral aciclovir
D. Topical aciclovir
E. Fluconazole

C. Oral aciclovir

This patient has genital herpes simplex virus (HSV). The guidelines recommend treatment with oral (or intravenous) aciclovir at any stage in pregnancy. Aciclovir is not licensed in pregnancy but is considered safe and not associated with birth defects. It is well tolerated in pregnancy. Paracetamol and topical lidocaine 2% gel can be used for symptomatic relief.

The primary purpose of treatment is to reduce the risk of transmission to the neonate at birth. The risk is much more considerable with primary genital herpes simplex within the final six weeks of pregnancy. Caesarian section should be the recommended mode of delivery for all women developing the first episode of genital HSV in the third trimester.

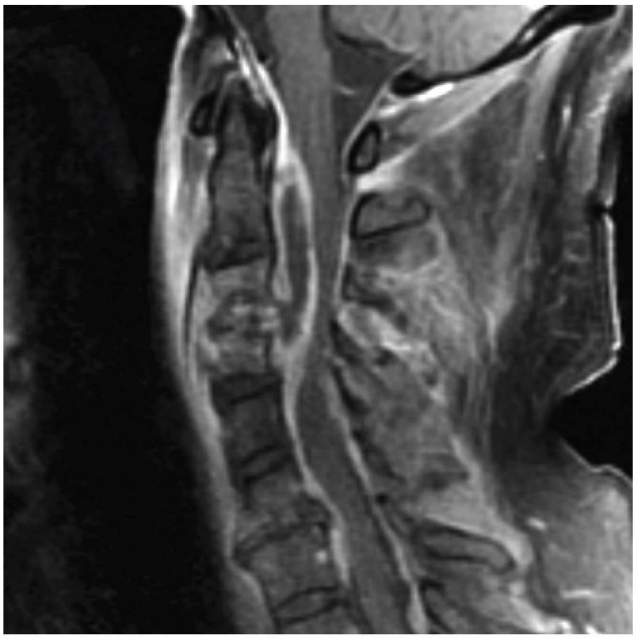
Question 123 of 277

A 54-year-old man presents with neck pain and feeling generally unwell. This has been getting progressively worse over the past two weeks and is now 'unbearable'. He feels hot and also complains of headaches.

He emigrated from Pakistan 30 years ago. He smokes 20 cigarattes/day and does not drink alcohol.

On examination pulse is 102/min, blood pressure 124/74 mmHg and temperature 37.9ºC. He has weakness in both arms

MRI of his cervical spine is shown below:



What is the most likely diagnosis?

A. Cervical disc prolapse
B. Syringomyelia
C. Cervical epidural abscess
D. Meningitis
E. Tuberculosis

C. Cervical epidural abscess

MRI demonstrates an epidural collection with peripheral contrast enhancement. The cord is displaced posteriorly and to the right. Features are consistent with an epidural abscess. There are associated changes at the C3/4 level consistent with advanced discitis osteomyelitis.

Question 124 of 277

A 29-year-old woman who is a former intravenous drug user is seen in the hepatology clinic. She is 12 weeks pregnant and has been referred as she is known to have chronic hepatitis C. Twelve months ago she was treated with pegylated interferon-alpha, ribavirin and a protease inhibitor which failed to result in her clearing the hepatitis C virus.

What is the most appropriate way, if any, to reduce the risk of vertical transmission?

A. Caesarean section
B. Further course of antiviral therapy during pregnancy
C. Advise against breastfeeding
D. Antiviral therapy for the neonate for the first 4 weeks
E. None of the above interventions is recommended

E. None of the above interventions is recommended

Question 125 of 277

A 45-year-old female presents with a history of headache and generalised malaise for the last two months. She describes her headaches as being a tight band like sensation which is present almost throughout the day and causes significant difficulty in sleeping at night. She also mentions occasional episodes of vomiting along with low-grade fever and weight loss of about 7 kg over the same duration of time. She suffers from generalised anxiety disorder and takes 0.5mg alprazolam TDS. She returned from Dubai 9 months ago where she had been spending her holidays with her family.

On examination, she has a fever of 37.5°C and a pulse of 105bpm. She appears slightly disoriented with a tendency to speak out of context but is otherwise cooperative.

There is diplopia on right sided gaze and mild neck stiffness, but the remaining clinical examination is essentially unremarkable.

Lab reports reveal:

Hb	115 g/l
Platelets	340 * 10 /l9
WBC	9.0 * 10 /l9

Na +	137 mmol/l
K +	4.2 mmol/l
Urea	5.9 mmol/l
Creatinine	102 µmol/l
Glucose	7.0 mmol/l
ESR	87 mm/hr

MRI shows meningeal enhancement but no evidence of any parenchymal lesions. CSF examination reveals:

Opening Pressure	Normal
Appearance	Turbid
Protein	3.2g/L (0.2 0.4 g/L)
Glucose	2.7 mmol/l
Lymphocytes	$371/mm^3$
Neutrophils	$42/mm^3$
ZN staining	No acid fast bacilli detected

Which of the following is the most appropriate treatment option?

A. IV acyclovir
B. IV ceftriaxone
C. Isoniazid, rifampicin, pyrazinamide and dexamethasone
D. IV benzylpenicillin
E. Artemether/lumefantrine

C. Isoniazid, rifampicin, pyrazinamide and dexamethasone

The 2-month history of headache, generalised malaise, low-grade fever and weight loss all go in favour of a diagnosis of tuberculous meningitis. This diagnosis is also supported by the examination findings of diplopia neck stiffness.

The complete blood count does not favour a bacterial infection as one would expect a leucocytosis. The raised ESR is also supportive of TBM.

The CSF shows a predominant lymphocytosis with greatly raised protein and significantly low glucose which once again goes with tuberculosis.

TBM typically commences with symptoms of a vague headache, lassitude, anorexia and vomiting. Acute meningitis may occur but it is uncommon. The development of meningitic signs often takes weeks. Common signs include diplopia, papilloedema and hemiparesis and seizures are also often commonly seen. Treatment is generally commenced on a presumptive basis since multiple CSF cultures are often required and it may take weeks before culture reports are available. Staining with ZN staining is often negative and PCR for mycobacterium tuberculosis is helpful but is often negative too and repeat PCR is often needed.

Treatment is with isoniazid, rifampicin, pyrazinamide and steroids. Ethambutol should be avoided due to eye complications.

Question 126 of 277

A 44-year-old woman with a background of asthma who has required frequent use of oral corticosteroids is inquiring about vaccinations available to her.

Which one of the following should be recommended?

A. 23-valent unconjugated pneumococcal polysaccharide vaccine and influenza vaccine
B. 13-valent conjugated pneumococcal polysaccharide vaccine only
C. 23-valent unconjugated pneumococcal polysaccharide vaccine only
D. 13-valent conjugated pneumococcal polysaccharide vaccine and influenza vaccine
E. Influenza vaccine only

A. 23-valent unconjugated pneumococcal polysaccharide vaccine and influenza vaccine

Patients with chronic respiratory conditions including asthma requiring frequent use of oral steroids should be offered both the 23-valent unconjugated pneumococcal polysaccharide vaccine and the influenza vaccine. In this population, the pneumococcal vaccine is usually given as a once off but may be required 5 yearly depending on the underlying condition and the age of the patient. The influenza vaccine, however, is given annually.

The 13-valent conjugated pneumococcal polysaccharide vaccine is routinely given to infants as it has been found to be more effective given their less mature immune systems.

Question 127 of 277

A 39-year-old female with end-stage renal failure secondary to IgA nephropathy is admitted to hospital. She was discharged 3 days earlier following an admission due to collapse in the context of hyperkalaemia (Potassium 7.8 mmol/l). She has been transferred to the medical assessment unit having developed rigors on dialysis earlier today.

Bloods taken at the end of dialysis reveal:

White cell count	15.2 *109/l
Sodium	134 mmol/l
Potassium	2.1 mmol/l
Urea	10.6 mmol/l
Creatinine	400 µmol/l
C-reactive protein (CRP)	119 mg/dL

What is the immediate priority in her management?

A. Replace potassium (K+)
B. Replace magnesium (Mg2+)
C. Intravenous antibiotics
D. Intravenous calcium gluconate
E. Insulin/dextrose infusion

C. Intravenous antibiotics

The patient is septic and infection is her most imminent threat. Post-dialysis bloods are often misleading in terms of electrolytes as it takes 30 minutes for intracellular and extracellular compartments to equilibrate. Assuming that the patients pre-dialysis bloods showed a highnormal K+ (which would fit with her recent hyperkalaemia presentation) then her total body K+ will be much higher than the post-dialysis sample suggests. The bloods should be repeated to confirm this but over-zealous correction of K+ in this situation can be dangerous.

Magnesium is important to correct in the presence of hypokalaemia, however, we do not think this patient genuinely has low potassium. Intravenous calcium gluconate and insulin/dextrose infusion are both treatments for hyperkalaemia and therefore are not appropriate.

Question 128 of 277

A 23-year-old student presented to his GP with fever and epistaxis. The fever had started 6 days earlier. It had been associated with a headache and malaise. Following clinical examination his doctor prescribed him amoxicillin which he took for 3 days but without any improvement. He later became so ill that he refused to eat and started to vomit.

His history included mumps at the age of nine. His father had been diagnosed with liver cirrhosis 2 years ago due to excessive alcohol consumption. He is a regular smoker for the last 10 years and lives in the dorm. Two weeks earlier he had been in rural Central Africa as a reporter covering the conflict there. He denied being vaccinated for any disease before going there but did take antimalarial tablets.

On examination he appeared ill. His temperature was 38ºC. He was jaundiced. Eye examination revealed conjunctival hemorrhages on both eyes. All other systems were normal.

The following investigations had been requested:

Hb	13 g/dl
platelets	170 * 10^9/l
WBC	4 * 10^9/l
MCV	85 fl
MCH	0.4 fmol/cell
MCHC	20 mmol/l
Na+	135 mmol/l
K+	4 mmol/l
Creatinine	80 µmol/l
Urea	3 mmol/l
ESR	60 mm/hr
Alkaline phosphatase	100 IU/l
Alanine transaminase	400 IU/l
Aspartate transaminase	200 IU/l
Bilirubin	25 µmol/l (direct 18 umol/l)
Serum albumin	40 g/l
Prothrombin time	prolonged
Partial thrompoblastin time	prolonged
Urine analysis	Albumin + ,acetone ++ ,bile pigment ++,urinary urobilinogen +

Thick Blood film for malaria	negative

What is the most likely diagnosis?

A. Yellow fever
B. Primary sclerosing cholangitis
C. Leptospirosis
D. Falciparum malaria
E. Dengue fever

A. Yellow fever

Yellow fever is endemic around the equator mainly in Africa. It is transmitted by the Aedes mosquitoes there. Characteristically the patient presents with fever and constitutional symptoms. Jaundice is a main clinical sign associated most of the times with conjunctival injection. Other important clinical signs are relative bradycardia, and hemorrhagic diathesis. The cause of death is due to multi-organ failure.

Blood tests generally show leucopenia with predominant neutropenia but this is not specific. Liver enzymes are elevated most of the time. Diagnosis depends on a high degree of suspicion for the disease and but also more important on serology which is highly specific for this lethal condition.

Treatment is mainly supportive.

Primary sclerosing cholangitis could present with fever and jaundice. This would happen in the context of ascending cholangitis (fever + pain + jaundice) with a long history of abdominal discomfort. Liver profile would reflect obstructive changes.

Malaria should be excluded in any patient who had traveled to an endemic area and developed fever. The picture in our patient was not typical and the blood film had been negative for malaria parasites. However one has to keep it in mind if the clinical picture fits. In that case one needs to repeat the blood film and to order serology.

Leptospirosis is a consideration here. But it usually responds to antibiotics. Liver enzymes would generally be more mildly elevated.

Dengue fever mainly presents with headache, fever and rash. It is mainly endemic in South East Asia.

Question 129 of 277

A 60 year old male who is a malnourished alcoholic presents with a chronic cough for the past 6 weeks associated with a low grade fever. The cough is productive of purulent sputum.

Six months previously he had been diagnosed with early stage non-Hodgkin's lymphoma, which had responded well to chemotherapy (doxorubicin, bleomycin, vinblastine, and prednisolone).

On examination his temperature is 37.8ºC, blood pressure 140/80 mmHg, and his pulse is 96/minute and regular. Auscultation of the chest reveals absence of breath sounds over the left middle lung field. Chest x-ray confirms left upper lobar consolidation.

The following investigations were ordered:

Hb	12 g/dl
Platelets	180 * 10^9/l
WBC	7 * 10^9/l
MCV	85 fl
Na+	140 mmol/l
K+	5 mmol/l
Creatinine	90 µmol/l
Urea	5 mmol/l
CRP	50 mg/l

Sputum stains partially acid fast bacilli with branching rods

What is the most suitable initial management of this patient?

A. Metronidazole + ampicillin
B. Clarithromycin
C. Ceftriaxone + clarithromycin
D. Trimethoprim/sulfamethoxazole + amikacin + ceftriaxone
E. Isoniazid + rifampin + pyrazinamide + ethambutol

D. Trimethoprim/sulfamethoxazole + amikacin + ceftriaxone

Nocardiosis typically occurs in immunocompromised patients with pulmonary involvement and in most cases with CNS or skin dissemination.

The clue here is the acid-fast stain which shows partially acid fast branching rods organism in contrast to mycobacterium which does fully stain.

Treatment of immunocompromised patients consists of multiple regimens. But mainly all of them involve Trimethoprim/sulfamethoxazole.

Nocardia species are ubiquitous soil organisms that often infect patients who are immunosuppressed, have pulmonary disease, or have a history of surgery or trauma. It is a Gram positive, acid fast bacilli.

Question 130 of 277

A 27 year old Caucasian man has just returned from a 12 week trip to Ivory Coast where he was working as a missionary. He had not consulted a travel clinic for immunisations and had taken no malaria prophylaxis. During his trip he slept in a hammock outside and he took a daily wash in the river near the church where he was working. For the last few days of his trip he felt very unwell. He developed fevers, muscle aches and a headache, however this was improving and he had been feeling much better when he arrived home in the UK.

He has been home for 24 hours. Today he felt very much worse and presented to A and E.

On admission:

- Temperature: 39.1C
- Blood pressure: 89/61mmHg
- Pulse: 68 / min
- Respiratory rate: 26 / min
- Oxygen saturations: 97% on room air.

His initial investigations show:

Hb	11.1 g/dl
Platelets	61 * 10 /l9
WBC	3.3 * 10 /l9
Neutrophils	2.6 * 10 /l9
Lymphocytes	0.6 * 10 /l9

Na +	146 mmol/l
K +	4.1 mmol/l
Bicarbonate	16 mmol/l
Urea	17.4 mmol/l
Creatinine	321 mol/l

Bilirubin	88 mol/l
ALP	322 u/l
ALT	821 u/l
γGT	421 u/l
Albumin	29 g/l

Following discussion with the ID consultant on call, he is isolated while a blood sample is sent to Public Health Englands imported fever service. He received empirical therapy for Malaria with Artesunate and for sepsis with Piperacillin/Tazobactam and Gentamicin, however he rapidly deteriorated and died within 24 hours of admission. Following discussion with Public Health England, who confirm that there was no evidence of a nosocomially transmitted Viral Haemorrhagic Fever, he has a post mortem examination which reveals Councilman bodies in his liver.

What would likely have prevented his death?

A. Sleeping under an insecticide treated bed net
B. Avoiding bathing in the river
C. Live attenuated Yellow Fever vaccine
D. Prophylaxis with doxycycline
E. Avoiding unprotected sex

C. Live attenuated Yellow Fever vaccine

This is yellow fever as suggested by:

- Travel to endemic area (West Africa and Central America)
- Fever, with initial resolution
- Progression to jaundice and renal failure

For exam purposes Councilman bodies (eosinophilic inclusion in the liver on post mortem) are diagnostic of yellow fever, although they can occasionally be seen in other Viral Haemorrhagic Fevers such as Crimean Congo Haemorrhagic Fever, (but this is nosocomially spread and therefore not the case in this example.

As such the vaccination is the only intervention which could have prevented his death.

Question 131 of 277

A 37 year old Caucasian male attends an outpatient clinic. He had recently spent three months in Jamaica on a beach-side yoga retreat. He only drank bottled water and ate well cooked vegetarian food. He ensured that any raw vegetables were peeled. He returned home three weeks ago.

During his final week in Jamaica he noticed an itchy spot develop on the side of his ankle. The rash has gradually spread from the original spot slowly 'like a snake up the side of his foot'. The lesion is currently 11cm long and is a raised itchy serpiginous linear lesion.

He is otherwise well.

What is the causative organism?

A. Strongyloides stercoralis
B. Ancylostoma braziliense
C. Necator americanus
D. Ascaris lumbricoides
E. Schistosomiasis mansoni \

B. Ancylostoma braziliense

The correct answer in this case is ***Ancylostoma braziliense***. The patient's presentation of a raised, itchy serpiginous linear lesion that has gradually spread 'like a snake' up the side of his foot is characteristic of cutaneous larva migrans (CLM), also known as creeping eruption. CLM is caused by the larval form of hookworms, most commonly *Ancylostoma braziliense*, which are found in tropical and subtropical regions such as Jamaica. The larvae penetrate the skin, usually through contact with contaminated soil or sand, and migrate within the epidermis, causing an intensely pruritic inflammatory reaction.

Strongyloides stercoralis is an incorrect option because this nematode causes strongyloidiasis, which typically presents with gastrointestinal symptoms such as abdominal pain and diarrhea. Skin involvement in strongyloidiasis can occur but usually manifests as pruritic papules or urticaria rather than the serpiginous linear lesion seen in this case.

Necator americanus is another species of hookworm, but it primarily causes human infection through intestinal penetration rather than cutaneous manifestations like CLM. Infection with *Necator americanus* can lead to iron-deficiency anemia due to blood loss from attachment sites in the small intestine.

Ascaris lumbricoides is a roundworm that causes ascariasis, one of the most common helminthic infections worldwide. Ascariasis typically presents with gastrointestinal symptoms such as abdominal pain and bloating; however, during the larval migration phase through the lungs, patients may experience coughing and wheezing. Cutaneous manifestations are not typical in ascariasis.

Schistosomiasis mansoni is a blood fluke that causes schistosomiasis, which is characterized by granulomatous inflammation in response to the eggs of the parasite. The primary manifestation of schistosomiasis is hepatosplenic involvement, with symptoms such as abdominal pain and hepatomegaly. Cutaneous manifestations can occur during the cercarial penetration phase (swimmer's itch), but this is typically a localized pruritic papular rash rather than the serpiginous linear lesion seen in this case.

Question 132 of 277

A 24-year-old Somali woman attends her booking appointment in the UK for her first pregnancy. Screening tests reveal that she is HIV positive. She is asymptomatic.

Her viral load is 150 000 copies/ml and her CD4 count is 523 cells/mm³. No viral resistance is detected. Her hepatitis serology is negative. Her husband consequently tests negative for HIV.

She is commenced on triple antiretroviral therapy (ART) with zidovudine, lamivudine and lopinavir/ritonavir. By 36 weeks her viral load is undetectable at <20 copies/ml.

Which of the following statements is true regarding her ongoing management?

A. She should have an elective caesarean section and continue to take her ART whilst breastfeeding.
B. She should have a vaginal delivery and continue to take ART whilst breast feeding.
C. She should have an elective caesarean section. ART should be continued.
D. She should have a vaginal delivery and formula feed. ART can be discontinued.
E. She should have a vaginal delivery and formula feed. ART should be continued.

E. She should have a vaginal delivery and formula feed. ART should be continued.

In this case, as her viral load is less than 50 copies/ml she may have a vaginal delivery. Formula feeding is recommended in the UK to all babies with HIV +ve mothers. In this case although her CD4 count is >350 cells/mm³ her ART should be continued to reduce the risk of onward transmission to her husband.

Question 133 of 277

A 48-year-old woman attends with a one-week history of a productive cough and shortness of breath. She has never smoked and has no past medical history. Observations are as follows: heart rate 105 beats per minute, blood pressure 125/70 mmHg, temperature 38.4ºC, respiratory rate 20 breaths per minute, oxygen saturation 92% on air.

Blood results are as follows:

Hb	122 g/L	Male: (135-180)Female: (115 - 160)
Platelets	246 * 10 /L 9	(150 - 400)
WBC	14.2 * 10 /L 9	(4.0 - 11.0)
Na +	128 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	105 µmol/L	(55 - 120)
CRP	96 mg/L	(< 5)

Bilirubin	22 µmol/L	(3 - 17)
ALP	115 u/L	(30 - 100)
ALT	262 u/L	(3 - 40)
Î³GT	114 u/L	(8 - 60)
Albumin	32 g/L	(35 - 50)

A chest x-ray was performed:

Chest x-ray	Bilateral patchy consolidation

What treatment is indicated?

A. Co-amoxiclav
B. Co-trimoxazole
C. Co-trimoxazole and prednisolone
D. Erythromycin
E. Piperacillin/tazobactam

D. Erythromycin

Macrolides such as clarithromycin are used to treat *Legionella*

Erythromycin is correct. The clinical features are suggestive of *Legionella* infection. The patient has an atypical pneumonia with bilateral patchy consolidation, hyponatraemia, and deranged liver function tests, all suggestive of *Legionella* infection. Most guidelines recommend either a fluoroquinolone or a macrolide as first-line treatment for Legionella pneumonia, often with the addition of a penicillin for a synergistic effect.

Co-amoxiclav is incorrect. This antibiotic is effective for typical organisms such as *Streptococci* and *Haemophilus*.

Co-trimoxazole is incorrect. This drug can be used to treat pneumocystis pneumonia (PCP) which is a serious infection caused by the fungus *Pneumocystis jirovecii*. Although this can present similarly, it is a condition which tends to only develop in patients with weak immune systems. The patient in this clinical case is immunocompetent making PCP an unlikely diagnosis.

Co-trimoxazole and prednisolone is incorrect. This regime of drugs can be used to treat severe PCP infections characterised by a PaO2 < 8kPa.

Piperacillin/tazobactam is incorrect. This drug has a similar spectrum to co-amoxiclav with the addition of activity against *Pseudomonas*.

Question 134 of 277

A 29-year-old woman is brought to the emergency department by her husband with drowsiness. Over the last day she had been complaining of headaches, nausea and fevers. About a week ago she had a period where she felt unwell with fever, headache and myalgia, but this self-resolved. She had returned from Poland 2 weeks ago where she had been on a camping holiday with friends. Her past medical history consists only of asthma, for which she takes salbutamol as required.

Examination reveals a Glasgow Coma Scale (GCS) of 14 with neck stiffness but no focal neurology. Her lungs are clear and her abdomen is soft and non-tender. There is no rash.

A lumbar puncture is performed which reveals mildly elevated white blood cells. An HIV test is negative. The patient is then started on ceftriaxone, dexamethasone and aciclovir.

The CSF culture and PCR come back negative. A sample had also been sent away to the infectious disease laboratory, which after serological testing comes back as positive for *flavivirus* antibodies.

Given the most likely diagnosis, what is the most appropriate management?

A. IV amphotericin B
B. IV aciclovir
C. IV pyrimethamine/sulfadiazine and folinic acid
D. IV quinine dihydrochloride
E. Supportive management

\

E. Supportive management

Treatment for tick-borne encephalitis is supportive

A presentation of headache, neck stiffness, fever and reduced GCS is suggestive of meningoencephalitis. The question revolves around determining what is the most likely causative agent and therefore the most appropriate treatment.

The history of recent travel should raise your suspicion for a potentially uncommon aetiology. The camping history combined with a biphasic illness is characteristic for tick-borne encephalitis. Ultimately, the finding of a *flavivirus* in the CSF confirms the diagnosis. Management for this condition is supportive.

Amphotericin B may be used in the treatment of primary amoebic meningoencephalitis. This is a very rare cause of meningoencephalitis caused by *naegleria fowleri.*

Aciclovir is used in the management of herpes simplex virus (HSV) encephalitis. HSV, along with varicella-zoster virus and enteroviruses make up 90% of cases of viral encephalitis. In this patient, the travel history and biphasic illness suggest an alternate, atypical cause.

IV pyrimethamine/sulfadiazine and folinic acid are used in the management of cerebral toxoplasmosis. Toxoplasmosis is usually asymptomatic or mild in immunocompetent patients. The patient only has a past medical history of asthma and is HIV negative, therefore this is a less likely diagnosis.

IV quinine dihydrochloride may be used in severe or complicated falciparum malaria. The patient has not come from a malaria-risk country and does not have other features suggestive of malaria, such as jaundice.

Question 135 of 277

A 40-year-old woman is referred to the infectious diseases team after attending her GP practice requesting advice regarding antibiotic prophylaxis for Lyme disease. The patient explains that she is planning on a 2 week long walking holiday in the Lake District National Park in Cumbria, United Kingdom and that she is concerned about the risk associated with receiving tick bites during this period. Lyme disease is a particular concern for the patient as her younger sister had suffered serious neurological complications from the condition secondary to a tick bite in the Scottish Highlands. Concern about contracting Lyme disease herself had prevented her from partaking in her hobby of cross country walking for the past 2 years but she had now decided to confront her fear by undertaking the planned trip. After undertaking research on the Internet, the patient was keen to receive prophylactic antibiotics against *Borrelia* species during her trip.

The patient's past medical history included a diagnosis of breast cancer seven years previously. Following this diagnosis, the patient had undergone a wide local excision of the tumour with postoperative chemotherapy. The patient had been given the all clear from her oncologists after five years and had been subsequently been discharged from follow-up. In addition, the patient had experienced long-standing and, at times, troubling symptoms of irritable bowel syndrome.

The patient took regular hyoscine butylbromide as treatment of her gastrointestinal symptoms. The patient stated that she was allergic to penicillin-based antibiotics. Close questioning on this topic revealed that her adverse reaction to a previous course of penicillin V had been a protracted episode of diarrhoea.

The patient lives with her husband and three teenage children. She was employed full-time as a music teacher. The patient did not smoke cigarettes and consumed approximately 10 units of alcohol per week.

What is appropriate management following the patient's request for antibiotic prophylaxis against Lyme disease during her walking holiday?

A. Prescribe amoxicillin for the duration of the patient's holiday
B. Prescribe amoxicillin for immediate use if she receives a tick bite
C. Prescribe doxycycline for the duration of the patient's holiday continued for an additional10 days after her return home
D. Advice on the prevention and management of tick bites only
E. Prescribe doxycycline for immediate use if she receives a tick bite

D. Advice on the prevention and management of tick bites only

There is no need for prophylactic antibiotics for Lyme disease in asymptomatic patients bitten by a tick

There is no role for antibiotic prophylaxis against Lyme disease. Simple advice on prevention of tick bites includes wearing clothing that adequately covers the patient's body and the use of insect repellent chemicals. Ticks that have attached themselves should be gently removed using tweezers to minimise the risk of rupturing the tick and potentially releasing infected material.

Individuals showing symptoms of Lyme disease - for example, erythema migrans - following potential exposure to tick bites should be treated with a 14-21 day course of doxycycline or amoxicillin immediately.

Individuals with a history of tick bite but without symptoms of Lyme disease do not normally require either treatment or serological testing. Treatment of asymptomatic individuals who have received a tick bite may be appropriate in certain situations; for example, in individuals who are immunosuppressed or who received tick bites in high-risk regions of the USA.

Question 136 of 277

A 35-year-old male attends clinic with a new diagnosis of chronic hepatitis B infection. He gives a history of unprotected sex with multiple sexual partners in the two years. His blood tests show him to be HIV, HCV antibody and HBeAg negative. The most recent liver function tests are shown below. On examination, he has no evidence of decompensated liver disease.

Bilirubin	18µmol/L
ALT	52iu/L
AST	38iu/L
ALP	190iu/L
Albumin	30g/L
Protein	93g/L

HBV viral load	2,000IU/mL

Which one of the following treatment options should be considered first line?

A. Peginterferon alpha 2a and entecavir
B. Entecavir
C. Peginterferon alpha 2a
D. Tenofovir disoproxil
E. Entecavir and tenofovir disoproxil

C. Peginterferon alpha 2a

Peginterferon alpha 2a is the first line treatment for adults with HBeAg-negative chronic hepatitis B with compensated liver disease. Tenofovir disoproxil or entecavir are second line treatment in those who have detectable HBV DNA after treatment with peginterferon alpha 2a.

Question 137 of 277

A 43-year-old gentleman presents with bloody diarrhoea. He is HIV positive and has a CD4 count of 150 cells/µL.

He had been on a trip to Zimbabwe 10 months previously. Over the past 2 weeks, he had symptoms of anorexia and mild abdominal discomfort. These had progressed on to severe abdominal cramps and bloody diarrhoea.

He has a temperature of 37.8ºC, a blood pressure of 100/60 and a pulse of 111/min. On examination, he looks unwell, is emaciated and has generalised tenderness on examination of his abdomen. There is no guarding or peritonitis.

What is the most likely causative organism?

A. Giardia lamblia
B. Toxoplasma gondii
C. Entamoeba histolytica
D. Cytomegalovirus
E. Strongyloides stercoralis

C. Entamoeba histolytica

Entamoeba histolytica is the only pathogen here which typically causes bloody diarrhoea in an immunocompromised individual and hence is the correct answer. Giardia typically causes steatorrhoea, *Toxoplasma gondii* is more likely to cause a central nervous system infection, and while CMV can cause diarrhoea it is rarely a presenting feature of the infection. While *Strongyloides stercoralis* can cause diarrhoea, it is usually watery rather than bloody.

Question 138 of 277

A 25-year-old woman returns from a holiday in Thailand with diarrhoea. She has no past medical history and takes no regular tablets apart from the oral contraceptive pill. She has no allergies apart from peanuts. She has a been suffering from diarrhoea for three days with mild abdominal cramps which started five days after returning from her trip. There has been a small amount of blood in her stool. Her observations are within normal range. She has no postural symptoms. Stool samples are requested and sent to the microbiology lab.

What is the most appropriate treatment?

A. Ciprofloxacin
B. Tetracycline
C. Oral rehydration solution
D. Metronidazole
E. Co-amoxiclav

C. Oral rehydration solution

The correct answer is oral rehydration solution. Empirical antibiotics are only indicated if systemically unwell, immunosuppressed or if elderly, even if the patient has bloody diarrhoea. CIprofloxacin is used to treat Salmonella, Shigella and Campylobacter, tetracycline can be used for cholera, metronidazole in parasitic infections or other bowel problems, and finally, co-amoxiclav is seldom used in enteric infections.

Question 139 of 277

A 25-year-old man presents to gastroenterology with a 6-month history of unexplained chronic diarrhoea and unexplained chronic weight loss. An HIV test is sent as part of his work-up and returns positive. His CD4 count is 150. He is started on anti-retroviral therapy.

Round oocysts measuring between 4 and 6 µm are seen during microscopy of the patient's stool sample. They stain red using the modified acid-fast stain. A diagnosis of Cryptosporidium is made. The first-line treatment of nitazoxanide is not available.

What other medication could be a potential treatment option for this patient?

A. Ciprofloxacin
B. Metronidazole
C. Nitrofurantoin
D. Prednisolone
E. Rifaximin

E. Rifaximin

Rifaxamin is licensed for the treatment of cryptosporidiosis

The oocysts described on stool microscopy are typical of *Cryptosporidium*. *Cyclospora* and *Isospora* oocysts will also stain with the modified acid-fast stain. The oocysts of *Cyclospora* look similar to those of *Cryptosporidium* but are larger at 8-10 µm. *Isospora* oocysts are oval shaped and are larger again at 10-20 x 20-30 µm.

Cryptosporidiosis is a protozoal infection that generally causes mild, watery diarrhoea in immunecompetent patients, although symptoms can persist for several weeks. It can cause chronic diarrhoea in immune suppressed patients, especially those with HIV infection. Treatment is not always required as the symptoms often improve once the immune system starts to recover. If treatment is indicated the first line option is nitazoxanide, followed by rifaximin.

Ciprofloxacin can be used for some causes of infectious diarrhoea, such as *Campylobacter* and *Salmonella* but does not treat *Cryptosporidium*.

Metronidazole is effective against anaerobic bacteria and some protozoa (including *Giardia*) but is not active against *Cryptosporidium*.

Nitrofurantoin is mainly used for the treatment of lower urinary tract infections due to Gram negative rods and will not treat *Cryptosporidium*.

Prednisolone may worsen the patient's symptoms by increasing his level of immune suppression so would not be a good treatment option in this case.

Question 140 of 277

A 38-year-old man from Nigeria presents to a gastroenterology clinic. He is a businessman, working for an iron and steel trading company and makes regular trips to Swaziland to visit mining executives.

For the previous four months, he has been troubled by diarrhoea, up to 8 episodes a day, with abdominal bloating and cramping. There is no blood visible in the stool. He has previously been treated for tuberculosis as a child.

A stool sample is sent to the lab, and Modified Ziehl-Neelson stain reveals multiple red staining round objects measuring 5 microns in diameter.

What will be the most appropriate treatment?

A. Highly active anti-retroviral therapy
B. Co-trimoxazole
C. Rifampicin, isoniazid, ethambutol, pyrazinamide
D. Metronidazole
E. Ciprofloxacin

A. Highly active anti-retroviral therapy

The diagnosis is cryptosporidium infection. It is the most common cause of chronic diarrhoea in HIV patients. Diagnosis is made by visualisation with modified Zeihl-Neelson stain of stool. You would very rarely expect to see *Mycobacterium tuberculosis* on a faecal sample.

Question 141 of 277

Mrs Stevens is a 60-year-old lady with pulmonary fibrosis secondary to dermatomyositis. She returns to your clinic seven weeks after being commenced on high dose steroids due to disease progression. During the review Mrs Stevens describes increasing shortness of breath, which is worse when she exerts herself. She has not noticed any fever and has not lost any weight. She has a chronic cough productive of white sputum. This remains stable.

On examination she looks comfortable at rest and auscultation of her chest is surprisingly clear. At rest her oxygen Sats are 97%. You ask her to walk to the end of the corridor and back. You notice that on returning her Sats have fallen to 82%. You request an urgent chest radiograph, which is reported as showing bilateral patchy infiltrates.

What is the most appropriate management option?

A. Fluconazole
B. Ambisome
C. Co-trimoxazole
D. Ribavirin
E. Stop steroids

C. Co-trimoxazole

Pneumocystis jiroveci penumonia is treated with co-trimoxazole, which is a mix of trimethoprim and sulfamethoxazole

The patient has PCP pneumonia, caused by *Pneumocystis jirovecii* - a yeast-like fungus which is an opportunistic pathogen. The treatment for this is co-trimoxazole.

All patients with dermatomyositis or polymyositis with pulmonary fibrosis who are treated with glucocorticoids are advised to receive PCP prophylaxis with co-trimoxazole. Stopping steroids would not be appropriate in this scenario.

It is important to note that not all patients taking glucocorticoids for rheumatological conditions require PCP prophylaxis. However, there is evidence that in non-HIV cohorts, the greatest risk for developing PCP is glucocorticoid use and deficiencies in innate and acquired immune components. Therefore, although there are currently no formal guidelines it is recommended that if an individual satisfies both these criteria in rheumatological conditions, they should be considered for PCP prophylaxis.

For example the following all should be considered for prophylaxis:

- A patient on the equivalent of 20 mg prednisolone or greater for one month plus the concomitant use of another immunosuppressive drug
- Dermatomyositis on high dose prednisolone for greater than one month and pulmonary fibrosis
- Allogenic or autogenic stem cell transplant or solid organ transplantation

Question 142 of 277

A 43-year-old man presents to his local sexual health clinic with an indurated well-circumscribed painless ulcer on the glans of his penis. Further examination demonstrates inguinal lymphadenopathy. He has had unprotected vaginal intercourse with a causal female partner within the last 14 days. He identifies as heterosexual, was born in London. He consents to a full sexual health screening and is prescribed a 14-day course of doxycycline as he reports a previous urticarial rash associated with penicillin.

The following day, the patient returns to the clinic with a high fever and widespread rash. He is concerned that he may have an allergy to doxycycline and would like advice regarding an alternate treatment. He reports no respiratory distress, tongue swelling or headache and consents to a set of monitoring blood tests, the results of which are within normal limits.

Given the likely diagnosis, which of the following would be the most appropriate course of action?

A. Advise the patient that his rash is likely due to sun exposure with concomitant doxycycline use
B. Give a cephalosporin based treatment regime instead
C. Reassure the patient that this reaction with treatment of syphilis and advice paracetamolwith good oral hydration
D. Admit immediately to hospital
E. Take a p24 antigen test and counsel the patient about possible HIV seroconversion

C. Reassure the patient that this reaction with treatment of syphilis and advice paracetamolwith good oral hydration

The Jarisch-Herxheimer reaction is a known phenomenon following syphilis treatment that does not require any specific treatment or investigations other antipyretics

This patient has syphilis and is experiencing a Jarisch-Herxheimer reaction, the mechanism of which remains poorly understood, but is felt to be related to the immune response triggered by the killed organisms.

Doxycycline is the treatment of choice in patients with a penicillin allergy and, given the reported allergy described by the patient, a cephalosporin would not be advised.

The Jarisch-Herxheimer reaction is usually self-limiting and best managed conservatively with antipyretics and good hydration unless there is evidence of organ compromise. Hospital admission is unnecessary unless there is evidence of organ compromise.

HIV seroconversion is possible given the recent unprotected intercourse, but this patient would be considered low risk given his exposure and a Jarisch-Herxheimer reaction is much more likely.

Question 143 of 277

A 57-year-old man who just returned from a cruise to the Bahamas comes to the emergency department with fever, non-productive cough and shortness of breath for the past 2 days. He has also had a headache, abdominal pain and diarrhoea since yesterday. The patient has a history of type 2 diabetes mellitus, and a smoking history of 20 pack-years. He does not use alcohol or illicit drugs. His temperature is 39.2ºC, blood pressure is 110/65 mmHg, pulse is 80/min and respirations are 18/min. Pulse oximetry shows 97% on room air.

Lung examination demonstrates crackles bilaterally. The abdomen is soft and non-tender. The patient seems confused at times during the examination. His serum glucose is normal; serum sodium is 128 mmol/l. Chest x-ray demonstrates bilateral interstitial infiltrates. He is admitted to the ward.

Which of the following antibiotics should be given to this patient?

A. Co-amoxiclav
B. Ceftriaxone
C. Clindamycin
D. Levofloxacin
E. Vancomycin

D. Levofloxacin

This patient has bilateral lung infiltrates, confusion and diarrhoea following travel. Legionella pneumonia (Legionnaires' disease) must be considered. Travel-associated Legionnaires' disease due to contaminated water supplies is a well-documented condition linked to cruise ships and hotels. *Legionella pneumophila* is a Gram-negative bacilli that stains poorly as it is primarily intracellular; hence Gram stain showing many neutrophils but no organisms is characteristic.

Legionnaires' disease is treated with antibiotics that achieve high intracellular concentration, particularly macrolides or fluoroquinolones (such as levofloxacin). The latter is favoured when the illness is severe enough to warrant admission.

Choice 1: Co-amoxiclav is typically used in some cases of CAP, but not Legionnaires' disease. It has activity against beta-lactamase-producing *Haemophilus* and *Moraxella* species.

Choice 2: Ceftriaxone has good activity against pneumococcus as well as *Haemophilus* and *Moraxella*. It does not have activity against *Legionella* or other causes of atypical pneumonia.

Choice 3: Clindamycin is used primarily to treat infections with anaerobic organisms; *Legionella* has aerobic activity.

Choice 5: Vancomycin has no activity against *Legionella* or most other causes of atypical pneumonia.

Question 144 of 277

A 64-year-old lady with a background of Alzheimer's dementia presents with a 3 day history of increased confusion, lower abdominal pain and foul smelling urine. Blood tests on admission show:

Hb	119 g/l	Na^+	136 mmol/l
Platelets	425 * 10 /l 9	K^+	3.7 mmol/l
WBC	15.9 * 10 /l 9	Urea	7.2 mmol/l
Neuts	13 * 10 /l 9	Creatinine	78 µmol/l
Lymphs	2 * 10 /l 9	CRP	140 mg/l
Eosin	0.02 * 10 /l9		

She is started on treatment for a urinary tract infection. 2 days later her blood tests show the following:

Hb	115 g/l	Na^+	141 mmol/l
Platelets	360 * 10 /l 9	K^+	5.2 mmol/l
WBC	10.2* 10 /l 9	Urea	8 mmol/l
Neuts	7.5 * 10 /l 9	Creatinine	105 µmol/l
Lymphs	1.5 * 10 /l 9	CRP	43 mg/l
Eosin	0.001* 10 /l9		

Which antibiotic was she likely to have been treated with?

A. Trimethoprim
B. Erythromycin
C. Co-amoxiclav
D. Nitrofurantoin
E. Ciprofloxacin

A. Trimethoprim

The correct answer is **Trimethoprim**. This is evidenced by the rise in serum potassium from 3.7 mmol/L to 5.2 mmol/L over two days of treatment. Trimethoprim is known to cause hyperkalaemia

through its action on the distal tubule of the kidney where it blocks the sodium channel ENaC, leading to reduced potassium excretion. This effect is particularly notable in elderly patients and those with reduced renal function. The patient's other blood results show an appropriate response to antibiotic therapy with falling WBC and CRP.

Erythromycin is not a first-line treatment for urinary tract infections in the UK according to NICE guidelines. While it can cause various side effects, significant changes in potassium levels are not typically associated with its use. Additionally, it has poor urinary penetration making it an unsuitable choice for UTIs.

Co-amoxiclav, while commonly used for UTIs, does not typically cause hyperkalaemia. The blood results show improving inflammatory markers which could be consistent with co-amoxiclav use, but the marked rise in potassium would not be expected with this antibiotic.

Nitrofurantoin is a common first-line treatment for uncomplicated UTIs, but it would be contraindicated in this patient due to her reduced renal function (eGFR likely <45 ml/min based on her age and creatinine). Furthermore, nitrofurantoin does not typically cause electrolyte disturbances.

Ciprofloxacin, while effective against urinary pathogens, does not cause significant changes in potassium levels. While it could effectively treat this infection, the characteristic rise in potassium seen in this case would not be expected with ciprofloxacin therapy.

Question 145 of 277

A 19-year-old man returning from Zimbabwe is admitted to the emergency department. He arrived back in the UK one week ago but for the last three days has complained of a severe headache and rigors. He has no significant past medical history. He smokes 10 cigarettes per day and does not drink alcohol.

On examination, the patient is sweaty and appears anxious. Pulse rate is 108/min, blood pressure 91/58 mmHg, temperature 39ºC and the respiratory rate 22/min. His chest is clear and heart sounds normal. A brief neurological examination is normal. An urgent blood film reveals malarial parasites.

Which of the following would suggest severe malaria infection?

A. Blood sugar > 14 mmol/l

B. Bicarbonate < 14mmol/l
C. CRP > 250 mg/l
D. Temperature > 38.5ºC
E. Infection despite use of appropriate antimalarial prophylaxis

B. Bicarbonate < 14mmol/l

The World Health Organisation states that the early recognition and treatment of severe malaria is vital to prevent rapid deterioration in the patient's condition and the onset of life-threatening complications.

Complications indicating severe malaria include:

- hypoglycaemia
- acidosis
- coma
- convulsions
- severe anaemia
- pulmonary oedema

Both coma and convulsions may represent cerebral malaria. In addition the parasite involved and percentage parasitaemia is important in the prognosis and management of malaria

Question 46 of 277

A 30-year-old woman with rheumatoid arthritis has been diagnosed in the community with a prolonged urinary tract infection. For her rheumatoid arthritis she has been stable on azathioprine for nearly a year and besides paracetamol she takes no other regular medications.

The GP has requested a follow-up blood test which is shown below. Baseline bloods were taken 2 months ago:

Hb	120 g/l
Platelets	310 * 10 /l9
WBC	4.5 * 10 /l9

Yesterday the bloods showed the following:

Hb	101 g/l
Platelets	296 * 10 /l9
WBC	1.9 * 10 /l9

Which of the following drugs is most likely responsible?

A. Trimethoprim
B. Nitrofurantoin
C. Cephalexin
D. Amoxicillin
E. Co-amoxiclav

A. Trimethoprim

It is likely she has received a protracted course of antibiotics, possibly more than one different antibiotic even.

An important side effect of azathioprine is cytopaenia. Azathioprine is metabolised to 6- mercaptopurine (6-MP) and then inactivated either by oxidation or methylation. Oxidation is catalysed by xanthine oxidase and methylation is catalysed by the enzyme TPMT. Factors that can lead to elevated levels of azathioprine are:

- Drugs that inhibit xanthine oxidase e.g. allopurinol
- Drugs that can also cause myelosuppression e.g.sulphonamides, trimethoprim
- Reduced activity of TPMT

Question 147 of 277

A 70-year-old female was admitted to the emergency department from a nursing home due to a progressive decline in her level of consciousness over the past two days. Her carer mentioned that she had been complaining of a burning sensation while urinating associated with a low-grade fever for the last week. Blood investigations showed:

Na +	130 mmol/l
K +	3.6 mmol/l
Urea	13 mmol/l
Creatinine	130 µmol/l

Urine dipstick showed increase leukocytes and nitrites. Urine culture showed a growth of extended-spectrum B-lactamase (ESBL) - producing *Escherichia coli*.

What is the first line treatment?

A. Ciprofloxacin
B. Ceftriaxone
C. Meropenem
D. Methoprim
E. Aztreonam

C. Meropenem

The regular use of B-lactam antibiotics for urinary tract infection has resulted in the emergence of new strains of bacteria that are resistant to these antibiotics. ESBL is one of the most problematic strains that is usually difficult to treat.

First line antibiotics are still carbapenems (imipenem, meropenem, ertapenem, doripenem).

Giving these antibiotics may further increase resistance so the advice is not to give antibiotics unless there are clinical signs and symptoms of a urinary tract infection.

Question 148 of 277

A 27-year-old nurse attends the emergency department and reports she has just suffered a significant needle-stick injury while caring for her patient on the intensive care unit. While providing her patient personal care with her colleague, she was injured in the hand by a wide bore stylet needle previously used to introduce an IV cannula to her patient that had not been placed in an appropriate sharps bin. The needle had been visibly blood stained. The nurse had been wearing gloves and had followed correct first aid procedure for needle-stick injuries.

The nurse was very concerned as the patient who had been the needle-stick donor was receiving treatment for the acute neurological phase of rabies. Review of the patients clinical notes (with the consent of the patients next of kin) indicated that he had contracted rabies following a dog bite two months previously in Pakistan. The diagnosis of rabies encephalitis had been made following clinical review by infectious disease experts and the detection of neutralising serum antibodies.

The nurse was previously fit and healthy with no significant past medical history. She did not use any regular medications and had no allergies. She was uncertain if she had had any previous vaccination against rabies, although did recall having a course of injections 10 years previously before she visited family in rural India.

What is the correct management of the needle-stick injury to prevent transmission of rabies?

A. Rabies immunoglobulin and full course rabies vaccination
B. Booster course rabies vaccination
C. Rabies immunoglobulin

D. Full course rabies vaccination
E. No action required

A. Rabies immunoglobulin and full course rabies vaccination

This situation represents a difficult clinical decision. Humans are considered to be an end-host for the rabies virus as inter-human transmission is not documented outside of transplantation cases. For that reason, only standard infection control precautions are recommended for health-care workers when in contact with individuals with rabies. However, the needle-stick injury described could foreseeably lead to transmission of the virus and given the severe consequences of rabies should be considered as possible rabies exposure.

The patient does not have a clear history of previous immunisation (the history stated could also be consistent with hepatitis B vaccination for example). Rabies immunoglobulin should be given to provide passive antibodies at the site of exposure prior to the development of an immune response. As far as possible, the dose (20 IU / Kg) should be administered locally around the wound. In addition, post-exposure vaccination should be provided, with the WHO currently recommending a four dose schedule (given on days 0, 3, 7 and 14).

If an individual has been previously vaccinated then immunoglobulin is not required and a two dose vaccination schedule (given on days 0 and 3) should be given.

Question 149 of 277

A 65-year-old man is referred to gastroenterology clinic for advice prior to planned overseas travel. The patient states that he is planning to visit relatives in Brazil in two months time and is very concerned about the possibility of contracting travellers' diarrhoea in light of his previous and current medical history.

The patient had undergone a total colectomy with ileostomy formation twenty years previously, as curative treatment for severe ulcerative colitis. He had subsequently learnt to manage his ileostomy well and had declined reconstructive surgery. Ten years previously, the patient had contracted diarrhoea while travelling in the Caribbean, which he reported had ruined his holiday and complicated his ileostomy management for weeks.

Of more pressing concern was a recent diagnosis of small-cell lung cancer, for which the patient was undergoing chemotherapy with cisplatin and etoposide. The patient's chemotherapy regime was due to be completed four weeks before his proposed travel.

Aside from the issues outlined above, the patient's only other past medical history included hypertension for which he took ramipril. The patient denied any drug allergies or intolerances.

Standard precautions regarding the avoidance of travellers' diarrhoea were discussed with the patient, who fully acknowledged the risks of travelling so soon after completing chemotherapy.

What is appropriate management to help prevent travellers' diarrhoea in this patient?

A. Vibrio cholerae vaccination
B. Standard advice regarding hygiene precautions only
C. Co-amoxiclav prophylaxis while overseas
D. Ciprofloxacin prophylaxis while overseas
E. Low-dose loperamide

D. Ciprofloxacin prophylaxis while overseas

Travellers' diarrhoea is most commonly caused by *Escherichia coli* species and *Campylobacter jejuni*. Less common causative pathogens include *Salmonella* and *Shigella* species, parasitic infections such as *Giardia lamblia*, and viruses such as norovirus.

In the majority of individuals, diarrhoea is annoying and unpleasant but does not lead to longterm sequelae. However, some groups of individuals may be unable to tolerate the consequences of dehydration from diarrhoea, or be vulnerable to invasive complications such as bacteraemia.

The patient presented in this question will be immunosuppressed secondary to his chemotherapy and has an under-lying bowel condition due to his ileostomy. Therefore, he should be considered for antibiotic prophylaxis to prevent travellers' diarrhoea, following discussion of the risks of antibiotic associated diarrhoea and other side effects.When antibiotic prophylaxis is used, typical choices of agent are ciprofloxacin, norfloxacin or rifaximin.

Anti-motility agents such as loperamide can be helpful in limiting diarrhoea in individuals unable to tolerate dehydration, but does not have a role in preventing infection. Symptoms of invasive colitis, such as severe abdominal pain or bloody diarrhoea, are contra-indications to the use of anti-motility agents due to the risk of intestinal perforation. Vaccination against cholera is effective, however is not a common cause of travellers' diarrhoea.

Question 150 of 277

A 19-year-old man attends the Emergency department with a fever for the past one week. He notes that the fever comes on alternate days. He reports also a co-existing headache, but no other particular symptoms. Of note, he returned from Afghanistan two weeks ago. Examination reveals a temperature of 38.1ºC, heart rate 89/min, blood pressure 123/78 mmHg, respiratory rate 17/min and oxygen saturations of 99%. There is no evidence of no neck stiffness, objective photophobia, jaundice or splenomegaly.

What is the most likely diagnosis?

A. Chikungunya
B. Zika virus
C. Plasmodium vivax
D. Plasmodium falciparum
E. Dengue fever

C. Plasmodium vivax

Fever in the returning traveller is a common presentation in the Emergency department. A knowledge of the areas travelled and incubation periods is essential to accurately diagnosing the potential infectious disease.

Chikungunya is a viral disease transmitted to humans via infected mosquitos. Fever and joint pain is the mos common presentation. The incubation period is 2-12 days.

Zika virus is currently not present in Afghanistan.

Dengue fever has a incubation period of 4-10 days.

This leaves plasmodium falciparum, which has a usual incubation of 7-14 days (but up to 3 months), and plasmodium vivax which has a typical incubation of 12-17 days (but reported up to 12 months) following exposure. Factors that point away from p. falciparum are the milder presentation and the much lower prevalence of it in Afghanistan (p. falciparum 5%, p. vivax 95%). Furthermore, fever due to malaria on alternate days, known as benign tertian malaria, is suggestive of either p. vivax or p. ovale. Comparatively, p. falciparum will typically cause more of a continuous fever.

Question 151 of 277

A 76-year-old female has been under the care of the medical team for the past week. She has been treated for a full sensitive *E. coli* bacteraemia with intravenous co-amoxiclav thought be sourced from the urinary system. On completing the course, the patient remains in for ongoing physiotherapy input. The next day, the patient has a temperature spike and cultures demonstrate regrowth of *E. coli*.

What is the most appropriate next step?

A. Escalate antibiotics to meropenem
B. Image the renal tract
C. Commence treatment for hospital-acquired pneumonia
D. Urology referral
E. Urgent nephrostomy

B. Image the renal tract

Discussion of this case with microbiology would likely result in the suggestion of imaging. In someone who has appropriate antimicrobial treatment, regrowth of the same organism would not be expected so soon. This may indicate there is a source of the bacteria that is not being adequately treated - a renal abscess in this case, which may be identified on ultrasound.

Escalation to meropenem should not be considered necessary if the organism has been fully sensitive to the narrower spectrum antibiotics.

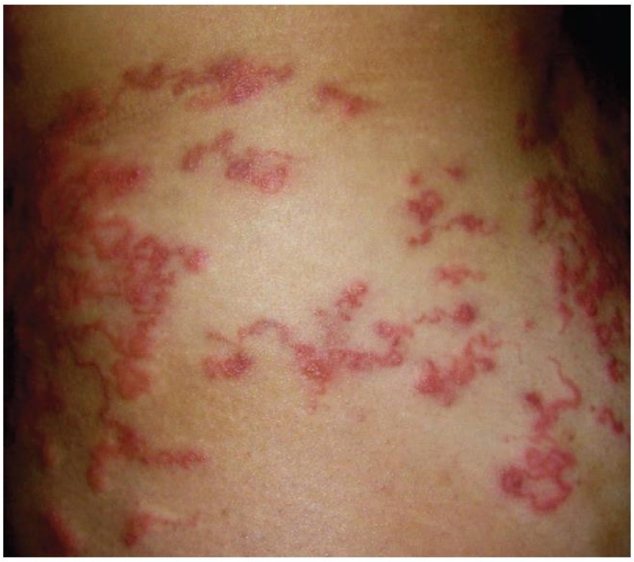
E. coli would be an unlikely source of hospital-acquired pneumonia.

Urology referral would be the next step should a renal abscess be identified. Imaging should first be carried out to determine whether a nephrostomy is required.

Question 152 of 277

A 26-year-old man presents with an intensely itchy rash which he thinks is spreading rapidly. He has recently returned from a holiday in Brazil, and mentions having seen many stray cats around the hotel resort. Symptoms began approximately 1 week after returning from the holiday. He denies having had any similar rashes previously, has no significant past medical history and is systemically well.

On examination, the rash appears as follows:



Given the most likely diagnosis, which of the following is the most appropriate management?

A. Doxycycline
B. Hydrocortisone
C. Ivermectin
D. Malathion
E. Permethrin

C. Ivermectin

The rash above has the appearance of cutaneous larva migrans, most commonly caused by infection with the cat hookworm *Ancyclostoma braziliense*. It is found in tropical regions throughout the world, including Brazil, from where this patient has recently returned, having mentioned a resort with many stray cats. The rash creeps due to the migration of the larvae. The photo above demonstrates this creeping, serpiginous eruption. Management involves the use of ivermectin, which is the correct answer here, or albendazole.

Doxycycline is incorrect. This is an antibiotic that would be used for the management of Lyme disease. This would instead present with erythema chronicum migrans - annular, bulls-eye lesions, rather than the tortuous lesions seen here.

Hydrocortisone is a topical steroid and is not involved in the management of cutaneous larva migrans. Ivermectin or albendazole should be given.

Malathion is a second-line option for the management of scabies. Whilst also presenting with intense pruritus, scabies lesions would instead appear as small, discrete burrows, particularly in the web spaces between fingers, as well as the palms and wrists. The serpiginous lesions seen here are more indicative of cutaneous larva migrans.

Permethrin is generally the first-line treatment used for scabies. Again, the lesions seen above are more associated with cutaneous larva migrans, not scabies.

Question 153 of 277

A 44-year-old businessman was admitted to the general medical take with fever, jaundice and headaches. He had returned from a business trip to Hong Kong one month ago. He is a keen river sailor and has been unable to sail for the last two weeks.

On examination, he is tachycardic with a temperature of 39.5°C. He appears confused and is combative during the examination. His chest has scattered crackles bibasally with some right upper quadrant abdominal pain

Investigations

Chest X-Ray	Hazy lung infiltrates bibasally

Haemoglobin	135 g/L (130-180)
White cell count	17.8 Ã— 109/L (4.0-11.0)
Neutrophil count	15.7 Ã— 109/L (1.5-7.0)
Platelet count	413 Ã— 109/L (150-400)

Serum C-reactive protein	345 mg/L (<10)
Serum urea	13.3 mmol/L (2.5-7.0)
Serum total bilirubin	110 mol/L (1-22)
Serum alanine aminotransferase	117 U/L (5-35)
Serum alkaline phosphatase	110 U/L (45-105)
Serum gamma glutamyl transferase	61 U/L (<50)

What is the most likely diagnosis?

A. Dengue Fever
B. HIV seroconversion
C. Acute hepatitis A
D. Malaria
E. Leptospirosis

E. Leptospirosis

Leptospirosis is the most likely diagnosis. The river sailing puts this gentleman at risk of contact with contaminated water from animal urine. Incubation is between 4-14 days. Typical symptoms include high fever, headache, muscle aches, vomiting and may have meningitis and jaundice.

Hong Kong is not a malaria endemic region nor is it a common region for Dengue Fever. HIV seroconversion would not explain jaundice or deranged liver function. Acute hepatitis A infection is prevalent in Hong Kong and incubation period is between 2 - 6 weeks but infection would not explain the neurological symptoms.

Question 154 of 277

A 23 year-old artist presents after he woke up with headache, neck stiffness, and photophobia. He is normally fit and well, but for the last three weeks has complained of feeling tired and irritable.

On examination, the left side of the palate does not elevate, and the tongue is deviated to the left upon protrusion. The remainder of the neurological examination is unremarkable.

Plain computed tomography of the head is unremarkable.

Lumbar puncture is performed with results of CSF analysis as follows:

Appearance	Turbid
White blood cells	28 cells/mm^3 (95% lymphocytes)
Red blood cells	<1 cells/mm^3
Gram stain	No organisms seen
Protein	1.32 g/L
Glucose	1.4 mmol/L
Serum glucose	7.5 mmol/L

What is the most likely diagnosis?

A. Meningococcal meningitis
B. Tuberculous meningitis
C. Subarachnoid haemorrhage
D. Skull base tumour
E. Malignant meningitis

B. Tuberculous meningitis

The prodromal phase of malaise and possible personality change, followed by meningism, with the onset of basal cranial nerve palsies, and coupled with the CSF findings of lymphocytic pleocytosis, raised protein, and low glucose, are all highly suggestive of tuberculous meningitis.

There is no particular suggestion of a primary malignancy, but malignant meningitis (leptomeningeal carcinomatosis) is a possibility and it would be reasonable to send a large volume of CSF for cytology. Like tuberculous meningitis, this condition typically presents with headache, meningism, and cranial nerve palsies. However, it is eye movements which are most often affected.

There is often also invasion of spinal meninges which involves nerve roots and mimics radiculopathy. The CSF is hardly ever normal, although there are no specific features other than the direct demonstration of malignant cells.

Meningococcal meningitis is an acute disease, so the three week prodrome described here would be unusual. The presence of cranial nerve palsies would be extremely unusual. The CSF would be expected to show a neutrophilic pleocytosis, with a low glucose (less that 50% of serum glucose), but not as low as in tuberculous meningitis.

Subarachnoid haemorrhage should be considered in any case of acute headache. The normal CT scan is reassuring but does not exclude the diagnosis, but in any case the CSF is not suggestive.

A tumour of the skull base might explain the lower cranial nerve palsies, but one would have expected some more suggestive symptoms and an abnormal CT head. This diagnosis would not explain the grossly abnormal CSF findings.

Question 155 of 277

A 38-year-old man is referred in by his GP with increasing frequency of diarrhoea over the last 4 days. He is a known ulcerative colitis patient who is well managed on azathioprine 200mg OD and mesalazine 2.4mg BD. He last had a flare 2 years ago and has been well in the interim. He is passing up to 10 watery motions a day and is suffering from faecal urgency and nocturnal episodes. He describes cramping left iliac fossa pain. There is no blood or mucus in the stools. On examination, he is febrile at 38.2 degrees celsius. His blood pressure is 120/75 mmHg and his heart rate is 100/min. On examination, he is underweight with a BMI of 18.5 and dehydrated. His abdomen is soft but he is tender in the left iliac fossa. He refuses a PR examination. Respiratory and cardiovascular examinations are normal.

His blood tests show:

Hb	110 g/l
Platelets	189 * 10 /l9
WBC	3.8 * 10 /l9
Neutrophils	0.89 * 10 /l9
INR	1.1 (0.9-1.2)

Na +	136 mmol/l
K +	4.9 mmol/l
Urea	8.0 mmol/l
Creatinine	100 µmol/l
Mag nesium	0.79 mmol/L (0.7-1.0)
Calcium	2.4 mmol/L (2.1-2.58)
CRP	78 mg/l

Bilirubin	5 µmol/l
ALP	78 u/l
ALT	28 u/l
Albumin	33 g/l

He is started on IV hydrocortisone 100mg QDS and IV fluids. Stool specimens are sent and are reported as negative for *C. difficile* toxin. He has a flexible sigmoidoscopy the next day which shows widespread left sided colitis. The biopsy results show the presence of inclusion bodies in the colonic mucosa.

What is the appropriate treatment to start for this gentleman?

A. Infliximab
B. Ganciclovir
C. Metronidazole
D. Fluconazole
E. Tazocin

B. Ganciclovir

This patient has CMV colitis. It can be a consequence of immunosuppressive agents such as azathioprine. It can present with fever and diarrhoea +/- blood. It can also present as an exacerbation of IBD patients in those on immunosuppressants. Inclusion bodies are characteristic at biopsy. It will respond well to an antiviral agent and ganciclovir is the treatment necessary here. Tazocin, metronidazole and fluconazole will not treat appropriately and infliximab would only be indicated if a colitis flare was not due to an infective cause.

Question 156 of 277

A 47-year-old man is referred by the emergency department with increasing shortness of breath. He is a known HIV patient managed by the local GUM consultants. He is not on any antiretroviral treatment. He presents with a two-week history of worsening shortness of breath. He is now breathless on minimal exercise. He has a non-productive cough and has felt lethargic for the last week. On examination he is afebrile, his blood pressure is 120/89 mmHg and he is slightly tachycardic at 110bpm. His respiratory rate is 18 at rest with saturations on 98% on air. When he mobilises to the toilet he becoming very tachypnoeic and his saturations drop to 90%. His blood tests are as follows:

Hb	110 g/l
Platelets	201 * 10 /l9
WBC	9.6 * 10 /l9
Neutrophils	4.5 * 10 /l9

Na +	138 mmol/l
K +	4.1 mmol/l
Urea	7.8 mmol/l
Creatinine	20 µmol/l
CRP	70 mg/l

Bilirubin	5 µmol/l
ALP	89 u/l
ALT	43 u/l
Albumin	34 g/l

An ABG is done which shows

pH	7.35
pO2	7.7
pCO2	4.6
HCO3-	21
BE	-3
Lactate	2.2

His chest x-ray shows fine bilateral reticular nodular shadowing.

What is the most appropriate treatment to start in this gentleman?

A. Tazocin
B. Co-trimoxazole
C. Aciclovir
D. Co-trimoxazole and corticosteroids
E. Highly active anti-retroviral treatment

D. Co-trimoxazole and corticosteroids

This gentleman is immunocompromised and has PCP. Patients with moderate to severe PCP should be treated with Co-trimoxazole and corticosteroids. Patients with mild to moderate PCP need only co-trimoxazole.

Mild:

- Breathlessness on mild exercise, which may be associated with a cough and sweats
- Arterial blood gases and oxygen saturation at rest, on air: PaO2 >11 kPa; SaO2 >96%
- Chest X-ray: normal or minor perihilar infiltrates

Moderate:

- Breathlessness on minimal exercise, fever (with or without sweats)
- Arterial blood gases and oxygen saturation at rest, on air: PaO2 8-11 kPa; SaO2 91-96% Chest X-ray: diffuse interstitial shadowing

Severe:

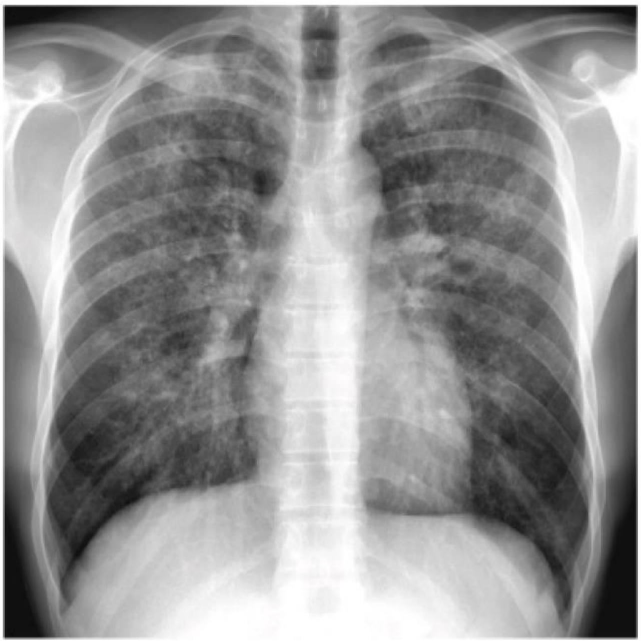
- Breathlessness at rest, persistent fever and cough
- Arterial blood gases and oxygen saturation at rest, on air: PaO2 <8 kPa; SaO2 <91%
- Chest X-Ray: extensive interstitial shadowing, with or without alveolar shadowing

Question 157 of 277

A 38-year-old man is admitted to the Emergency Department with shortness-of-breath and a nonproductive cough. He has recently emigrated from Russia and has just started anti-retroviral therapy for HIV.

Examination of his chest is unremarkable. His temperature is 37.7ºC and oxygen saturations are 95% on room air.

A chest x-ray is performed:



What is the most likely diagnosis?

A. Cytomegalovirus
B. Mediastinal lymphoma
C. Tuberculosis
D. Mycoplasma pneumonia
E. Pneumocystis jiroveci pneumonia

E. Pneumocystis jiroveci pneumonia

The key to answering this question is to look at the history rather than the x-ray. A combination of HIV + chest symptoms + unremarkable auscultatory findings in an exam are highly suggestive of Pneumocystis jiroveci pneumonia (more commonly known as PCP). X-ray changes in Pneumocystis jiroveci pneumonia are generally too subtle for non-radiologists to detect. The x-ray should however help you to exclude some of the other diagnoses.

The chest x-ray shows hazy, perihilar mid and upper zone opacification with some interstitial prominence. A few discrete cysts (termed pneumatocoeles) measuring up to 1cm are present. The presence of pneumatocoeles in a HIV patient suggests Pneumocystis jiroveci pneumonia.

Question 158 of 277

A 53-year-old lady comes into the Emergency Department with a cough productive of green sputum and palpitations. She feels very unwell, feverish and lethargic. On examination, she has bronchial breathing at her right base with respiratory rate 25/min, sats 95% on room air. Her heart sounds are normal with an irregularly irregular heartbeat. Her heart rate was 120/min and blood pressure 90/40 mmHg. An ECG shows atrial fibrillation with a fast ventricular rate. She has no history of atrial fibrillation.

What is the first treatment that should be given for her atrial fibrillation?

A. Bisoprolol
B. Digoxin
C. Intravenous fluids
D. Oral antibiotics
E. Flecainide

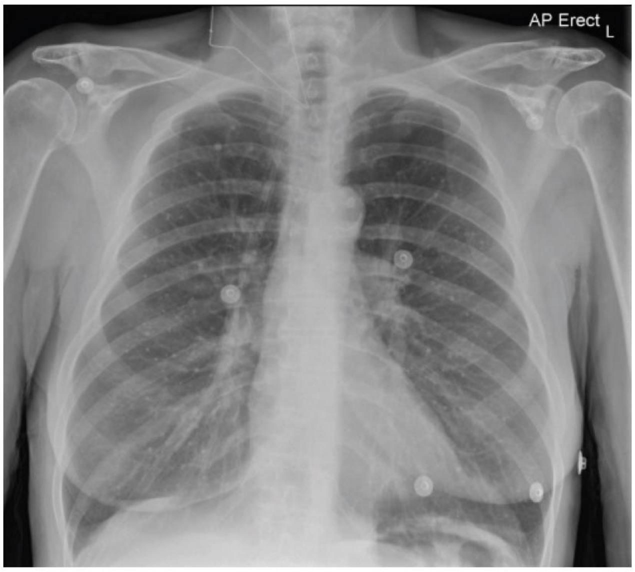
C. Intravenous fluids

This patient is clearly septic from pneumonia. This has tipped the patient into atrial fibrillation (AF) given there is no previous history of atrial fibrillation. It is important to treat the sepsis as the cause of the AF. To do this it is imperative to give IV fluids and IV antibiotics. If the patients AF does not settle following the resolution of the sepsis then other options would be considered.

Question 159 of 277

A 46-year-old woman presents with a 4 week history of cough. This is non-productive and not associated with dyspnoea or chest pain. The symptoms were preceded by a 'head cold'. Her past medical history includes asthma as a child and smoking. Respiratory examination reveals a clear chest with no added sounds. Oxygen saturations are 98% on room air. Temperature is 36.7ºC and heart rate 72/min.

A chest x-ray is requested as she is a smoker:



What is the most likely explanation for the changes on the x-ray?

A. Healed varicella pneumonia
B. Idiopathic pulmonary fibrosis
C. Cryptogenic organizing pneumonia
D. Tuberculosis
E. Sarcoidosis

A. Healed varicella pneumonia

The chest x-ray shows miliary opacities secondary to healed varicella pneumonia. Multiple tiny calcific miliary opacities noted throughout both lungs. These are of uniform size and dense suggesting calcification. There is no focal lung parenchymal mass or cavitating lesion seen.The appearances are characteristic for healed varicella pneumonia.

Question 160 of 277

A 26-year-old pregnant women is seen on the acute medical unit. She is 24 weeks pregnant with her first child and has been admitted by her GP after feeling generally unwell with 'flu like symptoms and developing jaundiced sclera. Her stay in Bangladesh lasted 2 weeks during which time she visited family. Prior to travelling she was vaccinated against hepatitis A.

On examination her sclera are visibly jaundiced. Blood pressure is 108/60 mmHg, temperature 38.1ºC and pulse 96/min. She is slightly tender in the right upper quadrant of the abdomen. Bloods show the following:

Bilirubin	72µmol/l
ALP	252 u/l
ALT	342 u/l
γGT	286 u/l
Albumin	38 g/l
CRP	154 mg/l

What is the most likely diagnosis?

A. Dengue fever
B. Hepatitis E
C. Hepatitis A
D. Intrahepatic cholestasis of pregnancy
E. Acute fatty liver

B. Hepatitis E

Hepatitis E is more likely to cause severe disease in pregnant women. Hepatitis A is unlikely given her previous immunisation against this. There are no other features to support the remaining three distractors.

Question 161 of 277

A 24-year-old recent immigrant from Albania presents to the emergency department with fever, headache and malaise. Over the past 24 hours he has also developed bilateral pain and swelling at the angle of the jaw, which is made worse by talking or chewing. On examination his pulse is 90/min, temperature 38.4ºC and bilateral palpable, tender parotid glands are noted.

Given the likely diagnosis, which one of the following complications is he most likely to develop?

A. Orchitis
B. Pancreatitis
C. Encephalitis
D. Myocarditis
E. Pneumonia

A. Orchitis

Orchitis is the most common complication of mumps in post-pubertal males.

There is a link between mumps and pancreatitis (the 'M' in GET SMASHED) but this is much less common than orchitis.

Question 162 of 277

A 41-year-old man with poorly controlled type 1 diabetes mellitus presents with a nodular lesion on the right-side of his face around the angle of the jaw. One month ago he had a tooth extraction at the dentist. The nodule is around 2 cm in diameter, raised and purple-red in colour. On examination a sinus tract is seen in the middle of the nodule which is draining a blood-stained fluid.

Microscopy of the discharge shows microscopic yellow granules.

What is the most likely causative organism?

A. Actinomyces israelii
B. Tunga penetrans
C. Klebsiella
D. Pseudomonas aeruginosa
E. Escherichia coli

A. Actinomyces israelii

The correct answer is ***Actinomyces israelii***. The patient's presentation of a nodular lesion with a sinus tract draining blood-stained fluid and the presence of microscopic yellow granules in the discharge are characteristic features of actinomycosis, which is most commonly caused by *Actinomyces israelii*. Actinomycosis is an indolent, slowly progressive infection that often occurs following dental procedures or oral trauma. The presence of microscopic yellow granules, also known as 'sulfur granules,' further supports this diagnosis.

Tunga penetrans, also known as the chigoe flea, causes tungiasis, which typically presents with pruritic papules or nodules on the feet. This clinical presentation does not match the patient's facial lesion and history of tooth extraction.

Klebsiella species are gram-negative bacteria that can cause a variety of infections, including pneumonia, urinary tract infections, and soft tissue infections. However, these infections do not typically present with nodular lesions and sinus tracts containing sulfur granules.

Pseudomonas aeruginosa is another gram-negative bacterium that can cause various infections such as skin and soft tissue infections, particularly in immunocompromised individuals. Although *Pseudomonas aeruginosa* can cause skin lesions, it does not produce sulfur granules nor form sinus tracts like those seen in actinomycosis.

Finally, ***Escherichia coli*** is a gram-negative bacterium commonly associated with gastrointestinal and urinary tract infections. It can occasionally cause skin and soft tissue infections but would not present with the characteristic nodular lesion containing sulfur granules seen in this patient.

Question 163 of 277

A 55-year-old man attends after puncturing the skin of his left hand with a small garden fork whilst weeding. On removing the temporary bandage there is no active bleeding but a puncture wound is noted. He has tried to clean the wound but there remains some soil in situ. He is unsure of his tetanus vaccination history but thinks he 'has never not had a vaccine he's been offered'. You can find no record on his tetanus vaccine history on his medical notes.

What is the most appropriate course of action?

A. Tetanus immunoglobulin
B. Tetanus vaccine booster
C. Tetanus vaccine booster + tetanus immunoglobulin
D. Oral co-amoxiclav
E. Tetanus vaccine booster + oral co-amoxiclav

C. Tetanus vaccine booster + tetanus immunoglobulin

This is a high-risk wound (soil contamination which may contain tetanus spores) in a patient without a clear history of tetanus vaccination. He therefore requires both a tetanus vaccine booster and tetanus immunoglobulin.

Question 164 of 277

A 52-year-old male presents with a cough, fatigue, fever, and shortness of breath. He had been feeling unwell for around 6 months with recurrent colds that he couldn't seem to shake off. Over this period he had lost around one and a half stone in weight. He attributed this to a poor appetite. His only past medical history was asthma. He had been a widower for 7 years and was a keen wildlife photographer which had allowed him to travel the world. His last trip had been to Africa 2 years ago.

On examination he had a temperature of 38.2ºC, heart rate is 102/min and regular, blood pressure 110/70 mmHg and saturations 92% air. He had fine bibasal crackles on chest auscultation. Heart sounds were normal. Arterial blood gas showed a type 1 respiratory failure. Chest x-ray showed bilateral pulmonary infiltrates. He was treated with intravenous antibiotics. After two days of admission, his condition worsened and his type 1 respiratory failure worsened and he was given continuous positive airway pressure (CPAP). The beta glucan test came back negative. Urinary antigens were negative. The patient remarked that he had noted that his vision in his right eye was blurred and he had noted flashing lights and spots in the same eye.

What is the most likely diagnosis?

A. Pneumocystis pneumonia
B. CMV pneumonia
C. Fungal pneumonia
D. Legionella pneumonia
E. Asthma exacerbation

B. CMV pneumonia

This gentleman has CMV pneumonia and then developed CMV retinitis on the background of an undiagnosed HIV infection.

CMV infection is typically unnoticed in healthy people but can be life-threatening for those who are immunocompromised, which would include transplant patients, cancer patients, dialysis patients, HIV-infected individuals and those on immunosuppressants.

CMV pneumonia often presents with a cough, fever, malaise, poor appetite, myalgia, shortness of breath and night sweats. CMV can be detected using serology. The virus can also be cultured from urine, throat swabs, bronchial lavages and tissue samples to detect active infection. PCR testing can also be done and this can help monitor viral load.

Ganciclovir or valganciclovir are treatments for CMV infection. Foscarnet or cidofovir are alternatives when patients are resistant to ganciclovir. Foscarnet can cause nephrotoxicity and electrolyte disturbance.

CMV retinitis often presents with blurred vision, floaters, flashing lights, eye pain, photophobia and can lead to blindness. CMV retinitis most commonly develops when the CD4 count is less than

50cells/mL. However, it can occur in 20-30% when then CD4 count is less than 100 cells/mL.

Question 165 of 277

A 32-year-old woman who has received a renal transplant from an unrelated donor some 4 weeks earlier, comes to the clinic complaining of fevers, arthralgia, abdominal pain and diarrhoea. She had initially made a good recovery after her transplant. Testing for human herpes virus 5 is positive and there has been a rise in CRP and serum creatinine, (values are shown below).

Hb	10.2 g/l	Na +	138 mmol/l
Platelets	203 * 10 /l 9	K +	5.2 mmol/l
WBC	10.9 * 10 /l 9	Urea	9.2 mmol/l
Neuts	8.7 * 10 /l 9	Creatinine	211 µmol/l
Lymphs	2.0 * 10 /l 9	CRP	88 mg/l
Eosin	0.1 * 10 /l9		

Which of the following is the most appropriate intervention?

A. IV acyclovir
B. IV ganciclovir
C. Oral lamivudine
D. Oral valganciclovir
E. Oral valaciclovir

B. IV ganciclovir

Human herpes virus 5 (HHV 5), is cytomegalovirus (CMV). In patients who are post-transplant, CMV infections can occur from reactivation of latent infection, infection via the transplanted organ, or because of a new primary infection. Treatment is with IV ganciclovir, and where there is ganciclovir resistance, foscarnet or cidofovir are alternative options. Without treatment, further deterioration in renal function is the likely outcome.

IV acyclovir is the usual treatment option for herpes simplex or herpes zoster infection and oral valaciclovir is an alternative option to oral acyclovir for the long term treatment of herpes simplex. Lamivudine is used in the treatment of HIV/AIDs and hepatitis B infection. Valganciclovir is an alternative oral option to IV ganciclovir with potential use for CMV prophylaxis.

Question 66 of 277

A 98-year-old lady presents with a fever and confusion and on initial review is started on broad spectrum antibiotics. Despite five days of therapy, her temperature is 38.9°C and her clinical condition seems to have deteriorated. She has no relevant past medical history. The diagnosis of urinary tract infection (UTI) is confirmed when urine cultures confirm an extended spectrum Blactamase (ESBL) producing *Escherichia coli* (E. coli).

Following the failure to respond to the first-line agent, which antibiotic is most likely to be effective?

A. Trimethoprim
B. Tetracycline
C. Amoxicillin
D. Cefalexin
E. Ertapenem

E. Ertapenem

Extended spectrum B-lactamase (ESBL) producing organisms are typically resistant to penicillins and cephalosporins and as such the carbapenem class of antibiotics are typically first-line although nitrofurantoin or fosfomycin are also frequently effective. ESBL producers are most commonly *Escherichia coli* (E. coli) and *Klebsiella* species.

Question 167 of 277

You see a 26-year-old Caucasian man with poorly controlled HIV (recent CD4 count of 113 cells/mm) with a negative Mantoux test. He was routinely tested after his father (whom he lives with) was diagnosed with active pulmonary disease, but himself shows no features of active disease. On examination, his chest is clear with no overt lymphadenopathy. Blood pressure is 132/91 mmHg, heart rate 85 beats per minute, respiratory rate 14 breaths per minute, oxygen saturation 96% on air and temperature 36.8°C.

What is the next step?

A. 5 days oral ciprofloxacin
B. QuantiFERON-TB (interferon gamma assay)
C. Induced sputum for AAFB
D. Monitor and repeat Mantoux in 2 weeks
E. Rifampicin and isoniazide for 6 months with pyrazinamide and ethambutol for 2 months

B. QuantiFERON-TB (interferon gamma assay)

In people with HIV and a CD4 count of less than 200 cells/mm an interferon-gamma test should be done alongside the Mantoux as it will be unreliable. If either test is positive a clinical assessment should be performed to exclude active TB and if no active disease found consideration made to treating a latent infection.

Question 168 of 277

A 72-year-old male diabetic is admitted to the hospital via the Emergency Department with severe cellulitis of his right arm. He is hypertensive and also suffers from coronary artery disease.

On examination he is febrile, with a temperature of 38.5°C. His pulse is 112 bpm and his blood pressure is 150/95 mmHg.

His right arm is grossly swollen and tender, with marked erythema and discharge of small amounts of pus.

Lab reports reveal:

Hb	90 g/l
MCV	71 fl
WBC	23 * 10 /l9
Plt	500 * 10 /l9
Urea	9.2 mmol/l
Creatinine	145 µmol/l

Urine examination reveals proteinuria 1+ and glycosuria 2+

Preliminary blood cultures post admission reveal the growth of MRSA.

Which of the following would be the most appropriate antibiotic for this patient?

A. IV Vancomycin
B. IV Flucloxacillin
C. IV Linezolid
D. IV Rifampicin
E. IV Gentamicin

A. IV Vancomycin

IV Vancomycin is the treatment of choice for MRSA septicaemia. The renal function is slightly deranged here so the dosing will need to be adjusted accordingly.

Question 169 of 277

A 28-year-old patient has presented with upper limb weakness. He is extremely anxious and tells you that this morning he noticed that he had a dry mouth and found it difficult to swallow. His friends also commented that his voice sounded different to normal. Several hours later he began to notice weakness in both of his arms. He has not noticed any weakness in his lower limbs. He has no relevant past medical history or family history of note.

He smokes 10 cigarettes a day, drinks approximately 30 units of alcohol per week and occasionally injects heroin.

His Glasgow Coma Score is 15/15. Neurological examination reveals power 3/5 in the upper limbs, 5/5 in the lower limbs. Biceps and supinator reflexes are absent. Knee and ankle reflexes are normal. His pupils are dilated and sluggish in reaction to light. He is unable to abduct either eye. You notice needle track marks on the patient's forearm and an erythematous wound in the patient's right antecubital fossa.

What is treatment would you give to the patient immediately?

A. IV Beta Interferon
B. IV immunoglobulin
C. Plasma exchange
D. Steroids
E. Trivalent antitoxin

E. Trivalent antitoxin

This patient has presented with typical features of botulism, which is likely to have been contracted via the patient's wound in this case. He has suffered from a descending weakness, initially affecting his bulbar and pharyngeal muscles, then his upper limbs. If untreated this would progress to involve his respiratory muscles and lower limbs. In contrast, Guillain Barre Syndrome (GBS) presents with an ascending weakness usually involving the lower limbs, then upper limbs then cranial nerves. Both conditions show autonomic features and progress rapidly.

One particularly distressing feature of botulism is that it does not affect GCS.

The immediate treatment of choice would be IV Trivalent antitoxin immediately and general supportive measures.

Question 170 of 277

A 32-year-old man presents to the emergency department with a three-week history of progressive shortness of breath, dry cough, and fever. He also mentions unintentional weight loss and generalized fatigue in the past two months.

On further questioning, he admits to having had multiple sexual partners in the past year and not using protection consistently.

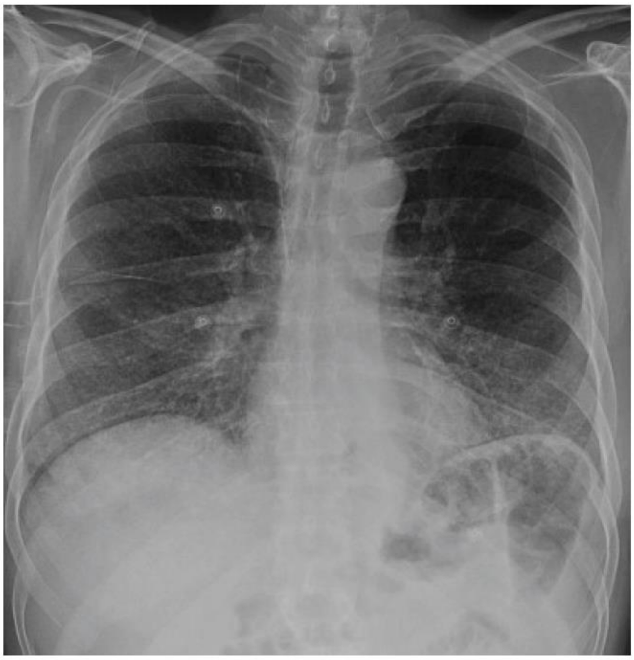
Observations are as below:

- Temperature 38.9°C (102°F)
- Respiratory rate of 28 breaths/min
- Oxygen saturation of 85% on room air

Arterial blood gases:

Bicarbonate	15 mmol/L	(22 - 29)
PaO2	8.8 kPa	(10.5 - 13.5)
PaCO2	3.8 kPa	(4.5- 6)

Chest examination is unremarkable. The chest x-ray is given below.



What is the most appropriate management in this case?

A. Co-trimoxazole
B. Co-trimoxazole and steroids
C. IV furosemide
D. IV pentamidine
E. Supportive treatment

A. Co-trimoxazole and steroids

Co-trimoxazole and steroids is the correct answer.

The chest x-ray shows increased bibasilar ground glass opacities, combined with the patient's clinical presentation and history of unprotected intercourse, strongly hint at a possible HIV infection complicated by *Pneumocystis jirovecii* pneumonia (also known as PCP). Co-trimoxazole is the first-line treatment for *Pneumocystis jirovecii* pneumonia. The addition of steroids is recommended in hypoxic patients (evidenced here by a PaO2 of 8.8 kPa on air). Steroids have been demonstrated to decrease the risk of respiratory failure by 50% and reduce mortality.

Co-trimoxazole on its own would be inadequate, as the pronounced hypoxia in this patient poses a significant risk of mortality, thus warranting the simultaneous use of steroids.

IV furosemide is not suitable. The imaging changes here are not in keeping with pulmonary oedema, due to peri-hilar distribution of opacification, and lack of other features such as costophrenic angle blunting or fluid in the fissures, and as such diuretic therapy would not be indicated.

IV pentamidine is not the best choice. It can serve as a second-line treatment for *Pneumocystis jirovecii pneumonia* if there are contraindications or adverse reactions to co-trimoxazole but there are no known reasons not to use co-trimoxazole in this case. This patient's marked hypoxia also calls for the administration of steroids.

Supportive treatment on its own isn't adequate. Although vital measures such as oxygen supplementation are necessary for symptom management, they fail to tackle the primary issue - the fungal infection.

Question 171 of 277

A 25-year-old woman presents to the clinic with a one-month history of persistent, watery diarrhoea that is sometimes difficult to flush but never bloody. She also reports associated bloating and flatulence. Since returning from a trip to South America, she has experienced increasing weakness and an inability to maintain her usual level of physical activity. Over this period, she has lost 10 kg in weight but denies joint pains.

On examination, she is afebrile. Neurological examination shows no abnormalities. Cardiac auscultation reveals normal first (S1) and second (S2) heart sounds without additional sounds or murmurs. There are no skin rashes present.

What is the most likely diagnosis?

A. Amoebic dysentery
B. Coeliac disease
C. Giardiasis
D. Traveller's diarrhea 2%
E. Whipple's disease

C. Giardiasis

Ongoing diarrhoea, lethargy, bloating, flatulence, steatorrhoea, weight loss +/- recent travel → ?giardiasis

Giardiasis is the correct answer.

Giardiasis should be considered in cases of persistent non-bloody diarrhoea, mainly when it presents as watery and sometimes steatorrhea. Accompanying symptoms may include lethargy, bloating, flatulence, and weight loss. G. lamblia transmission occurs via the fecal-oral route, often through contaminated water or food. The parasite can produce cysts resistant to chlorine and other disinfectants, complicating its eradication from water supplies. Upon ingestion, the cysts excyst within the small intestine and release trophozoites that adhere to the intestinal wall and proliferate.

Amoebic dysentery is incorrect. E.histolytica, the cause of amoebic dysentery, also follows a faecal-oral transmission route, usually via contaminated food or water. Post-ingestion, this parasite may invade the intestinal lining, causing abdominal discomfort and diarrhoea with potentially bloody stools. Additionally, it can disseminate to other organs, including the liver, lungs, and brain, leading to severe infections which could be life-threatening. However, given the presence of steatorrhea in this scenario, E.histolytica is less likely.

Coeliac disease is a long-term autoimmune disorder primarily affecting the small intestine, where individuals develop intolerance to gluten, which is present in foods such as wheat, rye and barley. Abnormal bowel response to the ingested gluten leads to villous atrophy and subsequent destruction of surface absorption observed in the duodenum and jejunum. Although the symptoms are similar to giardiasis, the relation between symptoms and travelling makes giardiasis more likely. Testing for coeliac disease may be considered part of investigations if the treatment for giardiasis is unsuccessful.

Traveller's diarrhoea is incorrect. *Enterotoxigenic Escherichia coli* (ETEC) is the most common cause of traveller's diarrhoea and is typically associated with watery diarrhoea that may occasionally contain blood rather than steatorrhea. The presence of steatorrhea makes it unlikely.

Whipple's disease caused by *T.whipplei,*—is a rare condition predominantly affecting middle-aged men and can manifest with gastrointestinal symptoms, including steatorrhoea. Nevertheless, the absence of additional signs like joint pain, central nervous system involvement or headaches makes this diagnosis unlikely in this context.

Question 172 of 277

A 23-year-old man presents to the emergency department with shortness of breath, fever and a cough. He has had a non-productive cough for two weeks. Before this, he had felt unwell with muscle aches and malaise. He went to his GP and was given amoxicillin but this has made no difference and now he is feeling more breathless and unwell. He has not been outside of the UK in the last year. He has no other medical problems and takes no regular medications. His cough is non-productive and comes in paroxysms which make him concerned.

On examination, there are a few bilateral crepitations, but the examination is otherwise normal. His observations show fever and mild hypoxia. Blood tests show mild anaemia and raised inflammatory markers. A chest X-ray shows bilateral consolidation, but he improves with IV coamoxiclav and clarithromycin over a few days.

What is the most likely causative organism?

A. Klebsiella pneumoniae
B. Legionella pneumophila
C. Mycoplasma pneumoniae
D. Chlamydia psittaci
E. Coxiella burnetii

C. Mycoplasma pneumoniae

The correct answer is Mycoplasma pneumoniae. There are several hints in this history and investigations to suggest Mycoplasma pneumoniae as the likely cause. First of all, he is a young and fit patient who describes a non-productive cough preceded by flu-like symptoms and not responding to penicillins. Secondly, he has anaemia which may be due to haemolysis, and finally there is bilateral consolidation on the chest X-ray. Klebsiella pneumoniae is more typical in alcoholics, Legionella pneumophila is associated with a history of foreign travel, Chlamydia psittaci is associated with contact and exposure to birds and finally, Coxiella burnetii is rare and associated with farm animal exposure.

Question 173 of 277

A 35-year-old gentleman presents to the emergency department with worsening shortness of breath on exertion. His symptoms have been progressing for two weeks, and he now finds it difficult to take a full breath. He has no chest pain and has not been coughing but he has been feeling increasingly fatigued. He has a past medical history of HIV. He has been struggling to take his tablets recently. He is unsure of the names of any tablets, but he knows that he is supposed to take one tablet each day at the same time and to take two tablets twice a day on Mondays, Wednesdays, and Fridays. He has no other medical problems.

On examination, auscultation shows normal breath sounds. Observations:

Saturations	93%
Respiratory rate	22/min
Blood pressure	136/71mmHg
Heart rate	91/min
Temperature	37.6°C

On mobilisation, his saturations reduce to 88%. Chest X-ray is clear.

What investigation is most likely to be diagnostic?

A. CT pulmonary angiogram
B. High resolution CT chest
C. ECG
D. Echocardiogram
E. Broncho-alveolar lavage

E. Broncho-alveolar lavage

The correct answer is broncho-alveolar lavage which is most likely to be able to demonstrate PCP characteristic cysts with silver staining. There are several factors highly suggestive of PCP. This gentleman is poorly compliant with his HIV medication and the other medication regime he is describing is PCP prophylaxis, suggesting a low CD4 count. He also is tachypnoeic with low saturations on mobilising and a clear chest X-ray. All of these factors suggest PCP. In the case of a productive cough, sputum could be obtained without the need for a broncho-alveolar lavage. Imaging can be suggestive of PCP but is not as sensitive or diagnostic as broncho-alveolar lavage. ECG and echocardiogram have no role in PCP diagnosis.

Question 174 of 277

A 42-year-old woman presents to the emergency department with a dry cough. Over the last five days, she has been suffering from a worsening dry cough, shortness of breath that is worse on exertion, and she has felt hot. She has a past medical history of HIV which was recently diagnosed, but no other medical problems. She has been started two months ago on antiretroviral treatment and PCP prophylaxis, to which she reports good compliance.

Fundoscopy shows white branches alongside blood vessels. She denies any eye pain or change in her vision.

Observations:

Saturations	93%
Respiratory rate	20/min
Blood pressure	131/70mmHg
Heart rate	89/min
Temperature	38.1°C

Blood tests:

Hb	122 g/l
Platelets	401 * 10 /l9
WBC	10.2 * 10 /l9
Na^+	138 mmol/l
K^+	4.2 mmol/l
Urea	5.1 mmol/l
Creatinine	71 µmol/l
HIV viral load	12,198 copies/ml
CD4 count	70 cells/mm^3

A chest X-ray shows bilateral interstitial infiltrates. A broncho-alveolar lavage is organised but shows no organisms on microscopy, including with silver staining. PCR studies are pending.

What is the most appropriate treatment?

A. Prednisolone
B. Low-molecular weight heparin
C. Tazocin
D. IV co-trimoxazole
E. Ganciclovir

E. Ganciclovir

The correct answer is ganciclovir as this patient is likely to have CMV pneumonitis. Prednisolone would be more appropriate during PCP treatment, heparin would be appropriate if a pulmonary embolus was expected, tazocin is a broad-spectrum antibiotic used in many bacterial infection whilst co-trimoxazole is first line treatment for PCP. There are are several factors strongly suggestive of CMV as the cause of infection; fever with desaturation in poorly controlled HIV and evidence of retinitis as well. 'Chest X-ray of bilateral interstitial infiltrates is highly suggestive too. The diagnosis should be confirmed by a biopsy or broncho-alveolar lavage which can use PCR to amplify CMV. The negative silver staining makes PCP less likely as well.

Question 175 of 277

A 71-year-old gentleman presented to the emergency department with a headache, myalgia and fever. These symptoms all started one day ago. He has a past medical history of hypertension, ischaemic heart disease, type 2 diabetes, congestive cardiac failure and bilateral hip replacement. His medications include amlodipine, ramipril, aspirin, atorvastatin, gliclazide, calcium carbonate with colecalciferol (Adcal-D3) and paracetamol. He denies any allergies. He is concerned that he about influenza as he visited a friend in hospital last week who had been diagnosed with influenza A.

On examination, he appears sweaty and feels hot to touch. His chest is clear on auscultation. He is placed in a side room for observation and viral throat swabs are requested.

Observations:

Oxygen saturation	96% on room air
Respiratory rate	18/min
Blood pressure	129/93mmHg
Heart rate	77/min
Temperature	38.1°C

What is the most appropriate treatment?

A. Supportive management only
B. Salbutamol
C. Zanamivir
D. Amantadine
E. Oseltamivir

E. Oseltamivir

The correct answer is oseltamivir. This is a patient presenting with symptoms of influenza following recent exposure. The first aspect to consider is if he needs any antiviral drugs. Since he presented within 48 hours of the onset of symptoms and is in an at-risk group because of his diabetes he would warrant antiviral treatment and therefore supportive management is not the most appropriate treatment. Salbutamol is not indicated for flu alone. Zanamivir is second line treatment for influenza, whilst amantadine is no longer recommended for use in the treatment of influenza.

Question 176 of 277

An 82-year-old gentleman inpatient is reviewed on the ward round. He originally presented with diarrhoea on a background of ulcerative colitis flare and is managed with oral and rectal mesalazine. His bowel has settled but he developed a rash around his left antecubital fossa, and he has developed a temperature of 38.2ºC. On examination, his chest sounds clear and his abdomen is soft, but the left antecubital fossa has a tender and warm erythematous rash. Stool results show no growth, abdominal and chest X-ray are clear but a MRSA swab from the nose is positive.

What is the most appropriate treatment?

A. Mupirocin and chlorhexidine
B. Benzylpenicillin
C. Tazocin
D. Vancomycin
E. Flucloxacillin

D. Vancomycin

The correct answer is vancomycin. This is a patient with a new fever and the most obvious cause is cellulitis. Given that the location of the cellulitis is in a location common for cannulation the most likely explanation is iatrogenic cellulitis. This makes MRSA a much higher likelihood and therefore the most appropriate treatment is vancomycin. Mupirocin and chlorhexidine are used to eradicate MRSA when present as commensal organisms. In non-iatrogenic cellulitis benzylpenicillin and flucloxacillin are commonly used.

Question 177 of 277

A 32-year-old gentleman presents to the emergency department with severe nausea, vomiting and diarrhoea. He was recently at a reunion where 18 out of 25 guests have developed similar symptoms shortly afterwards. On examination he appears clinically dehydrated but his vital parameters are all normal. He has no past medical history and otherwise his examination is normal.

You suspect norovirus; what is the most appropriate investigation?

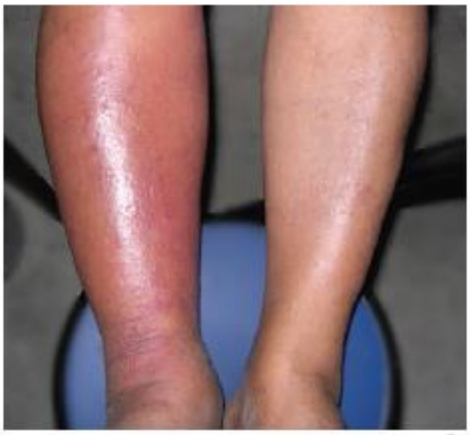
A. Serum serology
B. Faecal or vomitus toxicology
C. Faecal or vomitus viral PCR
D. Serum toxins
E. Serum viral PCR

C. Faecal or vomitus viral PCR

The correct answer is faecal or vomitus viral PCR which can confirm norovirus infection. Tests can detect antibodies by the ELISA method but these lack sensitivity and specificity and are therefore seldom used in the clinical setting. Norovirus does not make a toxin and therefore there is no such thing as norovirus toxin testing. The virus is not normally present in the bloodstream and therefore serum is likely to be negative for PCR testing. Norovirus is a viral cause of gastroenteritis commonly associated with large outbreaks in winter.

Question 178 of 277

A 69-year-old woman with diabetes and rheumatoid arthritis presents to the clinic complaining of malaise. She takes metformin, sulfasalazine and hydroxychloroquine daily and methotrexate once a week. She volunteers at a care home near her home. On examination, she appears frail, and her fingers and toes are deformed. She is alert, afebrile and comfortable at rest. Her pulse rate is 70 beats per minute, BP is 120/80 mmHg, and respiratory rate is 16 breaths per minute. On inspection of her legs, you notice the following:



What is the most appropriate next step in the management of this patient?

A. Admit and treat with intravenous antibiotics
B. Order for an x-ray of the limb
C. Order for blood cultures and review with reports after one week
D. Prescribe oral antibiotics and arrange a follow-up visit for the next week
E. Prescribe oral prednisolone and arrange a follow-up visit

A. Admit and treat with intravenous antibiotics

The most appropriate next step is to **admit and treat with intravenous antibiotics**. The image provided shows a swollen and erythematous right lower limb. Differential diagnoses for a swollen limb include cellulitis, deep vein thrombosis (DVT), lymphoedema, and fluid overload conditions such as chronic heart failure. Cellulitis should be suspected when there is a history of fever and malaise, with superficial bullae potentially observed over the affected area. DVT typically presents in patients who have risk factors (such as recent immobilisation, surgery, or pregnancy) with unilateral limb oedema, erythema, and tenderness. Lymphoedema often has an insidious onset and manifests as a slowly progressive swelling of a limb; it is commonly observed in patients postlymph node dissection proximal to the affected area. Fluid overload states usually present with bilateral pitting pedal oedema without associated warmth or tenderness.

In this case, we are presented with a frail, immunocompromised woman exhibiting symptoms of right leg cellulitis. These characteristics'frailty and an immunocompromised state'are indications for in-patient management according to NICE guidelines on admission criteria for cellulitis. It is important to note that methotrexate is typically withheld for patients who are being hospitalized with severe infections requiring intravenous antibiotic therapy.

Ordering an x-ray of the limb is not correct. While cellulitis is diagnosed clinically, an x-ray may be warranted only if there is strong clinical suspicion of osteomyelitis in the underlying bone; otherwise, it does not play a role in the management of cellulitis itself. Ultrasound (USG), computed tomography (CT), and magnetic resonance imaging (MRI) can help exclude deeper tissue infections such as myositis or detect abscess formation.

Ordering blood cultures and reviewing after one week is inappropriate for this scenario. This patient has an acute infection necessitating immediate antibiotic treatment. Blood cultures are indicated when sepsis is suspected but should not delay empirical antibiotic therapy aimed at preventing infection progression.

Prescribing oral antibiotics and arranging follow-up is incorrect for this patient's presentation. Given her frailty and immunocompromised status, she requires hospital admission for intravenous antibiotic therapy rather than outpatient management with oral antibiotics, which are reserved for Eron class I and II cases of cellulitis.

Prescribing oral prednisolone would be ill-advised here as it could exacerbate the infection by suppressing the immune response instead of treating it. Prednisolone may be indicated in patients experiencing acute rheumatoid arthritis flares but is not applicable to this clinical situation.

Question 179 of 277

A 14 month-old Syrian girl is brought to the health centre by her mother. They are living in a Jordanian refugee camp after fleeing violence in their country. She has a widespread maculopapular rash that first affected the face before spreading to the torso and limbs. On examination, she has a cough, rhinorrhoea and conjunctivitis bilaterally. White spotting is seen on her buccal mucosa. The mother reports that her other children have had similar symptoms.

Which is the most appropriate therapy?

A. Azithromycin
B. Vitamin A
C. Vitamin B1 (thiamine)
D. Aciclovir
E. Reassurance

B. Vitamin A

The child has a classical case of measles, showing signs of the three C's (Cough, Coryza & Conjunctivits). Although usually self limiting, measles can have severe consequences. All children in developing countries should receive two dose of vitamin A. This replenishes the low levels of vitamin A caused be measles which can lead on to diarrhoea, corneal perforation and secondary bacterial pneumonia. Vitamin A has been shown to reduce deaths from measles by 50%.

Passive immunity from maternal antibodies protects infants under the age of 1 from measles.

Question 180 of 277

A 23-year-old white Caucasian left-handed male presents with a 24-hour history of slurred speech. He is a 'frequent flyer' in the Emergency Department with repeated admissions and known is a known user of intravenous drugs and alcohol. His past medical history includes depression and previously treated in adolescence for functional neurological symptoms. He denies having had a drink for the past 2 weeks but used intravenous cocaine yesterday.

On examination, he is obviously unkempt and a lack of prominent veins. There is an old abscess scar over his right femoral crease. His speech is markedly slurred but he remains orientated to time and place. You also note a significant loss of forehead creasing and facial weakness on both sides of his face with normal facial sensation. In addition, his power his 4-/5 in shoulder abduction, shoulder adduction, hip flexion and hip extension, with 5/5 power on all other movements. Reflexes were present in biceps, supinator, patella and ankle, with absent triceps reflex. Both plantar reflexes were downgoing. Sensation to cotton wool, proprioception and pinprick was normal, with the patient reporting no pain.

What is the most likely diagnosis?

A. Heavy metal intoxication
B. Guillain Barre syndrome
C. Botulism
D. Chronic inflammatory demyelinating polyneuropathy (CIDP)
E. Myasthenia gravis

C. Botulism

The patient has presented with bilateral cranial neuropathies and symmetrical proximal weakness, in the context of intravenous drug use. The descending pattern of weakness is atypical for GuillainBarre syndrome. The time course of within 8 weeks also rules out CIDP. Myasthenia gravis is a possibility but there is no suggestion of fatigability. The distinction between heavy metal intoxication and botulism is difficult: intravenous drug users, particularly those sourcing from Eastern Europe, who have been known to present with manganese poisoning due to dirty constituents. Clinical features of course depend on the precise metal involved but acute poisoning typically includes encephalopathy, gastrointestinal upset and myalgia in addition to peripheral neuropathy. Significant sensory neuropathy causing neuropathic pain is commonly prominent. In the case of this patient, with bilateral cranial neuropathies and symmetrical proximal weakness, in the context of intravenous drug use, makes botulism most likely. Treatment is with antitoxin, removal of the original source of infection in addition to close monitoring of respiratory function.

Question 81 of 277

A 45-year-old male is brought into the emergency department by his partner. He is known to be HIV +ve and his partner reports good compliance with his medications since his diagnosis 4 years ago. A collateral history reveals persistent confusion over the past 3 weeks. His past medical history includes outpatient treatment 2 years ago for lymphogranuloma venereum and type 2 diabetes mellitus. On examination, the patient is not orientated in time or place. He scores 0/10 on the abbreviated mental test. Both heart sounds are present, include a mild early diastolic murmur. Neurological examination is difficult due to poor patient compliance but you note absent reflexes in both lower limbs, with an upgoing plantar on the left and withdrawn plantar on the right. You also note that he has erythematous soles on both feet. Blood tests and blood glucose are awaited.

What is the most likely diagnosis?

A. Subacute combined degeneration of the cord
B. Motor neurone disease
C. Neurosyphilis
D. Hypoglycaemia and diabetic peripheral neuropathy
E. HIV dementia and peripheral neuropathy

C. Neurosyphilis

A number of features suggest neurosyphilis from the history. Firstly, the likely aortic regurgitation on cardiovascular examination should make you suspicious of aortitis, of which syphilitic infection is a classic cause. He has had a range of sexually transmitted diseases. A painless red rash is also a classic sign of syphilis, particularly in palms of the hands or the soles of the feet. He also has a combined upgoing plantar with absent ankle jerks, which narrows the diagnosis to the classic five MRCP favourite of motor neurone disease, tabes dorsalis, subacute combined degeneration of the cord, Friedrich's ataxia and dual pathology of central and peripheral causes. There is little to suggest a genetic disorder presenting in his mid-40s or a vitamin B deficiency to account for SCDC. Neurosyphilis would be the most likely diagnosis.

Question 182 of 277

A 22-year-old lady, with lupus and antiphospholipid syndrome, presented to the Rheumatology clinic with sharp chest pain across her right side.

This pain had started 3 days prior to presentation. She had some shortness of breath. She reported that she has a vesicular rash that had started 1 day ago over that area.

She weighs 65KG Her medications include:

- Methotrexate 20mg once weekly
- Prednisolone 30mg once a day
- Aspirin 75mg once a day
- Folic Acid 5mg once a day

She was admitted to the rheumatology ward and underwent a CT pulmonary angiography which showed no pulmonary emboli, but widespread bilateral changes of subsolid nodules and groundglass opacification.

Her shortness of breath started to get worse and her observations were taken. Observations:

Temperature	39.1ºC
Blood pressure	107/55mmHg
Heart rate	122beats/min
Oxygen saturation	88% on air

What is the best treatment for her likely diagnosis?

A. Treat with dalteparin subcutaneously
B. Treat with intravenous amoxicillin and oral clarithromycin
C. Treat with intravenous amoxicillin
D. Treat with aciclovir intravenous
E. Treat with aciclovir orally

D. Treat with aciclovir intravenous

The most likely diagnosis for this immunocompromised lady with sharp pain and a vesicular rash is varicella zoster chickenpox. She is systemically unwell with it and has widespread pulmonary changes that are consistent with varicella pneumonitis.

The treatment of choice in an immunocompromised host with varicella zoster is intravenous aciclovir.

Answers 1,2 and 3 would not treat the varicella zoster infection.

Question 183 of 277

A 32-year-old lady of Ugandan origin presents to the HIV clinic.

She has been known to the HIV service since coming to the UK 10 years ago. She currently takes tenofovir, emtricitabine, and dolutegravir. She is extremely compliant with her current regime and is currently well.

She is 14 weeks pregnant and this is her first pregnancy. Despite some vomiting earlier in the pregnancy, she is excited and feeling well.

Her blood tests show:

CD4 count	0.84x10^9/L
CD8 count	1.01x10^9/L
Viral load	<20RNA/ml

She has come to discuss the management of her HIV with you.

What is the most appropriate management for this lady?

A. Stop this patients current regime and change her onto zidovudine, lamivudine and nevirapine
B. Continue the current medications, but at a lower dose so that the medications do notcross the placental barrier and effect the foetus
C. Continue current regime and advise patient she will need to deliver by caesarean sectionto prevent transmission during birth
D. Continue current management and advise patient there is currently no reason why sheshould not have a vaginal delivery
E. Stop all HIV medications and advise this patient she will have to deliver by caesareansection

D. Continue current management and advise patient there is currently no reason why sheshould not have a vaginal delivery

It is recommended that women conceiving on an effective antiretroviral (ART) regimen should continue this even if it contains efavirenz or does not contain zidovudine.

Exceptions are: (1) Protease inhibitor (PI) monotherapy should be intensified to include (depending on tolerability, resistance and prior antiretroviral history) one or more agents that cross the placenta. (2) The combination of stavudine and didanosine should not be prescribed in pregnancy

Although there is most evidence and experience in pregnancy with zidovudine plus lamivudine, tenofovir plus emtricitabine or abacavir plus lamivudine are acceptable nucleoside backbones. In the absence of specific contraindications, it is recommended that the third agent in ART should be efavirenz or nevirapine (if the CD4 cell count is less than 250 cells/L) or a boosted PI.

No routine dose alterations are recommended for ARVs during pregnancy if used at adult licensed doses.

With a viral load <50 at 36 weeks a vaginal delivery is recommended in the absence of any obstetric complications. Since her viral load has been undetectable for the last 6 years it is reasonable to assume this is likely to continue throughout her pregnancy. She will continue to need monitoring of her viral load throughout her pregnancy, particularly at 36 weeks.

In 2015 there were an estimated 1.5 million people living in Uganda with HIV.

Question 184 of 277

An 80-year-old gentleman presented with a 4 month history of feeling generally unwell, being more breathless and tired than usual, feeling feverish and having a dry cough. He had already been treated by the General Practitioner with 2 courses of antibiotics in the community with only temporary improvement. His past medical history includes previous myocardial infarction, permanent pacemaker (PPM) with box-change 8 months ago, hypertension, diabetes, anaemia and chronic kidney disease (stage 2). He is a lifelong smoker.

On examination his heart sounds were normal with no murmurs, he had scattered crackles and his abdomen was soft and non-tender. There was mild leg oedema and a faint purpuric rash on his shins. His vital signs revealed heart rate = 80 beats per minute, blood pressure = 130/70 mmHg, T=37.8oC, SaO2 = 96% on air and respiratory rate = 20 breaths per minute. His chest X-ray did not show and consolidation and his urine was clear.

The following blood tests have been obtained:

Hb	10.5 g/dl
MCV	95 fl
Platelets	160 * 10 /l9
WBC	13.4 * 10 /l9

Na +	132 mmol/l
K +	4.9 mmol/l
Urea	12 mmol/l
Creatinine	150 µmol/l
CRP	100 mg/l

Blood cultures grow coagulase negative staphylococci and you notice that during his previous admission in the hospital he also had positive blood cultures for coagulase-negative staphylococci.

What is the best next investigation?

A. Repeat blood cultures
B. Computed tomography thorax / abdomen / pelvis
C. Biopsy of the rash
D. Vasculitic screen
E. Urgent transoesophageal echocardiogram

E. Urgent transoesophageal echocardiogram

This question aims to raise awareness of the significance of blood cultures positive for coagulasenegative staphylococci.

Coagulase-negative staphylococci are often considered skin contaminant or apathogenic organisms. However, in the presence of prosthetic devices such as PPM, prosthetic heart valves, central venous lines and orthopaedic prostheses they are the commonest cause of infection causing device-related infection. This is because of their ability to establish biofilms on artificial layers. *Staphylococcus epidermidis* device-related infections: pathogenesis and clinical management, JPP 2008, 60:1551-1571

This patient presented with symptoms and sings suggestive of a chronic infection and had blood cultures positive for coagulase-negative staphylococci. The presence of the PPM and the purpuric rash indicate that the source of sepsis is possibly related to the medical device. The box-change also increases the risk of infection.

Repeating the blood cultures is a good idea but it does not help identify the source of sepsis. CT thorax / abdomen / pelvis is an investigation that can identify most sources of sepsis especially if there is a clinical suspicion of lung or intra-abdominal abscess. However, in this case, it will not be particularly useful to verify the source of sepsis. Vasculitis is less likely in that scenario and so biopsy of the rash or vasculitic screen should not be the next investigation.

Transoesophageal echocardiogram is the best investigation to rule out pacemaker-wire related infections. It requires a lot of expertise and it might not be readily available but even so it is the next best investigation in this scenario.

Question 185 of 277

A 19-year-old from Cameroon has moved to the UK to study nursing. She arrived three months ago. She has been having diarrhoea for a month and noticed a fleeting erythematous rash on her torso. Her GP orders a set of bloods, which reveal a dramatic eosinophilia. She has not lost weight and, if anything, seems concerned that she is becoming overweight since moving to the UK. She has been well previously with no allergies or medication. There is no significant family history but she tells you that her brother had an 'eye worm' last year.

A stool is sent for ova cysts and parasites and microscopy and culture. Multiple *Strongyloides stercoralis* larvae can be seen on charcoal culture. She is commenced on a seven-day course of Ivermectin.

Four days later she is brought into the Emergency Department, with a GCS of 6.

What is the diagnosis?

A. Disseminated Strongyloides infection
B. Co-infection with Onchocerciasis
C. Co-infection with Loa
D. Ivermectin related hypoglycaemia
E. Insulin abuse

C. Co-infection with Loa

The give away in this history is the family history of 'eye worm'. This suggests that she lives in an area of high Loa Loa endemicity.

Question 86 of 277

A 24-year-old Caucasian girl returned from a two week scuba diving holiday in Honduras four days ago. She had not taken malaria prophylaxis. She had been drinking alcohol moderately during her trip. She had unprotected sex during her holiday with her diving instructor. Yesterday she had felt hot and cold with pain all over her body and a headache. Today the pain is worst behind her eyes. It is a constant pain and there is no photophobia or neck stiffness. She has an erythematous rash over her trunk and back with patches of white skin surrounded by erythema. There is no lymphadenopathy

She is observed in hospital for 48 hours and tests for HIV (including PCR and antibody), malaria and blood cultures were negative. Further tests remain unreported.

She recovers and is feeling much better. Prior to discharge, she asks if she is safe to go back to Honduras next year.

What should you advise?

A. She should not go back to any Dengue endemic area as there is a risk of Dengue haemorrhagic fever (with a 20% mortality) with a second exposure to Dengue virus
B. She can go back to Honduras, although there is a small risk of Dengue haemorrhagic feverwith a second exposure, the risk is small enough not to be overly worried. She should takeprecautions not to be bitten by mosquitos during the day
C. She has had Dengue fever so will be immune to Dengue fever on subsequent exposure
D. She has had flu and therefore she can go back to Honduras next year
E. Staying in the UK from now on would be the most sensible given that she is at high risk ofmalaria, HIV and Dengue fever from her behavioral tendencies

B. She can go back to Honduras, although there is a small risk of Dengue haemorrhagic feverwith a second exposure, the risk is small enough not to be overly worried. She should takeprecautions not to be bitten by mosquitos during the day

There are four serovars of Dengue (1-4) and therefore infection with one serovar will not confer immunity to the other serovars. There is a theoretical risk that consequent infection with serovar 2 following infection with serovar 1 will increase your risk of progression to Dengue Haemorrhagic Fever. However, the risk is far smaller than other risks posed by travelling (e.g road traffic accident, acquiring HIV from unprotected sex etc.) Therefore universal travel advice (including avoidance of day biting mosquitos) is appropriate.

Question 187 of 277

You are called to see a 50-year-old Indian gentleman who has presented to the Emergency Department (ED) from Heathrow airport. He gives a 3 week history of a brown productive cough associated with fevers and drenching nights sweats. He denies any weight loss or haemoptysis, however his wife is concerned that his sputum has been very brown/red in colour since his illness started. On further questioning you find that the patient is a resident of a rural community in north east India and is visiting family who live in London. He is a non-smoker and had been in very good health apart from a bout of diarrhoea several weeks ago.

On examination of the patient he appears relatively well, his heart rate is 95 beats per minute and respiratory rate is 20 breaths per minute. You note that he has a productive cough, producing dark brown sputum which you send for routine microscopy sensitivity and culture (MC&S) and acid fast bacilli (AFB) and tuberculosis PCR. On auscultation of his chest you hear course crepitations at the right base with some bronchial breathing. The remainder of his physical examination is unremarkable.

You perform a number of investigations described below

Hb	110 g/l	Na^{+}	138 mmol/l
Platelets	500 * 10 /l 9	K^{+}	4.5 mmol/l

WBC	16.0 * 10 /l 9	Urea	6.0 mmol/l
Neuts	10.0 * 10 /l 9	Creatinine	99 µmol/l
Lymphs	2.0 * 10 /l 9	CRP	55 mg/l
Eosin	2.0 * 10 /l9		
Sputum MC&S	Negative		
Sputum AFB	Negative		
Chest X-Ray	Right lower zone consolidation		

What is the likely diagnosis?

A. Tuberculosis
B. Streptococcal pneumonia
C. Paragonimiasis
D. Malignancy \
E. Pulmonary hemorrhage

C. Paragonimiasis

The diagnosis is paragonimiasis or lung fluke infection.

Background

Paragonimiasis is a common tropical infection, the presentation of which can often be misinterpreted as tuberculosis. Patients classically present with a productive cough of brown / red sputum (which can often be mistaken for haemoptysis). Patients may also exhibit constitutional symptoms, however, these are often less severe than in tuberculosis or malignancy. Furthermore, paragonimiasis is often associated with an eosinophilia.

Although more commonly associated with East Asia, paragonimiasis is also prevalent in North East India, Africa and parts of the Americas.

Treatment of paragonimiasis is with praziquantel.

Question 188 of 277

You are called to the Emergency Department to review a 60-year-old Indian female who returned from a six month trip to the north east of India five days ago. She presented with a three week history of a productive cough, producing large quantities of brown sputum. She has also been experiencing fevers daily and complains of being extremely sweaty over night. On further questioning there is no history of weight loss or TB contacts. The patient reports that as she has felt relatively well with these symptoms she had not presented earlier. It was, in fact a concerned relative who thought the patient had coughed up blood who had brought her in to hospital today.

Examination reveals a comfortable patient with evidence of a right lower zone pneumonia. The is confirmed on chest radiograph. You send a number of investigations including sputum for routine culture and acid fast bacilli. The results of which are shown below:

Hb	120 g/l	Na +	139 mmol/l
Platelets	350 * 10 /l 9	K +	3.9 mmol/l
WBC	13.0 * 10 /l 9	Urea	8.0 mmol/l
Neuts	8.0 * 10 /l 9	Creatinine	110 µmol/l
Lymphs	1.5 * 10 /l 9	CRP	35 mg/l
Eosin	1.8 * 10 /l9		
Sputum MC&S	Negative		
Sputum TB PCR	Negative		

What is the most appropriate treatment for this patient?

A. Rifater and ethambutol
B. Amoxicillin
C. Praziquantel
D. Augmentin and clarithromycin
E. Fluconazole

C. Praziquantel

In this case the diagnosis is paragonimiasis, or lung fluke infection. Paragonimiasis is a common tropic al disease, which often presents in a similar fashion to tuberculosis. The patient will have a productive cough of classically brown or red sputum (which may be misinterpreted as haemoptysis). They often will also present with fever and night sweats as well as rashes or urticaria. Constitutional symptoms will often not be as severe as in tuberculosis and the patient may also have an eosinophilia.

Treatment of paragonimiasis is with praziquantel

Question 189 of 277

As the medical registrar on-call you are called to see a 25-year-old male in the Emergency Department (ED). The young male presented to the ED with a fever and productive cough of green sputum. When you arrive he looks unwell and although alert is a difficult historian.

Concerned, you immediately assess him from head to toe:

Airway	Airway patient, able to speak in sentences
Breathing	Sats 90% on room air, Resp Rate 25 / min, course creps bilaterally on auscultation
Circulation	Heart rate 110 beats per minute, blood pressure 90/55 mm/Hg
Disability	Glasgow coma sclae 15/15, capillary blood glucose 5.5
Exposure	Multiple boils noted distributed widely across the patients body

You inquire about the history of the boils identified on examination. The patient is unsure how long he has had them for, however, mentions that two of his family members recently were prescribed antibiotics by their family GP for similar lesions.

You start the patient on high flow oxygen, gain IV access taking blood cultures and give a fluid bolus. An urgent portable chest X-ray is requested which appears to show bilateral consolidation with multiple cavitating lesions.

What is the most likely diagnosis

A. Streptococcal infection
B. PVL-producing staphylococcal infection
C. Tuberculosis
D. Fungal chest infection
E. Klebsiella infection

B. PVL-producing staphylococcal infection

Panton-Valentine Leukocidin is a pore-forming toxin which is produced by staphylococcus aureus. It has an affinity for white blood cells and the endothelium. Clinically PVL will often present with a necrotising pneumonia, characterised by severe bilateral pneumonia with cavitations on X-ray. Often patients presenting will have a history of boils or necrotic skin lesions. As the staphylococcus is easily transmitted there may be a recent family history of similar infections / boils.

Although all of the answers in this stem could be associated with cavitating pneumonia, the severity of the clinical presentation and history of boils in the family points towards a PVLpneumonia.

Question 190 of 277

A 36-year-old male from India presents with worsening headache and vomiting. He is known to have HIV but has been lost to follow up over the last 5 years. His CD4 count from his last appointment was 400.

On examination he has no localising signs however fundoscopy revealed papiloedema. Investigations:

haemoglobin	115 g/L (115-165)
white cell count	9.4 Ã— 109/L (4.0-11.0)
platelet count	220 Ã— 109/L (150-400)
erythrocyte sedimentation rate	50 mm/1st h (<30)
serum urea	7.0 mmol/L (2.5-7.0)
serum creatinine	105 mol/L (60-110)
serum alanine aminotransferase	17 U/L (5-35)
serum aspartate aminotransferase	26 U/L (1-31)
Cryptococcal antigen test	Negative
CD4 Count	65 cells/mm3
CT Head	5cm ring enhancing lesion in right temporal lesion with surrounding oedema

What is most appropriate management?

A. Amphotericin, Fluconazole and prednisolone
B. Rifampicin, Isoniazid, Pyrazinamide, Ethambutol and prednisolone
C. Trimethorpim-Sulphamethoxazole, Rifampicin, Isoniazid, Pyrazinamide, Ethambutol andprednisolone
D. Start prednisolone but defer treatment until lumbar puncture performed
E. Pyrimethamine, Sulfadiazine, Rifampicin, Isoniazid, Pyrazinamide, Ethambutol, andPrednisolone

E. Pyrimethamine, Sulfadiazine, Rifampicin, Isoniazid, Pyrazinamide, Ethambutol, andPrednisolone

The question represents a real diagnostic conundrum. You should automatically think of compliance issues given that the patients has defaulted from treatment and is therefore unlikely to have been controlling his HIV. The CD4 count of 400 is therefore not going to be representative of his current immune system.

This leads us to the differential diagnosis of a intra-cerebral ring enhancing lesion in a severely immunocompromised host. This includes tuberculosis, lymphoma, toxoplasmosis and cryptococcus amongst others.

Amphotericin and fluconazole is used in the initial 2 week phase of treatment for cryptococcal meningitis. However we are told that the cryptococcal antigen test is negative. This test has a relatively high sensitivity and specificity is therefore reassuring.

We are also told that the patient has papilloedema and a 5cm lesion with oedema, as a result attempting a lumbar puncture at this early stage is fraught with risk. Although vital to diagnosis it would be prudent to reduce the intra-cerebral swelling first by which time the patient may have seriously deteriorated, therefore empirical treatment becomes a priority.

Diagnosis of CNS tuberculosis is notoriously difficult and without access to CSF it is likely that empirical treatment will be required in the interim. When CSF is available culture, staining and PCR can be used to help detect the organism. Toxoplasmosis is treated with pyrimethamine and sulfadiazine as a first line. Again, empirical treatment may be required before access to CSF is available. As a result the correct answer is treatment of TB and Toxoplasmosis with steroids to reduce oedema.

Question 191 of 277

A 36-year-old Somali male presents on the medical take with a severe generalised headache associated with nausea and vomiting. He has been living in the UK for the last 10 years. He was diagnosed with HIV 5 years ago and has been well maintained on therapy with an undetectable viral load and a CD4 count of 500 cells/mm3.

He has a long history of headaches since the age of 10 which are normally controlled with simple analgesia. Over the last 2 days he has been suffering with a particularly bad attack which culminated in him becoming aggressive and vomiting profusely. He was noted to have a tonicclonic seizure whilst in accident and emergency which resolved with diazepam.

Clinical examination reveals a pulse of 78 beats per minute, a blood pressure of 130/90, oxygen saturations of 98% on air and a temperature of 36.8 degrees. There was no focal neurological defects.

A CT scan subsequently showed cystic and calcified lesions within the brain and mild hydrocephalus.

What is the most likely diagnosis?

A. Tuberculous meningitis
B. Cryptococcal meningitis
C. Lymphoma
D. Neurocysticercosis
E. Human african trypanosomiasis

D. Neurocysticercosis

Cysticercosis is caused by the larval stage of the tapeworm Taenia solium. Clinical syndromes that can arise include neurocysticercosis (NCC) and extraneural cysticercosis. In endemic areas NCC is an important cause of adult-onset seizures.

Cysticercosis is transmitted by ingestion of T. solium eggs shed in the stool of a human tapeworm carrier. Following ingestion, embryos (oncospheres) hatch in the small intestine, invade the bowel wall and disseminate hematogenously to the brain, muscle, liver and other tissues. Cysts located in the brain result in neurocysticercosis and can lead to hydrocephalus if they obstruct the outflow of CSF from the ventricles. The condition can be chronic and develop over a protracted period of time.

This question relies primarily on knowledge of the relevant condition and your ability to think beyond the fact that the patient has HIV. While the other options are all plausible you are given clues throughout the question on which you can discount each one until you are left with the correct answer.

The first hint is that his HIV was diagnosed early and is very well controlled. This makes an opportunistic infection incredibly unlikely therefore discounting crypotcocosis and TB meningitis. There are two forms of human african trypanosomiasis both transmitted by the tsetse fly, T.gambiense a chronic condition contracted in west africa and T.rhodiesiense that is acutely progressive and contracted in east africa. Given that he has been in the UK for 5 years we can discount T.rhodesiense and the finding of calcified lesions on the CT would be most unusual for T.gambiense.

This leaves us with lymphoma and neurocistercicosis, lymphoma will generally present with progressive focal neurology over a period of time and is unlikely to show calcified lesions in the brain.

Question 192 of 277

A 69-year-old man from Pakistan presents to his general practitioner with a three month history of cough associated with episodes of haemoptysis and has had some episodes of shortness of breath. His only past medical history of note is asthma for which he takes salbutamol inhaler as required and 2 puffs of beclomethasone inhaler twice daily. He has a 25 pack-year history and he is teetotal. The patient's GP performs blood tests and refers the patient to the rapid access chest clinic.

Blood test results come back as all within normal reference ranges, however, chest x-ray shows a solid lesion at the apex of the right lung, that is associated with a rim of air.

Of the following options, which is the most likely diagnosis?

A. Tuberculosis
B. Mesothelioma
C. Aspergilloma
D. Squamous cell carcinoma
E. Small cell lung carcinoma

C. Aspergilloma

The most likely diagnosis in this case is an aspergilloma - a fungal ball located in a previous cavity in the lung, as seen by the solid mass coupled with the rim of air and the haemoptysis, which can sometimes be severe.

Question 193 of 277

A 34 year-old man from South Korea presents with a two week history of abdominal pain in the right upper quadrant, fever and weight loss. The pain does not radiate anywhere and is 6/10 on the pain scale. Apart from the above he has no other symptoms. His only family history is his father who has hepatitis B and HIV. Examination reveals a 3cm tender palpable liver edge, pyrexia of 38.9ºC, pallor and right upper quadrant pain. There is no jaundice.

Blood tests reveal:

Bilirubin	29 µmol/l
ALP	200 u/l
ALT	90 u/l
γGT	100 u/l
Albumin	38 g/l

An ultrasound scan is requested and shows a 3x3cm abscess in the right lower lobe of the liver. The liver abscess is subsequently aspirated.

Apart from aspiration of the large liver abscess, what is the most appropriate treatment?

A. Blood cultures
B. Karyotyping
C. Metronidazole treatment
D. Liver biopsy
E. Mebendazole treatment

C. Metronidazole treatment

The most likely diagnosis in this case is an amoebic abscess, which are normally found in endemic tropical countries. Aspiration of large liver abscesses and a course of metronidazole is the preferred treatment for this condition.

Question 194 of 277

A 19 year-old University student presented to her General Practitioner with a three month history of intermittent diarrhoea and anorexia. She had lost approximately 10 kg of weight over a similar period. The patient had no previous abdominal symptoms and no significant past medical history. The symptoms had started several weeks after her return from a gap year expedition to Mali. On close questioning the patient did recall a short-lived intensely itchy erythematous rash on one of her feet while she was in Africa. This had spontaneously resolved and not subsequently recurred.

Initial investigations are listed below:

Hb	12.8 g/dl
Platelets	198 * 10 /l9
WBC	10.8 * 10 /l9
Neutrophils	5.2 * 10 /l9
Lymphocytes	2.1 * 10 /l9
Monocytes	0.8 * 10 /l9
Eosinophils	2.7 * 10 /l9
Basophils	0.0 * 10 /l9

Na +	136 mmol/l
K +	4.2 mmol/l
Urea	3.9 mmol/l
Creatinine	78 µmol/l

Stool microscopy: *Strongyloides stercoralis* larvae

Strongyloides stercoralis filariform larvae IgG: positive Under supervision from Infectious Disease department the patient was treated with Ivermectin.

What is the best method to assess for Strongyloides stercoralis eradication six months after completion of treatment course?

A. Repeat blood eosinophil count
B. Assessment of patient symptoms
C. Repeat Strongyloides stercoralis serology
D. Repeat stool microscopy on two occasions one week apart
E. Repeat stool microscopy with stool concentration

C. Repeat Strongyloides stercoralis serology

Repeat serological testing is the best method of confirming *Strongyloides stercoralis* eradication following treatment. A post-treatment to pre-treatment titre ratio of < 0.6 is taken to represent a good indicator of treatment success.

Blood eosinophil count is also often found to decrease following treatment although this method clearly lacks specificity given the numerous other causes of eosinophilia.

Strongyloides stercoralis infection is often asymptomatic therefore resolution of symptoms does not provide good evidence of successful treatment. While stool microscopy is the gold standard diagnostic test for strongyloidiasis it has a sensitivity of only 50 % making it an unreliable tool to confirm eradication. Stool concentration techniques are used in specialist laboratories to improve sensitivity of stool microscopy for strongyloidiasis.

Question 195 of 277

A 22-year-old man presented to his General Practitioner with an itchy rash across his arms and legs. Symptoms had developed within the last few days and were causing the patient significant discomfort and preventing him from sleeping. The patient was a university student currently enjoying his summer vacation. He reported returning from a backpacking trip around Eastern Europe one week previously when he had stayed mostly in youth hostels. Since his return he had been staying in his parent's home. Interestingly, the patient had discovered on Facebook that a similar rash had afflicted a friend he had made at the end of his holiday.

He also worked part-time as a barman and denied coming into contact with any unusual chemicals at work. He had not recently introduced any new skin care products.

The patient had suffered from mild atopic eczema as an infant but had no recent skin complaints or other past medical history. He took no regular medications and had no known allergies. The patient smoked 10 cigarettes per day and drank roughly 40 units of alcohol each week.

On examination, the patient's arms and legs were covered with 2-5 mm maculopapular lesions with a central haemorrhagic punctum. In several places, several lesions were noted to be lying close together in a curve formation. There were minor marks of excoriation associated with the lesions. The patient's groin, abdomen, chest and back were free from rash. There was no axillary, cervical or inguinal lymphadenopathy.

What organism is the likely cause for the patient's rash?

A. Sarcoptes scabiei
B. Leishmania donovani
C. Ancylostoma braziliense
D. Mycobacterium leprae
E. Cimex hemipterus

E. Cimex hemipterus

The patient has symptoms and signs of exposure to bed bug infestation. In temperate regions this is caused by the insect *Cimex hemipteru* (or *Cimex lectularius* in tropical regions). A rash develops up to 11 days after exposure due to an allergic reaction. Bed bug infestation has increased in frequency over the past 10 years with the patient likely exposed during a recent stay at youth hostel.

The other organisms are all potential causes of skin disease in the returned traveller.

- *Sarcoptes scabiei* (scabies)
- *Leishmania donovani* (cutaneous leishmaniasis)
- *Ancylostoma braziliense* (cutaneous larva migrans)
- *Mycobacterium leprae*(leprosy)

Question 196 of 277

A 45-year-old female presents to your clinic with bilateral lower limb lesions. She said that it initially started as a small nodule on the right shin which then broke down into an exudative ulcer. Over the past year she has developed widespread 'cauliflower-like' lesions over her whole body. On examination you note a painless ulcer with scab over the anterior right shin, and generalised papillomas over the face, trunk, genitalia and buttocks.

Investigations demonstrate:

TPHA (Treponema pallidum Haem Agglutination test)	Positive

What is the most likely diagnosis?

A. Pinta
B. Syphilis
C. Yaws
D. Pyoderma gangrenosum
E. Kaposi's sarcoma

C. Yaws

Treponemal specific antibody tests (e.g. TPHA) are very specific to Treponema but not necessarily syphillis, as the species Treponema can cause a variety of diseases including syphilis, yaws and pinta

Care must be taken when interpreting syphilis investigations. Cardiolipin tests (e.g. VDRL and RPR) are non-specific and can be positive in many diseases such as TB, malaria and HIV. Treponemal specific antibody tests (e.g. TPHA) are very specific to Treponema, however the species Treponema can cause a variety of diseases including syphilis, yaws and pinta.

Yaws is a chronic infection that affects mainly the skin, bone and cartilage. The disease occurs mainly in low socio-economic communities in tropical areas of Africa, Asia and Latin America. The causative organism is a bacterium called Treponema pertenue, a subspecies of Treponema pallidum that causes venereal syphilis. However, yaws is a non-venereal infection.

In primary yaws, a single skin lesion develops at the point of entry of the bacterium after 2-4 weeks. This nodule can break down into an exudative ulcer. Without treatment, secondary yaws can occur, resulting in multiple lesions appear all over the body, more commonly over the face, trunk, genitalia and buttocks. Later on in the disease course, widespread bone, joint and soft tissue destruction can occur.

Question 197 of 277

A 25-year-old HIV-positive male goes to his GP with complaints of headache and left-sided weakness of recent onset. His temperature is 38ºC, blood pressure is 115/70 mmHg, respirations are 14/min and pulse is 73/min.

Neurological examination reveals decreased power, hyperreflexia in the left upper and lower limb with associated upgoing plantars. CT head shows multiple ring-enhancing lesions.

What is the most appropriate next step in management?

A. Trimethoprim-sulfamethoxazole
B. Sulfadiazine and pyrimethamine
C. Brain irradiation
D. Brain biopsy
E. Start albendazole

B. Sulfadiazine and pyrimethamine

HIV, neuro symptoms, multiple brain lesions with ring enhancement - toxoplasmosis

The most common cause of central nervous system mass lesion in AIDS patients is toxoplasmosis. This patient's findings are consistent with cerebral toxoplasmosis. Trimethoprim-sulfamethoxazole is used for prophylaxis of toxoplasmosis, while sulfadiazine and pyrimethamine are used for treatment purposes.

Choice 3: Brain irradiation is used in the management of primary CNS lymphoma. Patients with primary CNS lymphoma are usually afebrile; lesions are weakly enhancing and are single (can be multiple). This is suspected if the patient does not respond to antibiotic therapy.

Choice 4: Brain biopsy is reserved for patient's whose lesions do not respond to treatment with sulfadiazine and pyrimethamine.

Choice 5: Albendazole is used for neurocysticercosis. This condition is not usually seen in AIDS patients.

Question 198 of 277

A 44-year-old man is reviewed in the renal clinic. He has a diagnosis of end-stage renal failure due to IgA nephropathy. The team is working him up for a renal transplant.

As part of his transplant workup, he has an interferon-gamma release assay performed:

Interferon-gamma release assay	Positive

He subsequently has further testing:

Nucleic acid amplification tests	Negative for *Mycobacterium tuberculosis*.

Sputum acid-fast bacilli smear	Negative for acid-fast bacilli

Chest X-ray	Lung fields appear clear. Normal cardiomediastinal contour.

What is the most appropriate management?

A. No treatment required
B. Pyridoxine for 6 months
C. Rifampicin and isoniazid (with pyridoxine) for 3 months
D. Rifampicin, isoniazid (with pyridoxine), pyrazinamide, and ethambutol for 2 months, thenrifampicin and isoniazid for 10 months
E. Rifampicin, isoniazid (with pyridoxine), pyrazinamide, and ethambutol for 2 months, thenrifampicin and isoniazid for 2 months

C. Rifampicin and isoniazid (with pyridoxine) for 3 months

Positive IGRA, but asymptomatic and normal CXR → treat as for latent tuberculosis

Rifampicin and isoniazid (with pyridoxine) for 3 months is correct. This patient has latent *Mycobacterium tuberculosis* infection: he has a positive interferon-gamma release assay but negative sputum for acid-fast bacilli and nucleic acid amplification tests as well as a normal chest x-ray. Latent *Mycobacterium tuberculosis* infection can either be treated with 3 months of rifampicin and isoniazid or with 6 months of isoniazid.

No treatment required is incorrect. This patient has a positive interferon-gamma release assay. This suggests either active or latent *Mycobacterium tuberculosis* infection. Given the negative nucleic acid amplification test, sputum smear for acid-fast bacilli, and normal chest x-ray, it is likely this patient has latent *Mycobacterium tuberculosis* infection. This requires treatment with either 3 months of rifampicin and isoniazid or 6 months of isoniazid alone.

Pyridoxine for 6 months is incorrect. Pyridoxine is a form of vitamin B6 and is used for the prevention of isoniazid-induced neuropathy. It is not in itself used as part of the treatment of *Mycobacterium tuberculosis* infection.

Rifampicin, isoniazid (with pyridoxine), pyrazinamide, and ethambutol for 2 months, then rifampicin and isoniazid for 10 months is incorrect. This is the treatment regimen for active *Mycobacterium tuberculosis* infection with CNS involvement. It is also usually accompanied by a course of steroids. The patient in this case, however, has latent *Mycobacterium tuberculosis* infection, evidenced by the positive interferon-gamma release assay but negative sputum for acidfast bacilli and nucleic acid amplification tests as well as a normal chest x-ray.

Rifampicin, isoniazid (with pyridoxine), pyrazinamide, and ethambutol for 2 months, then rifampicin and isoniazid for 4 months is incorrect. This is the treatment regimen for active *Mycobacterium tuberculosis* infection without CNS involvement. The patient in this question has latent *Mycobacterium tuberculosis* infection, so this answer is incorrect.

Question 199 of 277

A 48 year-old civil servant was referred to the Acute Medical Unit by his general practitioner with progressive cognitive impairment and severe lethargy over the last 3 weeks. He had also become intermittently agitated and his sleep was disturbed during the night. He had returned from visiting his partners relatives in Zimbabwe 1 month ago. He suffered from type II diabetes which was well controlled through dietary modification. He smoked 10 cigarettes a day and drank 14 units of alcohol per week.

On examination, his temperature was 37.2ºC, pulse was 60 beats per minute and blood pressure was 134/88. His Glasgow Coma Score was 14/15 due to confused speech. His trachea was central and right-sided posterior cervical lymphadenopathy was present. His jugular venous pressure was not elevated and chest was clear on auscultation. Heart sounds were normal.

Investigations:

Haemoglobin	143 g/L (130-180)
White cell count	7.7 x 109/L (4.0-11.0)
Neutrophil count	3.0 x 109/L (2.0-7.5)
Lymphocyte count	1.8 x 109/L (1.3-3.5)
Eosinophil count	0.4 X 109/L (0.1-0.4)
Platelets	310 x 109/L (150-400)

Sodium	134 mmol/L (135-145)
Potassium	4.8 mmol/L (3.5-5.0)
Urea	9.0 mmol/L (2.5-7.5)
Creatinine	100 mol/L (25-95)
Fasting plasma glucose	4.4 mmol/L (3.0-6.0)

CT head	No abnormality detected

What is the most appropriate next investigation?

A. MRI brain
B. Lymph node biopsy
C. Lumbar puncture
D. Stool microscopy
E. Blood film

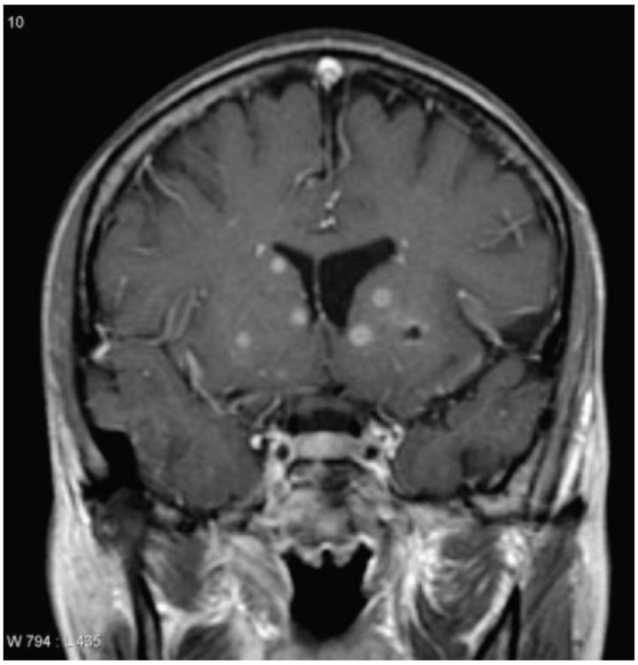
C. Lumbar puncture

This patient has African trypanosomiasis, sometimes known as sleeping sickness. The acute presentation and country of origin suggest the East African variant, caused by *Trypanosoma bruicei rhodesiense*. Although the parasites may be detected in a peripheral blood film or lymph node biopsy, determining whether they have penetrated the central nervous system (CNS) will most influence choice of drug therapy. Pentamidine is the treatment of choice in early infection, while choices for CNS infection include suramin, melarsoprol, eflornithine and nifurtimox. These medications are not widely available and can result in extremely severe side effects, so are only prescribed by tropical medicine specialists.

Question 200 of 277

A 33-year-old man who has recently emigrated from Zimbabwe is admitted after being found confused at home. His partner reports that he has been acting strangely for a number of weeks and complaining of altered taste and dizziness. She reports that she is HIV positive but her partner refuses to be tested as he does not believe in 'medical lies'.

On admission he is apyrexial with a blood pressure of 114/82mmHg and pulse 78/min. Rapid HIV testing confirms that he has the infection. His CD4 count is 11 cells/µl. An MRI (T1 C+) shows the following:



Other than starting highly active antiretroviral treatment, what is the most appropriate treatment?

A. Amphotericin B
B. Surgical resection
C. Steroids + methotrexate + whole brain irradiation
D. Rifampicin + isoniazid + pyrazinamide + ethambutol + steroids
E. Sulfadiazine + pyrimethamine

E. Sulfadiazine + pyrimethamine

HIV, neuro symptoms, multiple brain lesions with ring enhancement - toxoplasmosis

The correct answer in this case is **sulfadiazine + pyrimethamine**. The patient's presentation with confusion, altered taste, dizziness, and a low CD4 count of 11 cells/µl suggests that he has an opportunistic infection due to his HIV infection. The MRI image provided shows multiple ringenhancing lesions, which are consistent with cerebral toxoplasmosis. Cerebral toxoplasmosis is caused by the protozoan parasite *Toxoplasma gondii* and is a common opportunistic infection in patients with advanced HIV disease. The recommended treatment for cerebral toxoplasmosis is a combination of sulfadiazine and pyrimethamine.

Amphotericin B is an antifungal medication used primarily to treat invasive fungal infections such as cryptococcal meningitis or disseminated histoplasmosis. Although these infections can occur in patients with HIV, the MRI findings and clinical presentation are more suggestive of cerebral toxoplasmosis.

Surgical resection might be considered for space-occupying lesions such as brain abscesses or tumours. However, given the patient's multiple ring-enhancing lesions on MRI and low CD4 count, cerebral toxoplasmosis is much more likely than a primary brain tumour or abscesses.

Steroids + methotrexate + whole brain irradiation would be a treatment approach for primary central nervous system (CNS) lymphoma, which can also present with neurological symptoms in patients with HIV. However, CNS lymphoma typically presents as a solitary lesion rather than multiple ring-enhancing lesions seen in this case.

Rifampicin + isoniazid + pyrazinamide + ethambutol + steroids represent the standard regimen for treating tuberculosis (TB). While TB can involve the CNS in patients with HIV, the MRI findings are not typical for CNS TB. Moreover, the patient's symptoms of altered taste and dizziness do not fit well with a diagnosis of CNS TB.

Question 201 of 277

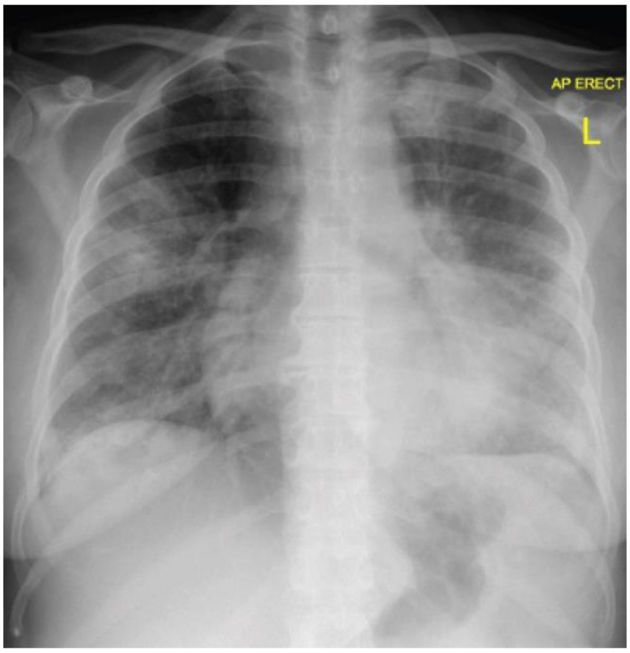
A 54-year-old woman presents to the Acute Medical Unit with a three day history of fever, myalgia and a non-productive cough. She initially thought her symptoms were due to the 'flu but over the past 24 hours has been feeling progressively more poorly. She now also has nausea, abdominal pain, headaches and diarrhoea.

On examination her pulse is 84/min, temperature 39.4ºC and blood pressure 106/76 mmHg. Bilateral scattered crackles are noted on auscultation.

Bloods show the following:

Hb	12.4 g/l	Na +	133 mmol/l
Platelets	363 * 10 /l 9	K +	5.0 mmol/l
WBC	12.1 * 10 /l 9	Urea	7.8 mmol/l
Neuts	10.8 * 10 /l 9	Creatinine	88 µmol/l
Lymphs	1.1 * 10 /l 9	CRP	145 mg/l
Eosin	0.2 * 10 /l9		

The chest x-ray is shown below:



Which investigation is most likely to be diagnostic?

A. Sputum culture
B. Cold agglutinins
C. Bronchoalveolar lavage
D. Blood serology
E. Urinary antigen

E. Urinary antigen

Legionella pneumophilia is best diagnosed by the **urinary antigen** test

The chest x-ray shows the asymmetrical, patchy bilateral consolidation typical of *Legionella*. This combined with high fever, hyponatraemia, abdominal pain and lymphopaenia make the diagnosis the most likely.

Question of 202 of 277

A 17-year-old man who has recently come to the UK from Rwanda is admitted to hospital. His friend describes him complaining of a headache and fever for the past four days. Further history reveals that he is very lethargic with a dry cough and generalised myalgia. The patient also describes passing some dark urine this morning. He has no past medical history of note. On examination his pulse is 110/min, temperature 38.1ºC, oxygen saturations 98% on room air and blood pressure 110/68 mmHg, His sclera are jaundiced and there is enlargement of the liver and spleen. Bloods show the following:

Na +	142 mmol/l
K +	4.8 mmol/l
Urea	12.3 mmol/l
Creatinine	144 µmol/l

What is the most likely diagnosis?

A. Typhoid
B. Dengue fever
C. African trypanosomiasis
D. Malaria
E. Leishmaniasis

D. Malaria

This patient clearly has an infective process so much of the data (headache, fever, myalgia, vital signs) can be discarded as being common to all the answers.

We're now left with more concrete findings: jaundice, hepatosplenomegaly and a raised creatinine. Now we take one of these findings, hepatosplenomegaly and consider the differential diagnosis:

Causes of hepatosplenomegaly

- chronic liver disease with portal hypertension
- infections: glandular fever, malaria, hepatitis
- lymphoproliferative disorders
- myeloproliferative disorders e.g. chronic myeloid leukaemia
- amyloidosis

This suggests that malaria is the most likely diagnosis. Jaundice and a raised creatinine are consistent with this.

Question 203 of 277

A 23-year-old woman presents to the emergency department. She was brought in by ambulance following left-sided weakness and difficulty in finding words. She also complains of a headache and nausea for the last three days. She has no past medical history and does not smoke nor does she drink alcohol. She recently emigrated from Tanzania to the UK.

On examination, she has marked weakness in upper and lower left limbs and is unable to walk without assistance. Her responses to questions are slow and limited.

Blood tests:

Hb	129 g/l
Platelets	316 * 10 /l9
WBC	8.9 * 10 /l9
Na +	141 mmol/l
K +	4.7 mmol/l
Urea	5.1 mmol/l
Creatinine	71 µmol/l
HIV-1 serology	positive
HIV-2 serology	negative
HIV viral load	pending
CD4 count	pending
Toxoplasmosis serology	pending
Cryptococcal antigen	pending

A CT scan of her head demonstrates multiple ring-enhancing lesions and mass effect. Dexamethasone is started immediately.

What is the most appropriate next step?

A. Antiretroviral treatment
B. Amphotericin
C. Methotrexate
D. MRI brain and whole spine
E. Pyrimethamine and sulfadiazine

E. Pyrimethamine and sulfadiazine

HIV, neuro symptoms, multiple brain lesions with ring enhancement - toxoplasmosis

The correct answer is pyrimethamine and sulfadiazine as the patient likely has cerebral toxoplasmosis as an AIDS-defining illness. Methotrexate is the treatment for a CNS lymphoma, alongside whole brain radiotherapy, but CNS lymphoma is unlikely since there are multiple lesions. Antiretroviral treatment will need to be started but should be done in specialist settings and not in the acute one. Further imaging would not be needed as there are sufficient evidence to start treatment at this point and would cause an unnecessary delay.

Question 204 of 277

A 36 year old male Intravenous drug user presents to genito-urinary clinic. He was diagnosed with HIV 3 years ago after presenting with tuberculosis (TB). He was treated for TB for 6 months. He is now on third line anti-retroviral therapy for previous virological failure and co-trimoxazole. His most recent CD4 count was 104, and his viral load was 3,000 copies/ml.

He complains of weakness on his left side, and deterioration in vision, getting worse for four weeks. He has a moderately severe headache. On examination his visual acuity is 3/60 in his left eye and 6/6 in his right eye. He has weakness, in his left arm and leg, brisk reflexes and mildly increased tone.

He is immediately admitted.

A CT scan shows several ring enhancing lesions in his right cerebral hemispheres and one on the left cerebral hemisphere.

On ophthalmological review he has a large area of retinal necrosis in his left eye.

What is the diagnosis?

A. CNS lymphoma
B. Cerebral toxoplasmosis
C. Cerebral TB
D. Cerebral abscesses
E. CNS Kaposi sarcoma

B. Cerebral toxoplasmosis

HIV, neuro symptoms, multiple brain lesions with ring enhancement - toxoplasmosis

The most important three differential diagnosis for a ring-enhancing lesion in an HIV patient is CNS lymphoma, TB and Toxoplasmosis.

In this case the retinal necrosis in characteristic of ophthalmic toxomplasmosis. Multiple lesion also favour toxoplasmosis. His poor compliance with HIV treatment (as indicated by the low CD4 count and the high viral load) suggest his compliance with co-trimoxazole is also poor.

Question 205 of 277

A 68-year-old man presents to hospital with progressive shortness of breath over the last four days and a low-grade fever. He has a past medical history of mild asthma for which he occasionally needs to use his salbutamol inhaler and has previously had bilateral knee replacements for osteoarthritis. He has smoked on average 5 cigarettes per day for the past 40 years and drinks a couple of glasses of wine per week. His travel history includes a holiday to Cyprus, from which he arrived back in the UK 5 days ago.

Examination revealed some right mid zone crackles and reduced breath sounds over this area. Observations revealed a temperature of 38.8ºC, heart rate of 110 bpm, blood pressure of 105/66 mmHg, respiratory rate of 22 breaths per minute and oxygen saturations of 91% on room air.

Blood tests revealed:

Hb	145 g/l
Platelets	290 * 10 /l9
WBC	9.4 * 10 /l9
Na +	132 mmol/l
K +	3.7 mmol/l
Urea	4.1 mmol/l
Creatinine	67 µmol/l

Urinary sodium concentration was measured and found to be 36mmol/L (normal range 40-220 mmol/d).

Which of the following investigations is most useful in the diagnosis of this condition?

A. Urine antigen test
B. Serum antibody test
C. Sputum PCR
D. CT pulmonary angiography
E. D-dimer

A. Urine antigen test

Legionella pneumophilia is best diagnosed by the **urinary antigen** test

This scenario is most likely due to the organism *Legionella pneumophila* (causing Legionnaire's disease) - an infection which is often due to air conditioning units and heating units. This patient may have got the infection when on holiday and his sodium is low, often a result of syndrome of inappropriate ADH secretion. The most accurate investigation for Legionella infection is via the urine antigen test, which is quick and specific.

Question 206 of 277

A 37-year-old gentleman presents to the Emergency Department with acute onset shortness of breath and right sided pleuritic chest pain. He is known to be HIV positive and his latest CD4 count is $190/mm^3$. The last clinic letter suggests he may be non-compliant with his anti-retroviral medication due to persistent diarrhoea. On examination, he has decreased breath sounds on the right with fine scattered crepitations in both lung fields. Oxygen saturations are 93% on breathing air. A chest x-Ray reveals a right sided pneumothorax measuring 1 cm at the hilum.

What pulmonary infection would you suspect?

A. Mycobacterium tuberculosis
B. Urine antigen test
C. Aspergillus fumigatus
D. Histoplasma capsulatum
E. Haemophilus influenzae

A. Urine antigen test

NICE guidance of pleural disease (pneumothorax):

- A spontaneous pneumothorax in someone known to be HIV-positive should warrant investigation for a diagnosis of *Pneumocystis jirovecii* pneumonia.

Invasive fungal infection (including *Pneumocystis jirovecii* pneumonia) is likely in this gentleman given the CD4 count $<200/mm^3$.

Question 207 of 277

An 81-year-old nursing home resident presents with a 48-hour history of pyrexia, myalgia and coryza. On examination, her temperature is 37.9ºC and she is visibly coryzal. Her chest is clear to auscultation. Her chest X-ray is clear. Her relatives inform you that the nursing home has recently been closed to visitors due to an Influenza outbreak.

Which of the following drugs should you also consider adding?

A. Empirical antibiotics for pneumonia
B. Zanamivir
C. Oseltamivir
D. Ribavirin
E. Salbutamol nebulisers

C. Oseltamivir

Oseltamivir (Tamiflu) is the first-line treatment recommended for patients with suspected or confirmed Influenza A. Ribavirin has not be shown to be efficacious in the management of influenza. Zanamivir is useful in patients with a poor swallow or in those with suspected or confirmed exposure to oseltamivir-resistant influenza.

Her chest X-ray is clear and therefore there is no role for the addition of antibiotic therapy at this stage.

Salbutamol nebulisers can be useful in patients with wheeze, however, appropriate isolation precautions should be secured prior to the administration of nebulisers in patients with Influenza infection.

Question 208 of 277

A 44 year-old lady presented to the medical outpatient clinic with leg swelling which had progressively increased over the last 2 years. Her past medical history consisted only of a hospital admission for malaria as a child. She had grown up in urban Nigeria and moved to the United Kingdom 6 years ago to work as a teacher, but had been forced to stop working due to mobility problems. She was a non-smoker and did not drink alcohol.

On examination, her temperature was 36.5ºC, heart rate 80 beats per minute, blood pressure 133/89 mmHg, respiratory rate 16 breaths per minute and oxygen saturations 98% on room air. Non-pitting leg swelling was apparent bilaterally extending proximally to the hips, with thickening of the overlying skin. Her chest was clear on auscultation and heart sounds were normal. The JVP was not elevated.

Investigations:

Haemoglobin	138 g/L
White cell count	7.0 * 10 /l9
Neutrophil count	4.8 * 10 /l9
Lymphocyte count	2.0 * 10 /l9
Eosinophil count	0.1* 10 /l9
Platelets	246 * 10 /l9

Sodium	142 mmol/L
Potassium	4.3 mmol/L
Urea	6.0 mmol/L
Creatinine	84 mol/L
Alkaline phosphatase	40 IU/L
Alanine aminotransferase	32 IU/L
Gamma-glutyl transferase	23 IU/L
Bilirubin	16 mol/L
Albumin	41 g/L
Fasting plasma glucose	5.3 mmol/L

What is the most likely causative organism?

A. Wuchereria bancrofti
B. Brugia malayi
C. Brugia timori
D. Onchocerca volvulus
E. Mansonella streptocerca

A. Wuchereria bancrofti

This patient has presented with elephantiasis caused by chronic lymphatic inflammation and blockage in the lower limbs. The condition is caused by infiltration of the lymphatic system by filarial nematodes, which are transmitted by mosquitoes. *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori* are all potential causative organisms, but *Wuchereria bacrofti* is by far the most common, accounting for 90% of cases. *Onchocerca volvulus* causes skin disease and river blindness, while *Mansonella streptocerca* causes skin disease alone.

Question 209 of 277

A 28-year-old male presents to the emergency department complaining of shortness of breath. For the last week he has felt generally unwell with a headache, malaise and lethargy, but felt breathless this afternoon hence his presentation. On systems review, he also admits to having some generalised abdominal pain throughout the day yesterday associated with diarrhoea. He is otherwise fit and well, takes no regular medications and does not smoke. He admits to drinking one or two beers every evening and occasionally more at the weekends. He is a primary school teacher and lives with his wife and two small children, none of whom have been unwell recently. On examination, he has a temperature of 38.9ºC, a heart rate of 105 beats/minute and a blood pressure of 105/70 mmHg. His respiratory rate is 26 breaths/minute, his oxygen saturations 92% breathing room air and on auscultation to his chest there are a few crepitations bibasally. He has some routine blood tests performed.

Hb	109 g/L
MCV	105 fL
Platelets	390 * 10 /L9
WBC	16.5 * 10 /L9
CRP	240 mg/L
Bilirubin	50 µmol/L
ALT	40 u/L
ALP	135 u/L

What is the most likely diagnosis?

A. Alcoholic liver disease
B. Gilbert's syndrome
C. Mycoplasma pneumonia
D. Hypothyroidism
E. Acute cholecystitis

C. Mycoplasma pneumonia

Mycoplasma pneumonia is one of the atypical pneumonias and classically occurs in clusters every few years. It normally produces a fairly mild picture with fairly normal clinical findings although the chest x-ray may have marked changes. It is associated with cold agglutinins in around 50% of cases which can result in a cold autoimmune haemolytic anaemia - as in this case, explaining the slight bilirubin rise and the raised MCV which represents a reticulocytosis. Other associations with mycoplasma infection include erythema multiforme, encephalitis, arthralgia and diarrhoea. Alcoholic liver disease is possible given this patients alcohol intake, bilirubin and MCV, but would be unlikely given his young age and no other clinical findings to support this. Gilbert's syndrome is hyperbilirubinaemia in the context of transient illness, viral or otherwise, and could explain many of the findings in this case but would not explain the raised MCV.

Question 210 of 277

A 39-year-old HIV-positive man complains of a two-week history of worsening headache, facial weakness and visual hallucinations. He also reports new onset eye pain. An MRI head reveals multiple ring-shaped contrast-enhancing lesions. He is regularly followed up in the HIV clinic and his latest CD4 count was 140 cells/mm³.

Which treatment should be started immediately?

A. Valganciclovir
B. Trimethoprim + sulfamethoxazole
C. Dexamethasone
D. Pyrimethamine + sulfadiazine
E. Ethambutol + rifampicin

D. Pyrimethamine + sulfadiazine

The symptoms and MRI findings are highly suggestive of toxoplasmosis, a disease caused by the protozoan *Toxoplasma gondii.*

A 6-month treatment regimen of sulfadiazine and pyrimethamine should be commenced immediately. Patients should be given lifelong secondary prophylaxis.

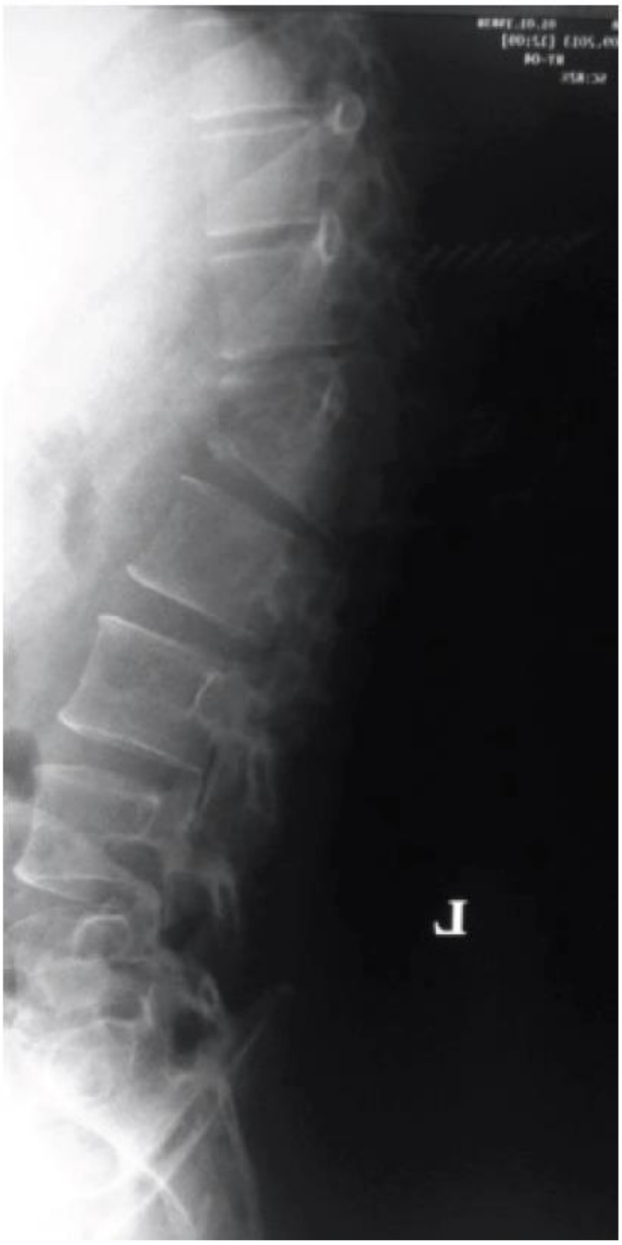
Question 211 of 277

A 34-year-old man presents with back pain and leg weakness. This has been getting worse for the past two months and he now complains that he is 'bent over'. Over the past three months he describes feeling generally unwell, with a poor appetite and night sweats.

His past medical history includes hypothyroidism. He emigrated from Bangladesh around 6 months ago.

On examination he has a kyphosis. He is most tender over the lower part of the thoracic spine. Neurological examination of his lower limbs demonstrates reduced power in both legs.

A lumbar spinal film is shown below:



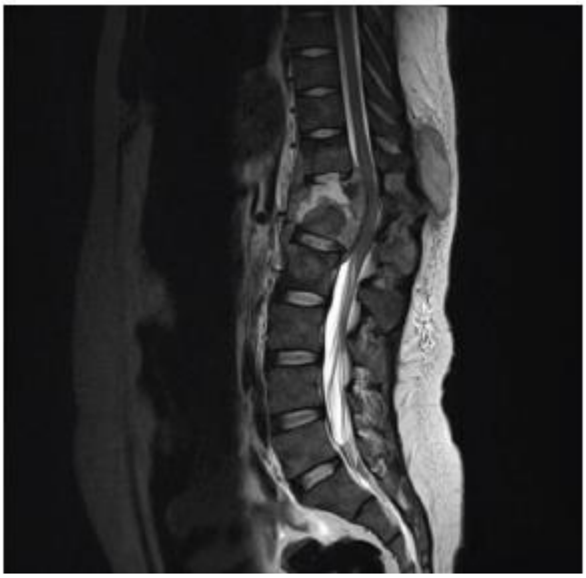
What is the most likely diagnosis?

A. Osteoporosis secondary to hypogonadism
B. Pott's disease
C. Actinomycosis
D. Sarcoma
E. Hodgkin's lymphoma

B. Pott's disease

The x-ray shows destruction of T12 and L1, with a resultant gibbus deformity (a short-segment structural thoracolumbar kyphosis resulting in sharp angulation). The destructive process is centred on the T12/L1 disc space.

A MRI from the same patient is shown below:

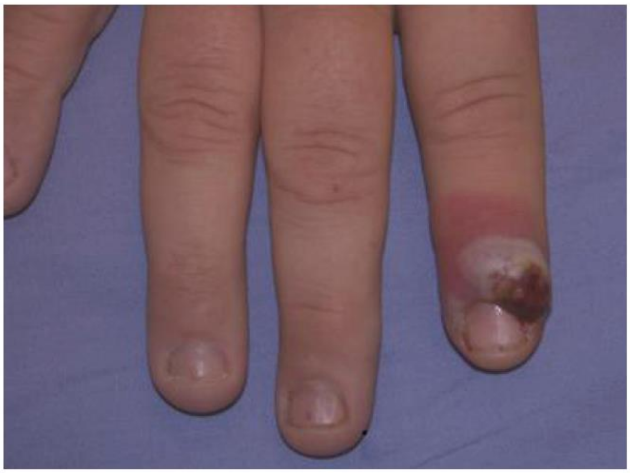


T12/L1 spondylodiscitis - with avid contrast enhancement involving the T11-L2 vertebral bodies, T12/L1 disc space and the adjacent paravertebral collections.

Hypogonadism is less likely given the systemic symptoms.

Question 212 of 277

A farmer presents with a tender lesion on his finger:



What is the most likely diagnosis?

A. Paronychia
B. Orf
C. Tetanus
D. Anthrax
E. Hand, foot and mouth disease

B. Orf

The correct answer is **Orf**. Orf, also known as contagious ecthyma, is a zoonotic disease caused by a parapoxvirus that primarily affects sheep and goats. Humans can contract the disease through direct contact with infected animals or via fomites. The typical presentation includes a painful, red nodule on the hand or finger, often with central ulceration. This aligns with the farmer's occupation and the clinical picture presented.

Paronychia is an infection of the skin around the nail, typically caused by staphylococci or streptococci bacteria. It presents with redness, swelling and tenderness at the side of the nail bed.

Although this could be plausible given the patient's profession, it does not account for all his symptoms nor does it match the image provided.

Tetanus, caused by *Clostridium tetani*, is characterised by muscle stiffness and spasms due to neurotoxins produced by this bacterium following wound contamination. While farmers are at an increased risk due to potential exposure to soil and animal faeces where *Clostridium tetani* spores reside, tetanus would not present as a single tender lesion on a finger.

Anthrax is another zoonotic disease caused by *Bacillus anthracis*. Cutaneous anthrax usually presents as a painless black eschar after an incubation period of 1-7 days post-exposure. However, in this case, there is no mention of exposure to livestock products such as hides or wool which would increase suspicion of anthrax.

Finally, **Hand, foot and mouth disease (HFMD)**, commonly caused by coxsackievirus A16 or enterovirus 71, primarily affects children under 10 years old. It presents with fever and vesicular lesions in the mouth and on hands/feet/buttocks. The age group affected and characteristic distribution of lesions make HFMD less likely in this scenario.

Question 213 of 277

A 26-year-old woman presents to the Emergency department some 2 weeks after returning from her honeymoon in the Seychelles. Since returning she has suffered from intermittent abdominal bloating and diarrhoea and feels she has lost a little weight. Physical examination reveals a blood pressure of 118/82 mmHg, and her pulse is 70 and regular. There is mild abdominal distension and her body mass index is 22 kg/m^2

Investigations:

Hb	110 g/l	Na +	138 mmol/l
Platelets	210 * 10 /l 9	K +	4.0 mmol/l
WBC	11.2 * 10 /l 9	Urea	6.9 mmol/l
Neuts	8.1 * 10 /l 9	Creatinine	89 µmol/l
Lymphs	1.5 * 10 /l 9	CRP	82 mg/l
Albumin	34 g/l		

Which of the following is the most appropriate intervention?

A. Amoxicillin
B. Ciprofloxacin
C. Gluten free diet
D. Lactose free diet
E. Metronidazole

E. Metronidazole

The most likely diagnosis, given the trip to a tropical region of Africa, intermittent bloating and diarrhoea, and an elevated CRP, is Giardiasis. Empirical treatment is often given, with either a course of metronidazole or a single dose of 2g tinidazole. Food intolerances may persist, particularly with respect to lactose, for some time after the initial infection.

Amoxicillin and ciprofloxacin would usually be used for listeriosis and campylobacter respectively, and neither infection is likely. Neither a wheat free diet nor a lactose-free diet is indicated given the likelihood of ongoing giardiasis, although many patients may suffer symptoms of lactose intolerance post-giardiasis.

Question 214 of 277

A 67-year-old woman is referred to the Emergency department by her GP because of an acute rise in serum creatinine. She has a history of Type 2 diabetes and takes lisinopril, amlodipine and indapamide as well as metformin and simvastatin, and has recently been prescribed trimethoprim for a UTI. Her blood pressure is 148/84 mmHg, with no postural drop on standing. There are no signs of fluid overload.

Na +	140 mmol/l
K +	4.9 mmol/l
Urea	5.8 mmol/l
Creatinine	162 µmol/l
Creatinine (one month earlier)	112 µmol/l

Which of the following is the most likely cause of her creatinine elevation?

A. Amlodipine
B. Lisinopril
C. Post-renal failure
D. Pre-renal failure
E. Trimethoprim

E. Trimethoprim

Trimethoprim is associated with a reversible elevation in serum creatinine because of a reduction in tubular excretion. Creatinine returns to normal once therapy ceases, and there is no effect on the GFR.

There is no suggestion of postural drop on blood pressure testing to support either pre-renal failure or amlodipine being the likely cause of creatinine elevation, and it's likely that the lisinopril has been prescribed for a prolonged period, rather than it being the cause of an acute rise in creatinine due to renal artery stenosis.

There are no symptoms of urinary obstruction to suggest post-renal failure.

Question 215 of 277

A 36-year-old gentleman was admitted to the Medical Admission Unit. His principle complaint was watery diarrhoea which has been present for the last few weeks. He had not noticed the presence of blood or mucus in the stool. He also complained of transient pain on swallowing, and weight loss of 2 stones over the last year. He denied the presence of respiratory symptoms and abdominal pain. He had no past medical history of note from his GP records. He consumes 20 cans of standard strength lager per week, smokes 20 cigarettes per day and denies recreational drug use. He had no fixed abode.

On examination, he was unkempt and dishevelled, with a BMI of 17.1 kg/m^2. Cardiovascular and respiratory examinations were unremarkable except for an oxygen saturation of 94% on room air. His heart rate was 92/min, blood pressure 112/62 mmHg and temperature 36.7ºC. Abdominal examination was also unremarkable though examination of the oral cavity revealed the presence of multiple aphthous ulcers. Examination of the neck revealed multiple small palpable cervical lymph nodes. Fundoscopy revealed the presence of white patches but otherwise, nil else and central and peripheral nervous system examination was otherwise normal. Skin examination revealed multiple pearly pink umbilicated nodules.

Initial investigations revealed the following:

Hb	122 g/l
Platelets	189 * 10 /l9
WBC	3.6 * 10 /l9

Chest x-ray: normal appearances of the heart and chest ECG: 92bpm normal sinus rhythm, no other abnormalities seen Urinalysis: normal

Stool MCS: normal interim results, pending further analysis

Which is the single investigation most likely to lead to the underlying diagnosis?

A. CT head, chest, abdomen and pelvis
B. Upper gastrointestinal endoscopy
C. Bone marrow biopsy
D. Colonoscopy
E. HIV serology

E. HIV serology

This gentleman has several conditions strongly suggestive of Acquired Immunodeficiency Syndrome (AIDS). He has features of cytomegalovirus (CMV) retinitis and oesophagitis caused by either CMV or other infections such as herpes simplex virus (HSV) and candidiasis. His loose stools are most likely representative of Cryptosporidium infection which would not be found on a conventional initial stool microscopy, culture and sensitivity test. He also has a skin infection in keeping with Molluscum contagiosum. Testing for HIV serology is, therefore, the best option.

Question 216 of 277

A 38-year-old male presented to the Emergency Department complaining of feeling unwell. He complained of a headache that had been present for the last two days which he described a continuous ache worse in the morning, as well as a sore throat. He later developed diarrhoea, opening his bowels three times per day passing watery loose stool. Since then he has deteriorated, complaining of nausea and vomiting on the day of admission. He also noted a new rash on his chest which developed over the last few hours and complained of pains in his muscles. He had returned two weeks ago from a six-month backpacking expedition around Africa and Far East Asia; he was prescribed doxycycline as antimalarial prophylaxis but had discontinued them two weeks into his trip after suffering from severe sunburns. He had not taken recommended vaccinations prior to his trip as he was engaged with work commitments. His past medical history comprised of asthma and depression for which he was prescribed sertraline 100mg OD and Clenil modulite 2 puffs BD.

Examination revealed the presence of an unwell gentleman. His temperature was 40.1ºC, heart rate 122 bpm, respiratory rate 22/min, oxygen saturations 95% on air and he had a blood pressure of 94/68 mmHg. He had a plethoric facial appearance, and multiple petechiae were noted on his chest and face. Examination of his cardiovascular system revealed the presence of normal heart sounds with a JVP of 2cm and a bounding radial pulse and vasodilated peripheries. Examination of his respiratory system revealed tachypnoea but with vesicular breath sounds. Examination of the gastrointestinal and neurological systems was unremarkable, with no neck stiffness, negative Kernig's and Brudzinski's signs. His GCS was 15. Multiple insect bites were noted on his legs and arms.

He was promptly transferred to the resuscitation area where two large bore cannulae were inserted and aggressive intravenous fluid resuscitation was commenced. A urinary catheter was inserted. The doctor inserting the cannulae noted that the sites of venepuncture continued to ooze despite the application of continual mechanical pressure.

Initial investigations revealed the following results:

Hb	102 g/l
Platelets	8 * 10 /l9
WBC	3.2 * 10 /l9
Neutrophils	2.2 * 10 /l9
Lymphocytes	0.8 * 10 /l9
Monocytes	0.1 * 10 /l9
Eosinophils	0.1 * 10 /l9
ESR	48 mm/hr

PTT	17 (NR 12-14s)
APTT	53 (NR 30-46s)
Fibrinogen	0.6 (NR 2-4g/l)
D-Dimer	428 (NR <230ng/ml)

Na +	130 mmol/l
K +	6.2 mmol/l
Urea	18.1 mmol/l
Creatinine	262 µmol/l
CRP	96 mg/l

Bilirubin	28 µmol/l
ALP	162 u/l
ALT	122 u/l
Total protein	52 g/l
Albumin	22 g/l

Blood MCS x3: awaiting result

Urine MCS: awaiting result

Thick film: negative

Thin film: awaiting result Portable chest x-ray: normal appearance of heart and lung fields

ECG: sinus tachycardia 122bpm

Urinalysis: trace protein, ketones ++, nil else

What is the most likely diagnosis?

A. Viral haemorrhagic fever
B. Malaria
C. Typhus
D. Thrombotic thrombocytopaenic purpura
E. Typhoid fever

A. Viral haemorrhagic fever

The Viral Haemorrhagic Fevers describe infection by a group of RNA viruses which include Yellow fever, Lassa fever and Ebola virus. Given the current outbreak in West Africa, this group of infections must be considered as a differential in returning travellers presenting with a fever. They are characterised by initially non-specific symptoms such as fever, headache, vomiting, sore throat, diarrhoea and myalgic muscle pains, progressing to shock, renal failure and the presence of disseminated intravascular coagulation (DIC). Investigations characteristically reveal an anaemia with thrombocytopaenia, low lymphocyte count, deranged liver function and the presence of DIC. This condition requires intensive supportive care and early diagnosis is imperative. There are of course many differentials, malaria being a key one here, but the absence of parasites on thick film make this a less likely diagnosis.

Question 217 of 277

A 17-year-old man is referred to the infectious disease department with a sore throat, fever and lymphadenopathy. He has been generally unwell for the previous 3 days but presented as he noticed some yellowing of his eyes. His routine blood test show

Bilirubin	55 µmol/l

ALP	54 u/l
ALT	402 u/l
AST	188 u/l
γGT	17 u/l
Albumin	43 g/l

He has no travel or sexual history and has never used intravenous drugs.

What is the most likely causative organism?

A. Viridans group Streptococci
B. Hepatitis B virus
C. Echinococcus granulosus
D. Hepatitis C virus
E. Epstein Barr virus (EBV)

E. Epstein Barr virus (EBV)

Epstein-Barr virus (EBV) is a herpes virus which commonly leads to infectious mononucleosis. This presents, often in teenagers and young adults with fevers, painful throat, lymphadenopathy and flu-like symptoms. Although it can last longer the symptoms are usually self-limiting within 2 weeks. Acute infection often leads to splenomegaly or hepatosplenomegaly and although a transient hepatitis is common it can lead to clinical jaundice.

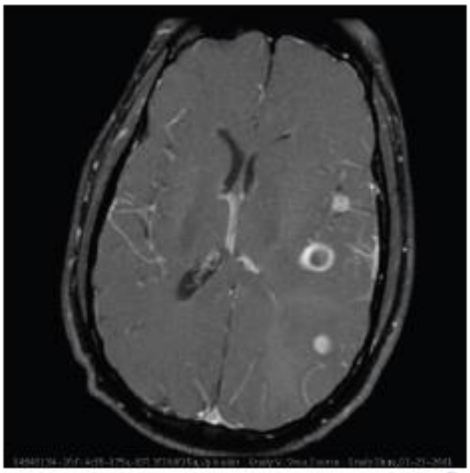
Question 218 of 277

A 50-year-old man with HIV presents to the emergency department with fits for 10 minutes. His vital signs are temperature 39 ºC, blood pressure 110/75 mmHg, and pulse 87 /minute. Examination reveals a Glasgow coma scale (GCS) score of 11 (E3V4M4). There is no focal neurological deficit.

Laboratory tests are requested as shown below:

Hb	135 g/L	(135-180)
Platelets	300 * 10 /L^9	(150 - 400)
WBC	4.5 * 10 /L^9	(4.0 - 11.0)
CD4 cell count	120 cells/mm^3	(500 - 1500)

An MRI brain is requested, as shown below:



© Image used on license from Radiopaedia

What is the most appropriate treatment for this patient?

A. Intravenous amphotericin-B
B. Methotrexate with whole brain irradiation
C. Oral pyrimethamine-sulfadiazine
D. Oral trimethoprim-sulfamethoxazole (TMP-SMX)
E. Surgical excision

D. Oral trimethoprim-sulfamethoxazole (TMP-SMX)

The most appropriate treatment option is **oral pyrimethamine-sulfadiazine** because the scenario describes a patient with HIV-related cerebral toxoplasmosis. MRI reveals intra-cerebral ringenhancing lesions with peri-lesional oedema. History of fits in an HIV-positive patient along with the MRI findings in this scenario confirms the diagnosis of cerebral toxoplasmosis. A 3-month treatment with pyrimethamine-sulfadiazine is the most appropriate management option.

Cerebral toxoplasmosis is not treated with **intravenous amphotericin B** . Amphotericin B treats cryptococcal meningoencephalitis, which is another important neuro-complication of HIV. The MRI scan in cryptococcal meningitis shows cryptococcomas, meningeal enhancement, abscesses, and gelatinous pseudocysts.

Methotrexate with whole brain irradiation is the most appropriate treatment for primary CNS lymphoma which is sometimes indistinguishable from cerebral toxoplasmosis in HIV patients. In this scenario, an important differentiating feature of primary CNS lymphoma and cerebral toxoplasmosis is the presence of a ring-enhancing lesion on MRI. Primary CNS lymphoma is characterised by a single mass lesion on an MRI scan that enhances homogeneously. When there is diagnostic uncertainty, a 3-month treatment with pyrimethamine-sulfadiazine is given.

Prophylaxis with **oral trimethoprim-sulfamethoxazole (TMP-SMX)** is given against cerebral toxoplasmosis in HIV patients when the CD4 count is below 100 cells /mm³. The patient in this scenario requires definitive treatment and not chemoprophylaxis with TMP-SMX because he has already developed cerebral toxoplasmosis, and has a CD4 count of above 100 /mm³.

Low-grade primary CNS lymphoma in HIV can be treated by **surgical excision** . Surgical excision has no role in treating cerebral toxoplasmosis, which is the case here. Primary CNS lymphoma is the most common HIV-associated brain tumour. The treatment of choice for primary CNS lymphoma is high-dose methotrexate with radiotherapy. Surgical excision can be considered for low-grade tumours.

Question 219 of 277

A 23-year-old man presents for the second time to HIV clinic. He was found to have positive HIV serology on opportunistic screening in a local GUM clinic and was referred to HIV services. He had originally presented with dysuria and had been diagnosed with non-specific urethritis and treated with doxycycline. Following his diagnosis, he has separated with his partner, as she feared contracting HIV from him. He is anxious with managing his disease and is keen to start treatment. He has no other symptoms, feeling systemically well and no significant past medical history.

During his previous consultation, his diagnosis was discussed with him, and the role of antiretroviral treatment was fully explained.

Blood tests:

Hb	134 g/l
Platelets	378 * 10 /l9
WBC	7.2 * 10 /l9
Na +	141 mmol/l
K +	4.1 mmol/l
Urea	4.6 mmol/l
Creatinine	64 µmol/l
HIV viral load	223 copies/ml
CD4 count	914 cells/mm3

What is the most appropriate management plan offer?

A. Start antiretroviral therapy and PCP prophylaxis

B. Start antiretroviral therapy
C. Start treatment when CD4 count becomes <350
D. Start treatment when CD4 count becomes <550
E. Start treatment once HIV related symptoms develop

B. Start antiretroviral therapy

This is a patient with newly diagnosed HIV and should be offered HIV treatment regardless of CD4 count or viral load. PCP prophylaxis is only necessary when the CD4 count becomes much lower.

Question 220 of 277

A young 27 year-old man who has been travelling on a jungle expedition across south east Asia presents to the local doctors with a 3 day history of fever, headache and a widespread maculopapular rash. He has been kayaking through rivers, trekking through long grass and jungle, and he reports being bitten by mosquitos, flies and mites. On close inspection he has a black necrotic eschar on his leg. A malaria rapid diagnostic test (RDT) is negative.

What is the most appropriate management?

A. Artemether / lumefantrine
B. Benzylpenicilin
C. Corticosteroids
D. Doxycycline
E. Supportive care

D. Doxycycline

The history describes a classical case of scrub typhus - and in particular the black eschar is the key diagnostic clue. Scrub typhus is caused by the tropical rickettsial bacteria *Orientia tsutsugamushi* and is transmitted by the bite of an infective trombiculoid 'chigger' mite. Its distribution is limited to South East Asia. Complications of disease include jaundice, meningoencephalitis, myocarditis, pneumonia and renal failure. However the disease can be easily treated with doxycyline.

Similar disease presentations are seen in other continents. *Rickettsia ricketsii* causes the potentially fatal Rocky Mountain spotted fever (RMSF), but its distribution is limited to North and Central America. African tick typhus is a mild and self limiting infection with no reported deaths and caused by *R. africae*. Other tropical rickettsial disease include endemic murine typhus and epidemic louse borne typhus which are more serious forms of disease.

The other answers are trying to catch you out as fever, headache and rash are non specific symptoms. Artemether / lumefantrine is the correct treatment for uncomplicated *Plasmodium falciparum*; Benzylpenicillin is the treatment for Leptospirosis; Corticosteroid would be used to treat Katayama fever (acute schistosomiasis); and supportive care would be appropriate in the setting of uncomplicated dengue fever (typically an urban disease).

Question 221 of 277

An 18-year-old male presents to the general medical take.

He presents with large grey lesions around his perineum and in his mouth which started 2 days ago. He reports that he has a more general rash on his trunk and the palms and soles of his feet. He generally feels unwell with malaise and fever. He has never had anything like this before but mentions that he did see a small ulcer on his scrotum a month ago that didn't hurt and healed on its own.

He reports that he is generally fit and well and has just moved to the area to start his university studies.

On examination, he has a symmetrical, widespread, macular papular rash on his trunk, limbs and the palms and soles of his feet. This is different from the large greyish lesions that you see in his mouth and perineum. He has general lymphadenopathy that is minimally tender on palpation. His chest is clear on auscultation, there are no added heart sounds and his abdomen is soft and nontender.

Investigations show:

Haemoglobin	13g/dl
WCC	11 x 10^9/l
Platelets	352 x 10^9/l
CRP	89mg/L
Sodium	145 mmol/l
Potassium	3.8 mmol/l
Urea	4 mmol/l
Creatinine	82 µmol/l

What is the most likely diagnosis?

A. Epstein Barr virus
B. HIV
C. Cytomegalovirus
D. Herpes simplex virus
E. Treponema pallidum

E. Treponema pallidum

This young man presents with a symmetrical rash on his trunk, palms, and soles that is pathognomonic for secondary syphilis. He also has a further rash of grey lesions in the mouth and perineum associated with syphilis. Although he was not concerned about it, he has also mentioned that he had a painless genital ulcer one month ago that may have represented his primary syphilis infection. He has general lymphadenopathy and epitrochlear nodes are particularly suggestive of the diagnosis.

He is a young man that has recently started university and is likely to be enjoying this period of parties and new acquaintances. It would be worth exploring his sexual history further as syphilis is more common in men who have sex with men.

Patients are often co-infected with other sexually transmitted diseases and this patient should be further investigated for these including HIV.

Answers 1,2 and 3 may all be associated with lymphadenopathy, but one would not expect to get genital ulceration or grey mucosal lesions. HIV can be associated with a rash on the limbs, palms and soles.

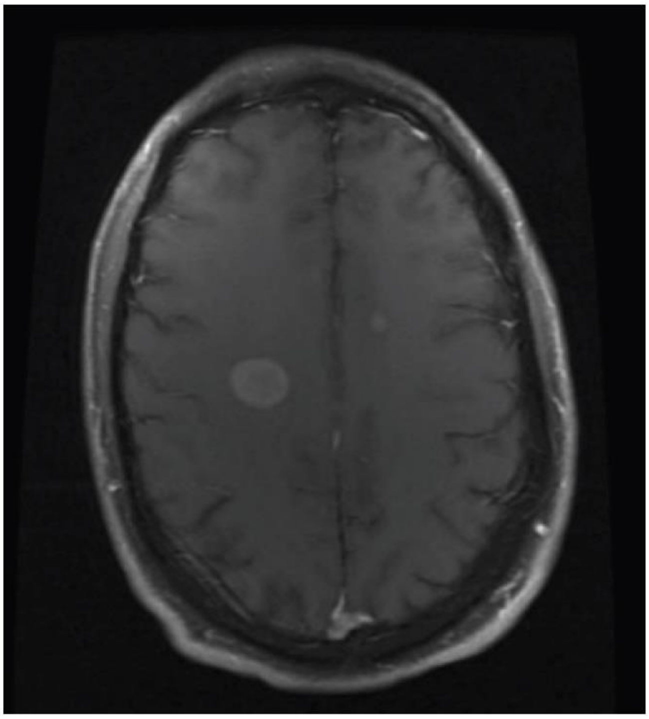
Answer 4 is associated with genital ulceration, but they are usually multiple, extremely painful and do not cause the systemic symptoms described in this question.

Question 222 of 277

A 45-year-old man presents to the emergency department with a 10-day history of progressively worsening headaches. Despite regular analgesia, the pain is not improving. He also complains of intermittent episodes of dizziness associated with nausea and vomiting. His past medical history includes human immunodeficiency virus for which he reports compliance with highly active antiretroviral therapy (HAART).

On examination, there is equal power and sensation in all 4 limbs. His cranial nerve and cerebellar examinations are unremarkable. Fundoscopic examination reveals bilateral papilloedema.

He is referred for neuroimaging, as shown below:



What is the most likely diagnosis?

A. CNS lymphoma
B. Cryptococcal meningitis
C. CMV encephalitis
D. Progressive multifocal leukoencephalopathy
E. Toxoplasmosis

A. CNS lymphoma

This patient's neuroimaging demonstrates 2 homogenous enhancing lesions; 1 larger lesion in the right hemisphere with 1 smaller lesion in the left hemisphere. Along with the history of worsening headaches associated with red-flag features (e.g. dizziness, vomiting), the presentation is in keeping with CNS lymphoma. CNS lymphoma accounts for up to 30% of cerebral lesions in patients with HIV and is associated with infection with the Ebstein-Barr virus. Like many cerebral lesions, presenting symptoms vary depending on the structures involved and include headache, nausea and vomiting, focal neurological signs and signs of raised intracranial pressure (e.g. papilloedema), as seen here.

Cryptococcus neoformans causes an opportunistic fungal infection that causes headache, fevers, confusion and signs of raised intracranial pressure. It is the most common fungal infection in patients with HIV. Imaging studies show leptomeningeal enhancement, cryptococcomas, hydrocephalus or dilated perivascular spaces. It does not account for lesions seen in this patient's MRI.

Cytomegalovirus (CMV) is a viral infection that commonly causes illness in patients with HIV, particularly in those with a CD4 count < 50 cells/mL. The most common form of CMV is CMV retinitis. However, CMV encephalitis is also common. On imaging, cerebral oedema may be seen. Meningoencephalitis and ventriculitis are also features of infection with CMV. These are not seen here, making CMV encephalitis unlikely.

Infection with JC virus is responsible for a condition known as progressive multifocal leukoencephalopathy, a demyelinating disease of the CNS. Symptoms include behavioural changes and alterations in speech, vision and movement. On imaging, single or multiple lesions may be seen, with demyelinating white matter lesions seen on MRI studies.

Toxoplasmosis is an opportunistic infection caused by the parasite *Toxoplasma gondii*. It is the most common cause of neurological brain abscesses in patients with HIV with symptoms including headache, fever and neurological changes including seizures, hemiplegia, cerebellar signs, or an acute confusional state. Domestic cats are a common source of transmission. Unlike CNS lymphoma, toxoplasmosis presents as ring-enhancing lesions on neuroimaging. These are not seen on this patient's scan, making it an unlikely diagnosis.

Question 223 of 277

A 45-year-old man presents to the Emergency Department. He told the admitting doctor that he had fallen onto his left hip last night while he had been drinking at home. He had extensive bruising around his hip and some bony tenderness which resulted in a hip x-ray being taken.

His x-ray shows no fracture nor bony abnormality, but several 2x4mm specs of calcification are visible in his psoas and thigh muscles.

Later on, his wife asks to speak to you in confidence. She states that over the last year her husband's personality has gradually changed and he is sometimes forgetful. He lost his job 3 months ago as an engineer. He had worked for 8 years in Peru on an engineering project in his thirties. He drinks 8 units of alcohol per day and seems to have had a low mood for several years.

Yesterday he had fallen, lost consciousness, and had a jerking of his arms and legs lasting 1 minute. He had hit his hip on a coffee table and had wet himself. Afterwards, he felt tired and lethargic but had refused to go to hospital.

What is the most likely diagnosis?

A. HIV dementia
B. Alcohol withdrawal seizure
C. Neurocysticercosis
D. Emboli secondary to calcified aortic value
E. Primary idiopathic epilepsy

C. Neurocysticercosis

This is neurocysticercosis. It is the most common cause of epilepsy worldwide. Eggs of the Taenia Solium tapeworm are ingested, oncospheres hatch and migrate to peripheral sites (classically muscles and brain) and become cysticerci. They may remain asymptomatic or cause inflammatory pathology when the cysticerci die. They eventually become calcified.

Diagnosis is made with MRI or CT imaging. Calcified cysts in skeletal muscle may be found incidentally on x-ray. Serology may be helpful.

Management is with praziquantel or albendazole and prednisolone.

Question 224 of 277

A 37-year-old man is referred to the medical outpatient clinic. He was born in Brazil but has been in the UK since university and now works in marketing.

He has been complaining of increasing breathlessness, worse on exertion, and is now breathless on climbing a flight of stairs. He has had several faints in the last few months, associated with feeling a 'funny' sensation in his chest, following which he blacks out. On one occasion he sustained a cut on his eye brow. There are no triggers to these episodes and there is a rapid recovery. He has never had any episodes of incontinence or tongue biting.

His past medical history is unremarkable. He was treated with several courses of antibiotics as a child in Brazil for an eye infection that persisted for several months. He has been seeing his GP for the past year for increasingly troublesome constipation. His medications are:

Senna 15mg at night

Movicol two sachets tds

On examination he has a displaced apex beat, normal heart sounds, and mild coarse crepitations at both lung bases.

What is the likely diagnosis?

A. Chagas disease
B. Endomyocardial fibrosis
C. Churg Strauss Syndrome
D. Hypertrophic Obstructive Cardiomyopathy
E. Vasovagal syncope

A. Chagas disease

This is Chagas disease caused by *Trypanosoma cruzi*. Keys is the question are presence of Romana's sign (periorbital swelling following inoculation of Trypanosome) as a child, and heart failure and constipation in later life.

Question 225 of 277

As the doctor on call you are called to review a 28-year-old male on the haematology ward. He recently underwent an allogenic stem cell transplant, which so far had been reasonably uncomplicated. Earlier in the week the patient had complained of coryzal symptoms and a dry cough. A nasopharyngeal aspirate (NPA) had been sent along with other routine tests 24 hours ago.

When you arrive to review the patient on the ward you note that he appears extremely sweaty. You take his temperature using a tympanic thermometer which reads 39.5ºC. His heart rate is 95 beats per minute and his respiratory rate is 16 breaths per minute. Blood pressure is 122/76 mmHg. Physical examination is unremarkable and chest X-ray reveals clear lung fields.

You review the patients most recent results:

Hb	95 g/l	Na +	134 mmol/l
Platelets	50 * 10 /l 9	K +	3.6 mmol/l
WBC	0.1 * 10 /l 9	Urea	3.0 mmol/l
Neuts	0.1 * 10 /l 9	Creatinine	65 µmol/l
Lymphs	0.0 * 10 /l 9	CRP	12 mg/l
Eosin	0.0 * 10 /l9		
NPA	Influenza A		

What is the most appropriate treatment to commence?

A. Amoxicillin
B. Oseltamivir
C. No treatment required
D. Flucloxacillin
E. Zanamivir

E. Zanamivir

In this case they key points to realise are that the patient is immunosuppressed (neutropaenic post transplant) with symptoms and PCR confirmed Influenza A infection.

Whilst in most cases, oseltamivir (a neuraminidase inhibitor) is first line treatment for influenza, the BNF advises that for severely immunocompromised individuals zanamivir should be first line treatment. This can help reduce the length of symptoms and prevent complications from developing during the course of the infection.

Question 226 of 277

A 44-year-old man presents with a 1 day history of fever. He returned to the UK 12 days ago after visiting his family in northern Uganda. He has been resident in the UK for the last 20 years and returns home on average once a year. He does not routinely take malaria prophylaxis.

On examination his temperature is 39.4ºC, pulse is 86 beats per minute, his blood pressure is 115/78 mmHg and his oxygen saturations are 98% on air. The remainder of the physical examination is normal. A thick and thin blood film are sent to the lab which confirms *Plasmodium falciparum* malaria. The report reads 2.1% parasitaemia with the presence of schizonts.

What is the most appropriate initial management strategy?

A. Intravenous artesunate
B. Oral quinine sulfate
C. Oral chloroquine
D. Oral atovaquone-proguanil (Malarone)
E. Intravenous quinine

A. Intravenous artesunate

This question examines your ability to differentiate severe malaria from uncomplicated malaria and then apply the correct therapy.

We are told the patient has been living in the UK for the last 20 years. As a result any natural immunity built up in earlier life would have dramatically reduced putting him at high risk of developing severe malaria with a relatively low level parasitaemia.

The most important information given is that schizonts are present in the blood film. Schizonts are the final step before red blood cells rupture and release more parasites (merozoites) into the blood.

Given his lack of immunity and an impending rise in parasitaemia it would be pertinent to consider this a case of severe malaria and treat accordingly with intravenous therapy early on. This excludes answers B, C and D. Furthermore chloroquine is only used routinely in the treatment of non falciparum malaria.

WHO guidelines recommend the use of intravenous artesunate for at least the first 24 hours until the patient can tolerate oral medication.

Question 227 of 277

A 30-year-old male refugee presents with fever, rigours and right flank pain. With the help of a translator you discover he has been unwell for 7 days with these symptoms that are getting progressively worse. He says he is otherwise fit and well and does not take any regular medications. He moved to the UK 2 months ago having lived his entire life in Sudan.

On examination he has a temperature of 38.2 degrees, a heart rate of 98 beats per minute, a blood pressure of 110/70 and a respiratory rate of 20. He is lying calmly in the bed but is tender over the renal angle on the right side.

Investigations:

serum sodium	138 mmol/L (137-144)
serum potassium	5.5 mmol/L (3.5-4.9)
serum creatinine	240 mol/L (60-110)
haemoglobin	98 g/L (130-180)
white cell count	15.4 Ã— 109/L (4.0-11.0)
eosinophil count	0.89 Ã— 109/L (0.04-0.40)

platelet count	378 Ã— 109/L (150-400)
urine microscopy	red cells 2+, white cells 3+, protein 2+
ultrasound scan of abdomen	right sided hydronephrosis and hydroureter, fibrotic and calcified bladder

What is the most likely underlying diagnosis?

A. Schistosomiasis japonicum
B. Chronic vesico-ureteric reflux and secondary pyelonephritis
C. Squamous cell carcinoma of the bladder
D. Schistosomiasis haematobium
E. Schistosomiasis mansoni

D. Schistosomiasis haematobium

The clinical picture here is of an acute pyelonephritis with fever, rigours and tenderness over the renal angle. However blood analysis and imaging suggest there is another entity at play that has predisposed the patient to this.

S. mansoni and *S japonicum*, *S. mekongi* and *S. intercalatum* produce eggs that can invade the

bowel wall causing an intense inflammatory reaction that gives rise to loose bloody stools. Eggs

can also migrate to liver through the portal venous system where they can elicit a granulomatous

fibrosing reaction. This can eventually lead to the blockade of venous blood and flow. Portal

venous hypertension results which can give rise to varicies and upper gastrointestinal bleeding.

S. haematobium on the other hand leads to granulomatous inflammation, ulceration of the vesicle

and ureteral walls. Subsequent fibrosis can cause bladder neck obstruction, hydroureter and

hydronephrosis. These changes can cause a chronic renal impairment and predispose to secondary

bacterial infection as well as squamous cell carcinoma.

In addition, all schistosome species can result in immune complex deposition in the kidneys leading to a proteinuria and nephrotic syndrome.

Question 228 of 277

A 42-year-old male from Bolivia presents with a 8 month history of progressive fatigue, dyspnoea and intermittent chest pains. He is a chronic smoker and during a recent severe episode of breathlessness had consulted his GP who prescribed amoxicillin and prednisolone to combine with his regular inhaler therapy. Shortly after this he experienced a febrile episode which had lasted 7 days before resolving. His breathlessness also worsened during this period.

On examination he has a temperature of 37.2 degrees, a heart rate of 98 beats per minute, a blood pressure of 110/70 mmHg and a respiratory rate of 24/min. His jugular venous pressure was raised, there was lower limb oedema to the mid shin and a pan systolic murmur heard best in inspiration in the left parasternal region. An ECG showed a prolonged PR interval.

What is the most likely underlying diagnosis?

A. Ischaemic heart disease
B. Chronic pulmonary emboli
C. Chronic Chagas cardiomyopathy
D. Sarcoidosis
E. HIV

C. Chronic Chagas cardiomyopathy

Teasing out the infective aetiology in this question is the key to finding the answer. Chagas disease can present as an acute illness or as a chronic disease years after infection and is caused by the parasite *Trypanosoma cruzi*.

Acute disease is usually asymptomatic but may manifest as a febrile episode in association with a swelling over the site of inoculation (if in the skin this is called a chagoma if through the conjunctiva of the eye this is known as Romanas sign). In severe cases an acute myocarditis can evolve with a secondary pericardial effusion.

Chronic disease begins to develop weeks or months after the initial inoculation and in some cases does not present until years after the infection (as in this case). Chronic disease can effect the heart causing a biventricular cardiomyopthy with predominant right sided features as well as varying degrees of heart block and conductive abnormalities due to fibrous inflammation around amastigotes embedded in the heart muscle. Chest pain can also be common and does not imply an ischaemic component. Chronic disease can also effect the bowel causing dilation.

The first clue in the case is that the patient is from an area where disease is endemic. Secondarily there is an absence of ischaemic related risk factors other than his smoking history and he is of a relatively young age. Perhaps the biggest clue of an infective cause is the febrile episode following steroids therapy. This likely represents a relapse of acute infection which is common with immunosupression. At this point you may be able to see trypomastigotes in the blood but they soon disappear on resolution of the fever.

Chronic PE is also a possibility given the predominance of right sided signs but does not explain the first degree heart block or fever following steroid therapy.

Question 229 of 277

A 50-year-old man presents to the Emergency Department after becoming increasingly unwell over the previous two weeks. His initial symptoms were fevers increasing shortness of breath. In the last 24 hours he had experienced several episodes of haemoptysis and bloody diarrhoea precipitating his attendance to hospital.

Past medical history included a diagnosis of systemic lupus erythematous five years previously. This disease had been poorly controlled in recent months requiring the patient to take prednisolone 40 mg daily and hydroxychloroquine 400 mg daily. The patient was originally from Mali and had emigrated to the UK twenty years previously. He had returned to visit family in Africa earlier in the year and had not taken malaria prophylaxis whilst abroad.

Initial assessment revealed the patient to be very unwell. Respiratory rate was 32 with O2 saturations of 94 % on high flow oxygen. Blood pressure was 80/50 mmHg with no improvement in hypotension following aggressive fluid resuscitation. The patient was intubated and ventilated and transferred to the Intensive Care Unit for inotropic support.

Results of immediate investigations are listed below.

Chest x-ray: widespread diffuse pulmonary infiltrates; left sided pleural effusion; no free air under the diaphragm

Abdominal x-ray: multiple loops of distended small bowel; no evidence of free air

Hb	11.2 g/dl
Mean cell volume	83 fL
Platelets	150 * 10 /l9
WBC	18.7 * 10 /l9
Neutrophils	14.8 * 10 /l9

Lymphocytes	2.0 * 10 /l9
Monocytes	1.0 * 10 /l9
Eosinophils	0.9 * 10 /l9
Blood film	no abnormality detected
Internationalised normalised ratio	1.2

Na +	124 mmol/l
K +	4.9 mmol/l
Urea	15 mmol/l
Creatinine	190 µmol/l

C-reactive protein	284 mg/dL

Blood cultures: Gram negative cocci (positive after 24 hours)

Pleural fluid microscopy: filariform larvae

What is the most likely underlying diagnosis?

A. Caecal carcinoma
B. Strongyloides hyperinfection syndrome
C. Churg-Strauss vasculitis
D. Plasmodium falciparum infection
E. Disseminated haematogenous tuberculosis

B. Strongyloides hyperinfection syndrome

Strongyloides hyperinfection syndrome occurs in immunosuppressed individuals with coexistent Strongyloides stercoralis infection. Uncontrolled proliferation of larvae occurs with dissemination to end organs.

As in this individual, systemic sepsis often occurs due to involvement of the gut wall allowing translocation of gut bacteria. Other features include pulmonary infiltrates, paralytic ileus, gastrointestinal bleeding and syndrome of inappropriate ADH secretion.

Filariform larvae can be found in body fluids by microscopy and it is this that confirms the diagnosis in this case. Due to immunosuppression, eosinophilia is often absent. Given the patient's country of origin, strongyloidosis is most likely to have been chronic, but could have been acquired on his recent trip to Africa.

Plasmodium falciparum infection can cause a similar presentation, although the normal blood film in this case makes this unlikely. Severe tuberculosis infection tends to predominantly involve the lungs with a varying degree of involvement of other organ systems.

Churg-Strauss vasculitis can cause severe abdominal symptoms including infarction and perforation. However, the normal eosinophil count, short history and immunosuppresion do not support this diagnosis.

Colonic carcinoma can lead to translocation of gut bacteria and gram-negative sepsis. However, this diagnosis would not explain all of the findings in this case and is not supported by the normal mean cell volume.

Question 230 of 277

A 23-year-old woman is admitted to the hospital with acute-onset fever, neck stiffness, headache and photophobia. She has no significant past medical history. A CT scan of the head is normal. The patient subsequently undergoes a lumbar puncture which confirms a diagnosis of bacterial meningitis.

She lives with a group of flatmates, including her partner, with whom she has had close contact up until 2 days ago. The patient visited her parents' house and had close contact with them 9 days ago; she visited her grandparents' house 16 days ago and had close contact with them.

What is the most appropriate next step?

A. No prophylaxis required for contacts
B. Prophylaxis required for all flatmates
C. Prophylaxis required for all flatmates and parents
D. Prophylaxis required for flatmates, parents and grandparents
E. Prophylaxis required for partner only

B. Prophylaxis required for all flatmates

People who have been exposed to a patient with confirmed bacterial meningitis should be given prophylactic antibiotics if they have close contact within the seven days before onset

Guidance around meningitis prophylaxis is quite clear. Prophylaxis should be offered to household members and those in close contact within the past 7 days. As such, it should be **given to all flatmates** as they have been in close contact up until 2 days prior. Oral ciprofloxacin or rifampicin may be used. Ciprofloxacin is now the drug of choice.

Advising **no prophylaxis** is therefore incorrect.

Similarly, advising **both flatmates and parents** to have prophylaxis is incorrect. Whilst the flatmates should be offered prophylaxis, the parents last had contact over 7 days ago.

Prophylaxis for **flatmates, parents and grandparents** is unwarranted. The parents and grandparents last had contact with the patient more than 7 days ago and so it is not needed for them.

Only advising the partner to have prophylactic antibiotics is incorrect. The entire household has had close contact with her and so all flatmates, not just her partner, should be offered them.

Question 231 of 277

A 35-year-old ex intravenous drug user has been diagnosed with has HBe-Ag positive Hepatitis B. Her investigation results are shown below:

HBV DNA	2100 IU/ml
ALT	60 IU/L

ALT last checked 3 months ago and found to be ALT 60 IU/L.

What is the recommended first line treatment for this patient?

A. Tenofovir disoproxil
B. Entecavir
C. Peginterferon alfa-2a
D. Telbivudine
E. Sofosbuvir

C. Peginterferon alfa-2a

The correct answer here is Peginterferon alfa-2a.

In patients who do not undergo HBeAg seroconversion or who relapse, tenofovir disoproxil is second line. Entecavir is an alternative second line when patients are unable to tolerate tenofovir disoproxil. Telbivudine is no longer recommended for the treatment of chronic Hepatitis B. Sofosbuvir is used for treating hepatitis C.

Question 232 of 277

A 32-year-old lady presented after returning from Nigeria 3 weeks ago to her GP complaining of feeling feverish and pain in her joints making walking difficult. She denied any rash, or headaches however she has been very drowsy and lethargic in the past week. She spent a week in Nigeria and visited her relatives both in urban and rural areas. She has been taking her malaria prophylaxis tablets. She denies being sexually active for the past year. Her GP sent off three malaria screens which were negative.

Two months later she represents to the emergency department following a seizure and is found to be confused and disorientated. She is irritable, and you notice her hand is trembling. Her sister says she has lost her appetite and weight and has been behaving strangely in the past month. She spends most of her time in bed during the day complaining of a headache and has become withdrawn. On examination, there is hypertonia in her limbs, with hyperreflexia, but the rest of

examination is difficult as she is uncooperative. Investigations:

Na+	140mmol/l
K+	4.3 mmol/l
Urea	5.3 mmol/l
Creatinine	85 µmol/l
Serum bilirubin	15 µmol/l
Serum alkaline phosphatase	85 IU/l
Serum aspartate aminotransferase	19 IU/l
Serum Albumin	25 g/l
C Reactive protein (CRP)	25 mg/l
Erythrocyte Sedimentation Rate (ESR)	75 mm/hr
Haemoglobin	96 g/l
White cell count	10.2 x 10^9/L
Neutrophils	8.9 x 10^9/L
Eosinophilia	0.1 x10^9/L
Lymphocytes	1.8 x 10^9/L
Platelets	140 x 10^9/L
INR	1.0

What is the likely causative organism?

A. Plasmodium vivax
B. Borrelia burgdorferi
C. Trypanosoma gambiense
D. Trypanosoma rhodesiense
E. Trypanosoma cruzi

C. Trypanosoma gambiense

This lady of African background presents initially with fever after travelling from Nigeria and goes on to develop chronic symptoms of daytime somnolence, continuous headaches and behavioural changes. These symptoms suggest African Sleeping Sickness or African Trypanosomiasis. *Trypanosoma gambiense* is more common than *Trypanosoma rhodesiense* in patients from West Africa, such as Nigeria.

Early stages of the disease tends to present about 3 weeks after being bitten by an infected tsetse fly. Symptoms include fevers, arthralgia, lethargy, drowsiness. Late stages include behavioural and mood changes, headache and the pathognomonic daytime somnolence with nocturnal insomnia.

Borrelia burgdorferi is transmitted by ticks (Ixodes spp.) and causes Lyme disease. They occur in the USA, northern and central European countries, and temperate forested areas of Asia.

Plasmodium vivax is one species of Plasmodium, the parasite that causes malaria. It is spread by infected mosquitoes. It is an important differential of fever in the returning traveller, however as the initial malaria screens were negative, and the central nervous system symptoms in the late stages are not consistent with a malarial infection.

Trypanosoma cruzi is responsible for American Trypanosomiasis (or Chagas' disease). It is transmitted by contamination with infected faeces of assassin bugs (reduviid bugs). It is found in South America and the south USA. Chronic infection can lead to chronic congestive heart failure, megaoesophagus and megacolon.

Question 233 of 277

A 42-year-old immigrant from Nigeria has been referred to the infectious disease clinic. He was feeling tired and generally unwell over several weeks since last visiting Nigeria, his country of origin. He has also travelled for business to the United States six months ago. He has had fever and rigors as well as headaches. Posterior lymph nodes have been present and have been aspirated one week ago, and trypomastigotes were present.

What is the most likely causative organism?

A. Trypanosoma rhodesiense
B. Trypanosoma gambiense
C. Trypanosoma cruzi
D. Leishmania mexicana
E. Leishmania tropica

B. Trypanosoma gambiense

The correct answer is Trypanosoma gambiense. This is a patient with a clinical history suggestive of African trypanosomiasis with a slow wasting course. The presence of trypomastigotes means that there will be a Trypanosoma infection. The species can be determined by geography. Rhodesiense occurs in east Africa whilst gambiense occurs in west Africa, including Nigeria. Uganda is the only country with both. Cruzi is endemic in South America and causes American trypanosomiasis. Leishmania are other protozoa occurring in Africa, South America and India.

Question 234 of 277

A 23-year-old gentleman presents to GUM clinic. He has been referred by his GP as he presented with dysuria and a negative urine dipstick test. A sexual health screen, including blood tests for HIV and syphilis serology, are requested.

What form of consent is required?

A. No consent
B. Implied consent
C. Verbal consent
D. Written consent
E. Written consent for HIV testing and verbal consent for sexual health screening

C. Verbal consent

The correct answer is verbal consent. Consent clearly is needed as an investigation is done but since syphilis and HIV are transmittable diseases consent needs to be specific towards each. This means that the patient must be aware that they are being tested for HIV and syphilis rather than just aware that they are having a routine blood test. Written consent is not needed, and may discourage patients from having testing.

Question 235 of 277

A 30-year-old man returns from a stag do in Amsterdam with fever, headache and abdominal pain. He was away for 2 days and drunk 40-50 units of alcohol. He also had unprotected sex with a local girl and vaguely remembers falling in the canal on the second night. He is febrile with a blood pressure 100/70 mmHg. His bloods tests reveal :

Routine tests in the emergency department are ordered: Hb 95 g/l WBC 20 10 /l , Platelets 150 10 /l Na 135 mmol/l , K 5.0 mmol/l

Urea 15 mmol/l , Creatinine 300 µmol/l Bilirubin 35 µmol/l , ALP 200 u/l , ALT 70 u/l CXR - pulmonary haemorrhage

What is the most likely diagnosis?

A. Acute hepatitis A
B. Acute hepatitis B
C. Goodpastures syndrome
D. Leptospirosis
E. Atypical pneumonia

D. Leptospirosis

This gentleman should be screened for viral hepatitis and have an HIV test, however given the results of his investigations infection with Leptospira from falling in the contaminated water is the most likely diagnosis. The acuity and neutrophilia go against Goodpasture's syndrome and an atypical pneumonia would not classically cause pulmonary haemorrhage.

Question 236 of 277

A 68-year-old female was admitted to the ward with left arm cellulitis. She was septic on admission and the sepsis 6 bundle was completed in one hour. She is treated with IV flucloxacillin initially and was switched to oral flucloxacillin on day 2. On day 3 of admission you receive a call from the duty microbiologist with the following results:

Anaerobic blood culture bottle	Positive for *Staphylococcus aureus*
Aerobic blood culture bottle	Positive for *Staphylococcus aureus*

How will you manage this patient?

A. IV vancomycin
B. Oral linezolid
C. IV flucloxacillin for two weeks
D. Oral flucloxacillin for two weeks
E. Oral flucloxacillin for one week

C. IV flucloxacillin for two weeks

Staphylococcus aureus bacteraemia (SAB) is a serious condition which may occur secondary to soft tissue, joint, bone, indwelling IV line or cardiac infection. It is treated with a minimum of two weeks IV flucloxacillin

Staphylococcus aureus bacteraemia (SAB) is a serious condition with significant morbidity and mortality. SAB is generally caused by soft tissue, joint, bone, indwelling IV line or cardiac infections. Once the bacteria has entered the bloodstream, they are particularly effective at infecting various organs, potentially causing infective endocarditis, septic arthritis, discitis, and osteomyelitis.

Treatment is with intravenous high dose (2 grams) flucloxacillin for a minimum of two weeks. An MRSA risk assessment should be performed. If the patient is at high risk of MRSA then they should be treated with vancomycin instead.

It is important to look for sources of infection and to consider investigating for sequelae (e.g. transthoracic echo to assess for endocarditis).

Question 237 of 277

A 34-year-old female attended the emergency department with a rash. Her past medical history was unremarkable apart from being on the oral contraceptive pill. She had been recovering from a widespread, pruritic, vesicular rash over the past 8 days after coming into contact with her nephew with chickenpox. Yesterday she began to feel lethargic and unwell, with a high temperature and a painful left calf. This morning she had noticed an area of erythema on her lower leg which seemed to get larger and more painful throughout the day.

On examination, she looked unwell. There were healed varicella scars and a few crusted scabs present over her lower limbs and torso. There was a diffuse erythematous rash extending from her mid-calf to her ankle. The area was oedematous and very tender. She had a normal range of movement in all joints of the leg, albeit limited by pain.

Her observations were as follows:

- temperature 39.7ºC
- respiratory rate 24/min
- blood pressure 91/55mmHg
- heart rate 112bpm
- oxygen saturations 98% on room air

Her blood results were as follows:

Hb	109 g/L	115 - 160
WBC	20 * 10 /L 9	(4.0 - 11.0)
CRP	208 mg/L	(< 5)

She was started on intravenous fluids and given analgesia. Her IV morphine was titrated up to control her pain and she was started on broad-spectrum antibiotics.

The following morning she remained tachypnoeic and tachycardic. The area of erythema now extended proximally to 2cm below her knee. A small area of dark purple-black discolouration was present at the distal aspect of the rash.

What is the next most appropriate step in management?

A. IV aciclovir
B. Plasmapheresis
C. MRI lower leg
D. Surgical debridement
E. Treatment dose low molecular weight heparin

D. Surgical debridement

Chickenpox is a risk factor for invasive group A streptococcal soft tissue infections including necrotizing fasciitis

This is a case of bacterial superinfection complicating acute varicella infection. The systemic involvement and rapid spread of cellulitis despite broad-spectrum antibiotics should alert you to the possible diagnosis of necrotising fasciitis. Whilst the most common type of necrotising fasciitis is type 1 (caused by polymicrobial infection), most cases of post-varicella necrotising fasciitis are caused by a monomicrobial infection by group A streptococcus (e.g. *Streptococcus pyogenes*).

Bacteria are introduced into the skin via skin trauma (in this case, the varicella skin lesions formed a portal of entry) and track along fascial planes, extending beyond the area of overlying cellulitis.

The definite management of necrotising fasciitis is surgical debridement of all infected tissue. As the infection progresses, necrosis and hypoperfusion of the area limit the delivery of antibiotics to the area. Without debridement, mortality is 100% and any delay increases the risk of death.

Whilst IV aciclovir is important in the treatment of acute varicella infection, the most important next step is to remove the source of the bacterial infection. Chickenpox has contributed to this presentation but is not the cause of her acute deterioration or necrotic skin.

Whilst MRI can confirm the extent of necrotising fasciitis, it may delay surgical debridement. This patient is clearly unwell and needs immediate definitive management.

Treatment dose low molecular weight heparin would be appropriate if the cause was a deep vein thrombosis but this presentation is more in keeping with a rapidly progressive bacterial infection.

Plasmapheresis does not have a role in the management of necrotising fasciitis.

Question 238 of 277

A 27-year-old male presents with high-grade fever and vomiting for 8 days. He recently went to Africa for a jungle safari with a group of friends and began feeling unwell whilst he was there. During the trip, he spent most of the time camping outdoors. He does not have any history of fits or loss of consciousness, although he has been feeling drowsy and complains of generalised malaise. He also has pain in his wrist and shoulder joints but they are not swollen. He takes alcohol regularly and smokes cannabis socially.

On examination, he has a fever of 39°C and a pulse of 135bpm. His blood pressure is 100/70mmHg. He is icteric but does not have any flapping tremors. There is evidence of an enlarged spleen which is palpable 3 finger breadths below the left costal margin. The liver span is normal.

Lab reports reveal:

Hb	115 g/l
Platelets	100 * 10 /l9
WBC	9.5 * 10 /l9
Reticulocytes	5% (0.2 - 2%)

Na +	140 mmol/l
K +	4.6 mmol/l
Urea	5.1 mmol/l
Creatinine	83 µmol/l

Bilirubin	49 µmol/l
AST	50 u/l
ALT	25 u/l
Glucose	6.0 mmol/l

CT scan brain: Normal CSF examination reveals:

Appearance	Clear
Protein	0.3 g/L (0.2 0.4 g/L)
Glucose	5.3 mmol/l
Lymphocytes	$15/mm^3$

Neutrophils	10

Which of the following is the most appropriate treatment option?

A. Chloroquine
B. Artemether/lumefantrine
C. Primaquine
D. IV acyclovir
E. Co-trimoxazole

B. Artemether/lumefantrine

The high-grade fever, history of travel to an endemic area, splenomegaly, thrombocytopaenia, evidence of haemolysis (raised bilirubin and reticulocytosis) and normal blood leucocyte count all favour a diagnosis of cerebral malaria

The treatment modality most suited would be a combination of artemether and lumefantrine which would provide adequate coverage from plasmodium falciparum.

Diagnosis is through examination of blood films (thick and thin films) for evidence of parasitaemia and the ICT-MP.

The CSF findings are non-specific with the only abnormality being a mild lymphocytosis which is of no bearing on the scenario. It, however, rules out bacterial or tuberculous meningitis.

The mildly raised AST is in keeping with his history of alcohol intake.

Question 239 of 277

A 38-year-old woman presents to her HIV clinic for her 6-monthly review having had her routine blood tests two weeks prior to her clinic visit. She has diagnosed with HIV seven years ago and has been stable on antiretroviral therapy since then. Her other medical problems include asthma which is well controlled. She reports generally good compliance with her medications but has unfortunately missed two of her treatment doses as she was on a weekend holiday and forgot to take her tablets with her. She feels well in herself.

Blood tests:

Today	Two weeks ago	One year ago	
HIV viral load	110 copies/ml	<50 copies/ml	<50 copies/ml
CD4 count	983 cells/mm^3	912 cells/mm^3	Not tested

How should she be further investigated?

A. Urgent CD4 count
B. Urgent viral resistance testing
C. Urgent HIV-1 and HIV-2 serology
D. Repeat viral load in one month
E. Routine viral load and CD4 count in six months

D. Repeat viral load in one month

The question describes a possible viral blip, a single viral load that is detectable but less than 200 copies/ml. This is a common feature in chronic HIV management and does not imply failure of treatment. However, good compliance should be reinforced and viral load should be repeated within one month so exclude virological failure or rebound. A CD4 count would not be reassuring in this circumstance as if normal there could still be a rebound happening. Serology only aids diagnosis. Viral resistance testing is useful in order to determine the cause of virological failure. Routine monitoring is not appropriate as a viral rebound will need to be excluded.

HIV monitoring

HIV, once stable, should be monitored with a viral load every six months and CD4 counts annually at least once virological suppression, defined as sustained viral load less than <50 copies/ml, is established. If the viral load increases to between 50-200 copies/ml on a single sample this is defined as a viral blip and is unlikely to be significant, but a viral load should be re-tested within one month. If a viral load above >200 copies/ml is sustained this is a virological rebound and can imply failure. This can be due to new viral resistance, and, if suspected, would need resistance testing.

Question 240 of 277

A 15-year-old male is investigated following a one week history of fever, non-productive cough, sore throat and headaches. Today he noticed a skin rash. His temperature is 38.5ºC, pulse is 90/min, blood pressure is 115/78 mmHg and respirations are 16/min.

On examination his throat is hyperaemic, but there is no cervical lymphadenopathy. Chest auscultation and percussion reveal no abnormalities. You note dusky red, target shaped skin lesions over all four extremities. Chest x-ray reveals interstitial infiltrates in the left lower lobe. Sputum Gram stain reveals polymorphonuclear cells but no organisms.

Which of the following organisms is most likely responsible for this presentation?

A. Streptococcus pneumoniae
B. Haemophilus influenzae
C. Legionella pneumophila
D. Mycoplasma pneumoniae
E. Epstein Barr virus

D. Mycoplasma pneumoniae

Stereotypical history of mycoplasma pneumonia: worsening flu-like symptoms and a dry cough. Erythema multiforme is noted on examination

This young man presents with a history suggestive of atypical pneumonia. Atypical pneumonia is distinguished from typical pneumonia by its more indolent course, non-productive cough and higher incidence of extra-pulmonary symptoms. This patients low grade fever and weeks worth of symptoms are consistent with an indolent course. Furthermore, he has multiple extra-pulmonary symptoms including headache, sore throat and skin rash. The different types of atypical pneumonia can present similarly and are at times challenging to distinguish. In this case, the skin rash (erythema multiforme) is typical of *Mycoplasma*. *Mycoplasma* is an organism that does not have a cell wall, and therefore does not stain with Gram stain; hence the finding of only polymorphonuclear cells on sputum Gram stain analysis.

Choice 1: *Pneumococcus* is the most frequent cause of community-acquired pneumonia requiring hospitalisation. Cough is often productive of rusty-coloured sputum. Compared to atypical pneumonias, pneumococcal pneumonia causes fewer extra-pulmonary manifestations but has a more virulent course. Sputum Gram stain would revel Gram positive diplococci.

Choice 2: *Haemophilus influenzae* is another common cause of community-acquired pneumonia. It presents like a typical pneumonia. Sputum Gram stain reveals small Gram negative bacilli.

Choice 3: *Legionella pneumophila* causes pneumonia with extra-pulmonary symptoms. Environmental water sources are often involved in its spread. It occurs most frequently in elderly patients and smokers. The urine *Legionella antigen* test is helpful in making the diagnosis.

Choice 5: Epstein Barr virus causes infectious mononucleosis, common in adolescents. Sore throat is the most common presenting symptom. Fatigue, malaise, headache and abdominal pain are also common. Concomitant pneumonia is not usually seen.

Question 241 of 277

A 24-year-old man attends the sexual health clinic complaining of urethral discharge and dysuria following an episode of unprotected intercourse. Examination of the external genitalia confirms purulent discharge but no other abnormalities. There is no previous history of sexually transmitted infection.

You undertake microscopy of the discharge which reveals many white blood cells but no organisms. A urine sample is sent for nucleic acid amplification tests (NAAT) for *Chlamydia trachomatis* and *Neisseria gonorrhoea*. You treat him empirically with a course of doxycycline for presumed chlamydial infection.

He returns for review a week later. You note both NAAT results to be negative. However, the patient tells you his symptoms have fully resolved.

What is the most likely explanation?

A. Mycoplasma genitalium infection
B. False negative NAAT for Chlamydia trachomatis
C. False negative NAAT for Neisseria gonorrhoea
D. Herpes simplex virus infection
E. Urinary tract infection

A. Mycoplasma genitalium infection

Urethritis in a male, negative for Gonorrhoea and Chlamydia →?Mycoplasma genitalium

The correct answer is ***Mycoplasma genitalium* infection**. This has emerged as the leading cause of non-gonococcal urethritis (NGU). Urethritis is evidenced in this case by the symptoms of dysuria and discharge combined with the presence of white cells in the discharge. NGU is diagnosed when features of urethritis exist in the absence of a positive test for gonorrhoea. Other explanations include infection with *Chlamydia* or organisms such as *Ureaplasma urealyticum*.

False negative NAAT for *Chlamydia trachomatis* is incorrect. Although improvement with doxycycline would fit with *Chlamydia*, the sensitivity of NAATs reaches 97% in some studies, making this a less likely explanation.

False negative NAAT for *Neisseria gonorrhoea* is incorrect. The sensitivity of NAATs for gonorrhoea reaches 98-99% in some studies. We would also not expect a symptomatic improvement with doxycycline.

Herpes simplex virus infection is incorrect. HSV most commonly presents with painful genital ulceration. Less commonly, patients may present with dysuria and discharge in the absence of visible ulceration. However, we are told this patient has had no previous STIs. The first episode of genital HSV is often severe and prolonged in the absence of anti-viral treatment and the spontaneous improvement in 7 days described here would be unusual. Subsequent recurrences are often less severe and more short-lived.

Urinary tract infection is incorrect. Urinary tract infection frequently causes dysuria but urethral discharge would be an unusual feature. It is also very unusual to see urinary tract infections in young males in the absence of a structural abnormality of the urinary tract or an iatrogenic cause such as catheterisation.

Question 242 of 277

A 28-year-old woman presents to the genitourinary medicine clinic with four days of dysuria and vaginal discharge. She has no past medical history and is on no regular medications. She had unprotected sexual intercourse with a casual partner two weeks previously.

Speculum examination revealed cervicitis and clear vaginal discharge. Examination of the genitalia was otherwise unremarkable.

A nucleic acid amplification test demonstrates the culprit organism.

Based on the clinical history, the patient is prescribed doxycycline and makes a full recovery.

Which organism is likely to be responsible for the clinical presentation?

A. Trichomonas vaginalis
B. Candida albicans
C. Chlamydia trachomatis
D. Gardnerella vaginalis
E. Neisseria gonorrhoeae

C. Chlamydia trachomatis

Chlamydia - treat with doxycycline

Chlamydia trachomatis is the correct answer. This sexually transmitted infection can either be asymptomatic or may present with dysuria, cervicitis and a clear vaginal discharge. It is diagnosed by a nucleic acid amplification test. The first line antibiotic is doxycycline.

Trichomonas vaginalis is incorrect. This can cause dysuria and cervicitis and is also diagnosed by a nucleic acid amplification test.. However, the discharge tends to be green-ish and the treatment is with metronidazole.

Candida albicans is incorrect. The clinical picture in this case tends to be a creamy, itchy discharge. It is a fungal infection and is treated with topical or oral anti-fungal agents.

Gardnerella vaginalis is incorrect. This is a typical cause of bacterial vaginosis. A 'fishy' odour is commonly described in this disorder and the treatment is with metronidazole.

Neisseria gonorrhoeae is incorrect. This shares many of the same symptoms as *Chlamydia trachomatis* and can also be diagnosed via a nucleic acid amplification test. However, the treatment is with ceftriaxone.

Question 243 of 277

A 28-year-old male presents to the emergency department complaining of an 8-day history of red eyes, fever, myalgia and headache. He has no significant past medical history and is on no regular medications. He has recently returned from a holiday with friends where they were kayaking and swimming in a freshwater lake. They had to abandon their trip earlier than expected as there was concerns about exposure to raw sewage in the lake.

His observations are heart rate 87 beats per minute, blood pressure 111/56 mmHg, respiratory rate 19/minute, oxygen saturation 96% on air and temperature 38.3ºC.

On examination, there is bilateral erythema of the conjunctiva. Cardiovascular and respiratory examinations are unremarkable. Abdominal examination reveals mild right upper quadrant tenderness and hepatomegaly. There is no photophobia or nuchal rigidity.

Urinalysis is unremarkable.

Plain radiography of the chest demonstrates clear lung fields.

Blood tests:

Hb	141 g/L	Male: (135-180)Female: (115 - 160)
Platelets	414 * 10 /L 9	(150 - 400)
WBC	11.8 * 10 /L 9	(4.0 - 11.0)
Na +	141 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	141 µmol/L	(55 - 120)
CRP	68 mg/L	(< 5)
Bilirubin	38 µmol/L	(3 - 17)
ALP	167 u/L	(30 - 100)
ALT	190 u/L	(3 - 40)
Î³GT	111 u/L	(8 - 60)
Albumin	34 g/L	(35 - 50)

Given the clinical context, what is the most appropriate investigation to make the diagnosis?

A. Blood culture
B. Urine polymerase chain reaction (PCR)
C. Serology
D. Urinary antigens
E. Urine culture

C. Serology

Serology is the most commonly used test for the diagnosis of leptospirosis, however, antibodies may not be present until after 7 days

Serological testing is the correct answer. The diagnosis is leptospirosis, as evidenced by a history of fever, myalgia, headache and subconjunctival haemorrhage in association with hepatorenal failure in a patient with a potential geographic exposure to infected urine (freshwater exposure). The most commonly used test to diagnose leptospirosis is serological testing for IgM antibodies to leptospirosis. The disadvantages with this method of investigation are false positives, the inability for the test to diagnose early infection and the fact that antibodies can persist in the sera for months after initial infection, making interpretation of timing of infection difficult in cases of diagnostic uncertainty. Antibodies are not usually present until the infection has been present for seven days. In this case, the patient has presented with eight days of symptoms and therefore antibody testing should be positive.

Blood culture is the wrong answer. Culture testing for leptospirosis can take up to three months and is therefore predominantly used for retrospective diagnosis.

Urine polymerase chain reaction (PCR) testing is incorrect. While this technique is effective in identifying leptospira infection, it is not as commonly used as serological testing as its use is precluded by cost and technical factors in non-reference laboratories.

Urinary antigen testing is incorrect. This is used to diagnose pneumococcal and legionella pneumonia infections. The clinical history is not suggestive of a pneumonia.

Urine culture is incorrect. The use of this method of testing is precluded by the fact that cultures may take 8-12 weeks to form.

Question 244 of 277

A 34-year-old man is referred to the medical admissions unit with joint pain and swelling in his hands and feet. One month prior to his attendance, he had developed an illness while travelling in Colombia, which was characterized by fever, headache, rash and debilitating polyarthralgia. His treating physicians noted mild hepatomegaly at the time. He recovered well from this episode without intervention, except for his ongoing musculoskeletal symptoms.

Examination reveals a small joint polyarthritis of the hands and feet. Abdominal examination was unremarkable.

Serological testing is positive for an RNA virus.

What is the likely diagnosis?

A. Chikungunya virus
B. Dengue
C. Epstein Barr Virus (EBV)
D. Parvovirus
E. Zika virus

A. Chikungunya virus

Chikungunya can present with debilitating joint pain

Chikungunya is the correct answer. This is an RNA alpha-virus characterized by sudden onset fever accompanied by skin rashes and joint pain followed by persistent rheumatic symptoms. In contrast to the other diagnoses, which can all cause headache, fever and rash, the polyarthralgia is said to be far more debilitating and it is most associated with the development of persistent musculoskeletal symptoms. Furthermore, hepatomegaly can be a feature of this condition but this is not seen in Zika or dengue. While hepatomegaly is a feature of EBV, this is a DNA virus and is less likely to cause persistent musculoskeletal symptoms.

Zika virus is characterized by a pruritic maculopapular rash accompanied by other symptoms such as fever, headache, conjunctivitis, myalgia and arthralgia. It is an RNA virus but is much less likely to cause persistent musculoskeletal symptoms.

Dengue is incorrect. This is another RNA arbovirus that causes fever, rash and arthralgia in addition to other features such as thrombocytopenia. However, hepatomegaly is not a feature and it is not associated with the development of persistent arthritis.

Epstein Barr Virus (EBV) is incorrect. This is a DNA virus. Musculoskeletal manifestations are less prominent.

Parvovirus is incorrect. This can cause rash, hepatomegaly and polyarthritis but it is a DNA virus.

Question 245 of 277

A 38-year-old farmer is admitted to the acute medical unit with a 2-week history of fever and dry cough. He describes feeling increasingly more lethargic with generalised body aches and headaches. He has no past medical history of note and takes no regular medications.

On auscultation, there are scattered crackles. His cardiovascular examination is unremarkable. There is mild tenderness in the right upper quadrant, but his abdomen remains soft with no palpable organomegaly.

Laboratory tests:

Hb	139 g/L	(135-180)
Platelets	499 * 10 /L $_9$	(150 - 400)
WBC	16.1 * 10 /L $_9$	(4.0 - 11.0)
Na$^+$	144 mmol/L	(135 - 145)
K$^+$	4.6 mmol/L	(3.5 - 5.0)
Urea	6.1 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
Bilirubin	15 µmol/L	(3 - 17)
ALP	80 u/L	(30 - 100)
ALT	120 u/L	(3 - 40)
CRP	199 mg/L	(< 5)

What is the most likely causative organism for this patient's presentation?

A. Brucella melitensis
B. Coxiella burnetii
C. Mycoplasma pneumoniae
D. Staphylococcus aureus
E. Streptococcus pneumoniae

B. Coxiella burnetii

Coxiella burnetii is a cause of atypical pneumonia and Q fever. It is usually transmitted by infected cattle or sheep

This patient has an infection with ***Coxiella burnetii*** a zoonotic disease more commonly seen in those who work with animals such as farmers and veterinarians. Infection gives rise to Q fever that can present with a variety of symptoms ranging from fever, malaise and myalgia to atypical pneumonia or infective endocarditis. Auscultatory crackles and a dry cough with fever and fatigue are suggestive of atypical pneumonia. Furthermore, *Coxiella burnetii* can cause transaminitis as demonstrated by this patient's deranged liver function tests.

Brucella melitensis is another zoonotic disease secondary to close contact with infected animals or from ingestion of unpasteurised milk or undercooked meat. It is more common in the Middle East, farmers, vets, and abattoir workers. Symptoms include fever and malaise, as seen here. However, features of pneumonia are not common in Brucellosis making it a less likely diagnosis.

A ***Mycoplasma pneumoniae*** infection commonly presents with a preceding phase of flu-like symptoms before the onset of respiratory symptoms including shortness of breath and productive cough. Extra-pulmonary symptoms are common in patients with *Mycoplasma pneumoniae* and include erythema multiforme and haemolytic anaemia. The absence of these extra-pulmonary symptoms and the occupational history as a farmer make the diagnosis of Q fever more likely.

Staphylococcus aureus is a common cause of pneumonia in patients following infection with the influenza virus. Although this patient gives an initial history of flu-like symptoms, it does not explain his transaminitis and suggests an alternative diagnosis is more likely.

Streptococcus pneumoniae is the most common bacterial cause of community-acquired pneumonia. However, it does not explain this patient's transaminitis or prodrome of fever and myalgia. Furthermore, an occupational history as a farmer makes alternative zoonotic diseases, such as Q fever, more likely.

Question 246 of 277

A 49-year-old man is admitted to the acute medical unit with a 2-week history of pain and difficulty when swallowing. He reports having lost approximately 2-3kg in weight from reduced oral intake. His past medical history includes previous hospital admissions for lower respiratory tract infections and lower limb deep vein thrombosis.

On examination, he appears cachectic. There are multiple, well-defined white plaques over the oral mucosa. His abdomen is soft and non-tender with no palpable masses.

F. CD4 count	G. < 100 cells/mm^3

What is the most appropriate management for this patient?

A. Aciclovir
B. Caspofungin
C. Co-amoxiclav and metronidazole
D. Fluconazole
E. Nystatin and chlorhexidine mouthwash

D. Fluconazole

Candidiasis in immunocompromised patients should be treated using high dose fluconazole

This patient has a diagnosis of oesophageal candidiasis given the classical history of painful swallowing and visible white mucosal plaques on examination. It is particularly more common in immunocompromised individuals (e.g. such as patients with HIV). The treatment of choice for treating candidiasis in immunocompromised patients is with high-dose **fluconazole** or itraconazole.

Aciclovir is used to treat viral infections, including herpes simplex and herpes zoster. Typically viral rashes such as herpes simplex present with ulceration or vesicles. The presence of a white mucosal coating in an immunocompromised patient is highly suggestive of candidiasis, for which antifungal medication is needed, rather than antivirals like aciclovir.

Caspofungin is not a first-line treatment for oesophageal candidiasis. It is reserved for cases of refractory disease that do not respond to initial treatment with fluconazole. As first-line therapy has not yet been initiated, it would be inappropriate to start the patient on more invasive treatment such as caspofungin.

Co-amoxiclav and metronidazole would be indicated if there were concerns that this patient was suffering from a bacterial infection. However, the classical history of odynophagia and white mucosal coating in an immunocompromised patient makes candidiasis much more likely to be the diagnosis.

Nystatin and chlorhexidine mouthwash would normally form part of the initial management in immunocompetent patients. However, this patient has a CD4 count of < 100 cells/mm^3 suggesting significant immunocompromise. Therefore, stronger treatment such as high-dose fluconazole is needed.

Question 247 of 277

A 55 year old man attended his General Practitioner to complain of on-going fatigue and lethargy over recent months. He reported experiencing recurrent minor infections meaning that he had rarely been feeling well for any significant length of time. His GP records supported this story with the patient having been prescribed courses of antibiotics for a leg cellulitis, suppurative otitis media and sinusitis (twice) over the past 9 months. The patient reported a good appetite and no recent weight loss, fevers or night sweats. He denied any symptoms of arthritis, skin rashes, photophobia or dry eyes. There were no significant gastrointestinal or genitourinary symptoms.

Past medical history included obesity, hypertension, impaired fasting glucose tolerance and osteoarthritis of the knees. Drug therapy included ramipril 2.5 mg daily, bendroflumethiazide 2.5 mg daily and paracetamol as required. The patient was divorced with two grown up children. He was an ex-smoker who rarely drank alcohol. The patient had recently retired having previously worked as a salesperson for luxury yachts, an occupation that had involved extensive travel around the world.

On examination, the patient was significantly overweight (BMI 36 kg / m^2). Abdominal examination did not demonstrate any jaundice or signs of chronic liver disease and no lymphadenopathy. Cardiovascular, respiratory and musculoskeletal examination was unremarkable. Given the patients concerns, his General Practitioner arranged some basic blood tests.

Haemoglobin	16.0 g / dL
Mean cell volume	85 fL
White cell count	5.2 * 10 /l9
Neutrophils	4.2 * 10 /l9
Lymphocytes	0.6 * 10 /l9
Monocytes	0.1 * 10 /l9
Eosinophils	0.1 * 10 /l9
Basophils	0.2 * 10 /l9
Platelets	358 * 10 /l9
Urea	6.8 mmol / L
Creatinine	110 micromol / L
Sodium	141 mmol / L
Potassium	3.9 mmol / L
Albumin	34 g / L (reference 35-50)
Alkaline phosphatase	98 U / L (reference (35-100)
ALT	28 U / L (reference 3-36)

Bilirubin	21 micromol / L (reference < 26)
Total protein	85 g / L (reference 60-80)
B12	355 pmol / L (reference 74-516)
Folate	30 nmol / L (reference 7-36)
Serum immunoglobulins	Normal electrophoresis strip

Comparison with a routine blood test taken 6 months previously had shown a similar full blood count differential.

What is the most appropriate next line investigation?

A. Human immunodeficiency virus antibody testing
B. Anti-nuclear antibody
C. Rheumatoid factor
D. Epstein-Barr virus serology
E. Serum angiotensin-converting enzyme

A. Human immunodeficiency virus antibody testing

The patient has a persistent lymphopenia, raised total protein and low albumin in the setting of fatigue and recurrent minor infections. These findings could all be explained by nascent HIV infection. The patients history of international travel may place him at increased risk of HIV infection and a full sexual history would be required.

The other investigations listed would assess for other possible causes of isolated lymphopenia, however there is no clinical evidence of connective tissue disease, EBV infection or sarcoidosis to

Question 248 of 277

A 28-year-old man who has recently immigrated from Nigeria presents with a penile ulcer. He reports that it initially started as a small lump but then later progressed to a painful ulcer.

On examination, there is a 7mm diameter tender single ulcer with an undermined ragged edge just proximal to the glans of the penis. Examination of the testes and anal region is unremarkable. There is tender inguinal lymphadenopathy.

What is the most likely diagnosis?

A. Syphilis
B. Herpes simplex virus
C. Granuloma inguinale
D. Lymphogranuloma venereum
E. Chancroid

E. Chancroid

Chancroid is a bacterial sexually transmitted infection characterised by painful sores on the genitalia. It is caused by the gram-negative coccobacillus *Haemophilus ducreyi*. It is a disease found primarily in developing countries.

H. ducreyi enters the skin through microabrasions incurred during sexual intercourse. A local tissue reaction leads to the development of an erythematous papule, which progresses to a pustule in 4- 7 days. It then undergoes central necrosis to ulcerate.

The ulcer can range in size from 3 to 50 mm across. It is painful and has sharply defined undermined borders

Other features include:

- Irregular or ragged borders
- A base that is covered with a grey or yellowish-gray material
- A base that bleeds easily if traumatised or scraped
- Painful lymphadenopathy in 30 to 60% of patients.
- Dysuria and dyspareunia in females

About half of infected men have only a single ulcer. Women frequently have four or more ulcers, with fewer symptoms.

Question 249 of 277

The Medical Emergency Team (MET) is summoned to the Surgical Unit to assist with the management of an acutely unwell patient.

The patient is a 21-year-old male who underwent open surgery for perforated appendicitis 3 days ago. The Surgical Registrar informs you that faecal contamination of the abdomen was noted during the operation and that a peritoneal washout was performed.

24 hours later, the patient began to complain of worsening abdominal pain. He became febrile in the early hours of the morning and blood cultures were taken. Since then, he has become progressively more unwell. He was taken down for an urgent abdominal ultrasound midafternoon, but the nurses were so concerned about his condition when he arrived back on the ward that a MET call was put out.

On examination, the patient is responsive to voice. He is febrile at 38.9ºC, his pulse is 131bpm and his blood pressure is 72/53mmHg. His peripheries are warm and clammy. Palpation of the abdomen reveals localised tenderness and guarding in the right iliac fossa. The surgical wound appears clean with minimal surrounding erythema.

As you prepare to place a large bore IV cannula the Surgical FY1 passes you some results that have recently been phoned through:

Abdominal ultrasound	Anechoic fluid collection in the right iliac fossa
Blood culture	Gram-positive cocci both bottles - further information to follow

Which of the following organisms is most likely to be isolated from the blood culture?

A. Staphylococcus epidermidis
B. Escherichia coli
C. Streptococcus pyogenes
D. Enteroccocus faecalis
E. Staphylococcus aureus

D. Enteroccocus faecalis

Although on first glance this may appear to be a 'surgical case', it is important to remember that MET or 'crash' teams are called to attend a variety of patients, some of whom may be admitted under the care of other specialties. On-call medical doctors need to be able to apply their knowledge to a range of situations, particularly when they fall outwith the remit of their day-today practice.

A significant amount of surgical information is presented in this vignette, however, the underlying diagnosis is given to the candidate and the question is actually designed to test the candidate's knowledge of pathogenic bacteria and the illnesses they cause.

Strep. pyogenes is a common cause of pharyngitis and soft tissue infections, occasionally giving rise to septicaemia. It would be unlikely to cause illness in the case described above.

Staph. aureus and Staph. epidermidis are commensal organisms that commonly cause septicaemia in critically ill patients, often secondary to the colonisation of indwelling lines. This vignette makes no mention of any such devices and we are told that the surgical wound is clean, making primary staphylococcal wound infection unlikely.

Escherichia coli is a gram-negative bacillus and is, therefore, inconsistent with the blood culture results described.

Enterococcus faecalis is a group D streptococcus. It is a gut commensal and a well-known cause of intra-abdominal infections. In the case described, it is likely that faecal contamination of the abdomen lead to the formation of an abscess and consequent Enterococcus bacteraemia.

Question 250 of 277

A 32 yr old Indian lady presented at the clinic with history of a gross swelling on her right leg from more than four years with associated fever and pain in her groin. Swelling was not reversible at night. On examination, the whole leg was oedematous ,bluish in colour, deep skin fold at junction of middle and lower one third, non discharging sinus above the fold anteriorly. There were no nodules or warts on her limbs.

Hb	144g/l (130 - 180)
Platelets	310 * 10 /l (150 - 400)9
WBC	9.2 * 10 /l (4.0 - 11.0)9
Neutrophil	3.5 * 10 /l (1.5 - 7.0)9
Lymphocyte	2.1 * 10 /l (1.5 - 4.09
Eosinophil	2.4 * 10 /l (0.04 - 0.4)9
Monocyte	1.1 * 10 /l (0<0.8)9

What is the drug of choice for the most likely diagnosis for the scenario above?

A. Praziquantel
B. Niclosamide
C. Ivermectin
D. Diethylcarbamazine
E. Metronidazole

D. Diethylcarbamazine

Diethylcarbamazine is the drug of choice for lymphatic filariasis

Filariasis is a disease group caused by filariae that affects humans and animals. In lymphatic filariasis, repeated episodes of inflammation and lymphedema lead to lymphatic damage, chronic swelling, and elephantiasis of the legs. Eosinophilia is a feature of filariasis. Diethylcarbamazine is the drug of choice for lymphatic filariasis.

In contrast, Praziquantel is used to treat infections caused by Schistosoma worms, which enter the body through skin that has come into contact with contaminated water. Symptoms include abdominal pain, diarrhea, bloody stool, or blood in the urine. Niclosamide is an antihelminthic that is active against tapeworm infestation which is transmitted mainly by eating infected raw or uncooked fish or beef and usually have intestinal discomfort, diarrhea, vomiting, weakness, and weight loss. Metronidazole is useful in treating infective diarrhoea with susceptible organisms.

Question 251 of 277

Randy is a 45-year-old male presenting with a new fever. He works as a farmer and noted fevers up to 39.6ºC over the past 72 hours with a dry cough. He has also been struggling to manage his sheep due to the ongoing headache and worsening muscle aches that have accompanied the fever. The headache was significant but was not associated with any neck stiffness or photophobia.

Randy does not note any other symptoms. He has not been in contact with anyone unwell and he has not been travelling out of the country recently.

Physical examination was otherwise unremarkable with only mild crackles heard on auscultation on his chest. No insect bites were noted. No lymphadenopathy was palpable.

Blood tests are as follow:

Hb	150 g/L	Male: (135-180)Female: (115 - 160)
Platelets	140 * 10 /L 9	(150 - 400)
WBC	6.0 * 10 /L 9	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	3.9 mmol/L	(3.5 - 5.0)
Urea	6.0 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
Bilirubin	13 µmol/L	(3 - 17)
ALP	90 u/L	(30 - 100)
ALT	110 u/L	(3 - 40)
AST	100 u/L	(5-40)
Albumin	37 g/L	(35 - 50)

What would be the likely organism causing the likely diagnosis?

A. Rickettsia prowazekii
B. Coxiella burnetti
C. Francisella tularensis
D. Legionella spp.
E. Bartonella henselae

B. Coxiella burnetti

Farmer, fever, transaminitis ?Q fever

Given that the patient is a farmer, this exposes him to zoonotic infections. The presence of fevers and associated transaminitis raises the suspicion for Q fever, caused by *Coxiella burnetti*. Its natural reservoir exists within cattle and sheep. It typically presents with fevers, headaches, fatigue and muscle aches. Diagnosis of this is often made by serological testing and is treated with doxycycline. Chronic Q-fever is possible and can present with endocarditis.

Francisella tularensis causes tularemia. This is less likely given the lack of risk of exposure to its natural vector, rabbits or deer. Also, this will tend to present with unilateral lymphadenopathy with associated skin ulcers at the site of inoculation.

Legionella spp. causes Legionnaires disease which presents with fevers and headaches. However, this is less likely given the lack of risk factors of exposure including recent repairs to water supplies and exposure to a known Legionnaires case. Also, this tends to cause a productive cough rather than a dry cough.

Bartonella henselae causes cat-scratch disease and this is not likely given the absence of lymphadenopathy or rash at the site of inoculation. Besides, there is no mention that he has been exposed to a cat.

Rickettsia prowazekii causes epidemic typhus. This typically occurs in overcrowded areas as the disease is spread by body lice. This is also typically associated with a generalized rash beginning at the trunk before spreading to the extremities (sparing of face, palms and soles).

Question 252 of 277

A 23-year-old female presents to her general practitioner complaining of a two-day history of rash at the back of her knee. She has a past medical history of eczema and asthma and is on regular Symbicort and emollients. She is a non-smoker and non-drinker and has recently returned from a camping holiday where she had been doing some hiking through a forested area.

On examination, there is a bulls-eye lesion just above her right popliteal fossa. She is otherwise systemically well and apyrexial.

What is the most appropriate initial management?

A. Oral doxycycline
B. Oral flucloxacillin
C. Serological testing for Borrelia antibodies
D. Skin biopsy
E. Topical steroid

A. Oral doxycycline

Lyme disease can be diagnosed clinically if erythema migrans is present → give antibiotics

Oral doxycycline is correct. This patient has a clinical diagnosis of Lyme disease and therefore treatment should be started as soon as possible. Doxycycline is the first-line antibiotic choice. NICE recommend a course length of 21 days. Second-line options include amoxicillin and azithromycin.

Serological testing for *Borrelia* antibodies is incorrect. NICE states that Lyme disease can be diagnosed clinically if erythema migrans is present. Given the typical appearance of the rash and the suggestive clinical history of a recent visit to a forest, we can make a clinical diagnosis in this case. This patient should receive antibiotics in the first instance and we do not need to wait for laboratory results.

Oral flucloxacillin is incorrect. This would be an appropriate choice for cellulitis but this is not the correct diagnosis.

Skin biopsy is incorrect. There is no uncertainty regarding diagnosis.

Topical steroid is the wrong answer. This would be a treatment for a flare of eczema but the description of the rash in association with the clinical history does not fit this description.

Question 253 of 277

A 54-year-old man is brought into the emergency department with a 4-day history of fever, headache and reduced appetite. His partner brought him into the hospital today as he became more lethargic and drowsy today. He has a past medical history of coeliac disease and HIV.

On examination, his GCS is 12 (E2V4M6) with equal and reactive pupils. He has a temperature of 38.1ºC with a heart rate of 99 beats/min and a blood pressure of 135/80mmHg. There are no visible rashes.

A lumbar puncture is performed, the CSF results are shown below:

Opening pressure	30 cmH20	(10 - 20)
White cell count	50 x10 /L mostly lymphocytes 6	(< 5)
Protein	3.5 g/L	(0.2 - 0.4)
Glucose	2 mmol/L	(2.8 - 4.2)

What is the most likely causative organism?

A. PassMedicine
B. *Cryptococcus neoformans*
C. *Herpes simplex virus*
D. *Listeria monocytes*
E. *Neisseria meningitidis*
F. *Streptococcus pneumoniae*

B. Cryptococcus neoformans

In cryptococcal meningitis, CSF shows high opening pressure and elevated protein. The white cell count may vary according to HIV status

Cryptococcus neoformans is correct. This patient has evidence of meningitis given the history of fever, headache and neurological dysfunction. The background of HIV suggests a likelihood of immunosuppression. In immunocompromised patients, it is important to consider alternative organisms that could cause this presentation rather than just those that are most prevalent in the general population. Looking at the lumbar puncture results from this patient, there is a significantly raised opening pressure, elevated protein and low glucose. The white cell count is only marginally raised and is predominantly lymphocytic. It is important to remember that the white cell count in CSF analysis can vary in patients with HIV depending on the severity of their immunocompromise. *Cryptococcus neoformans* is the most common fungal infection of the CNS in patients with HIV. It causes the lumbar puncture findings seen with this patient's presentation and is, therefore, the most likely causative organism.

Herpes simplex virus is incorrect. Viral meningitis can be seen in immunocompromised and immunocompetent individuals with common responsible viruses including enteroviruses (most common), herpesviruses, mumps and measles. Viral meningitis produces a CSF with elevated protein and a raised white cell count of mostly lymphocyte predominance as seen here. However, it would not cause a raised opening pressure and the CSF glucose is not reduced in patients with viral meningitis making this an unlikely diagnosis.

Listeria monocytes is incorrect. *Listeria monocytes* is an important organism to consider in patients with meningitic symptoms who are over the age of 50 years. Although the majority of bacteria cause neutrophil-dominant leucocytosis in the CSF, *Listeria monocytes* can also cause a lymphocytic predominance. However, the raised opening pressure points away from *Listeria monocytes* as the causative organism.

Neisseria meningitidis is incorrect. This is one of the more common causes of bacterial meningitis. Whilst *Neisseria meningitidis* can cause an elevated opening pressure, the white cell count is generally made up of neutrophils rather than lymphocytes as seen in this scenario.

Streptococcus pneumoniae is incorrect. Like *Neisseria meningitidis*, this is one of the most common causes of bacterial meningitis. However, the lymphocyte-predominant white cell count on CSF analysis makes this organism less likely to be responsible for this patient's presentation.

Question 254 of 277

A 29-year-old man presents to his first HIV clinic appointment. He has routine three month HIV tests. He received contact tracing notification last week and was tested and found to be HIV positive. He has just started antiretroviral treatment.

At clinic he mentions that he is due to go to South Africa. He hasn't yet had his travel vaccinations and is worried about what affect the new diagnosis of HIV will have on his travel plans. He is aware that currently immunosuppressed and at risk of infections and is committed to taking his tablets.

Investigations:

Haemoglobin	113 g/L (130-180)
White cell count	6.5 109/L (4.0-11.0)
Neutrophil count	5.4 109/L (1.5-7.0)
Platelet count	170 109/L (150-400)
CD4 count	180 cells/mm3 (600-1500)

Which of the following vaccinations is safe to be given?

A. Yellow fever
B. BCG
C. Oral polio
D. Meningococcal C
E. Varicella

D. Meningococcal C

Given this gentleman recent diagnosis with HIV he is immunocompromised which is reflected by his low CD4 count. He should not be given live vaccines as he is at risk of disseminated infection.

Yellow Fever, BCG, Oral Polio and Varicella are all live vaccines. Meningococcal C is a conjugate vaccine and can be given cautiously to an immunocompromised patient.

Question 255 of 277

A 34-year-old man with chronic immune thrombocytopenia has not responded to medical therapy and so is scheduled to undergo an elective splenectomy.

According to guidelines, he requires the following vaccinations:

A. Pneumovax (Pneumococcus), Haemophilus Influenzae, MMR (Measles, Mumps, Rubella), Annual influenza vaccine
B. Haemophilus Influenzae, Meningococcus C, Annual influenza vaccine
C. Pneumovax (Pneumococcus), Haemophilus Influenzae, Meningococcus C, Annual influenzavaccine
D. Pneumovax (Pneumococcus), Haemophilus Influenzae, Meningococcus C
E. Meningococcus C, Haemophilus Influenzae, MMR (Measles, Mumps, Rubella), Annualinfluenza vaccine

D. Pneumovax (Pneumococcus), Haemophilus Influenzae, Meningococcus C, Annual influenzavaccine

Risk of infection following splenectomy is with encapsulated bacteria e.g *Streptococcus pneumoniae*. *Haemophilus influenzae* type B, *Neisseria meningitidis*. Therefore patients should be immunised against these infections. MMR vaccination is not required.

Question 256 of 277

A 66 year old lady, originally from Pakistan, has lived in the UK for 10 years. She has type 2 diabetes mellitus which is controlled with metformin only.

For the last few years she has had multiple lumps over her whole body but this hasnt bothered her as it has been there for several years and not got too much worse. She has been seeing the diabetic foot care team due to several traumatic show healing ulcers on her feet.

Over the past few weeks she has been feeling increasingly unwell. She has had a fever, pain in her knees and elbows, sore painful eyes. She also complains of painful swelling in her ring and little fingers on her right hand.

On examination her temperature is 37.8C. Her pulse is 91 beats/minute and her RR is 18 breaths/minute. Her oxygen saturations are 97% on room air.

She has a multiple nodular lesions over her whole body in a symmetrical distribution. Sizes of these nodule range from 2cm - 4cm. These lesions are not painful, in fact with the larger ones she is unable to feel you touching them. On her shins there are several hot painful nodules which are uncomfortable to touch. She has a saddle deformity of her nose. There are several scars on her hands, and an ulcer on the lateral dorsum of her foot. Cardiorespiratory and abdominal examination is essentially normal. Both knees and elbow are slightly erythematous and swollen. She has weakness abducting her little and index finger on her left hand and has no sensation in her left little finger. There is a non-painful 1x4 cm lump two centimetres distal to her left medical epicondyle.

Urinalysis reveals ++ of protein and + of blood. Blood sugar: 8.8 mmol/L

On the clinical information alone what investigation is most likely to secure the diagnosis?

A. Serum cANCA antibody
B. Serum dsDNA antibody
C. Renal biopsy
D. Skin biopsy
E. Serum ANA antibody

D. Skin biopsy

With skin lesions and peripheral nerve involvement leprosy should certainly be on a differential diagnosis. Other give away features here are the anaesthetic skin lesions and nerve thickening. The erythema nodosum like lesions and the joint, renal and conjunctival involement indicate a type 2 reaction which occur in patients with lepromatous leprosy (usually following treatment).

Skin biopsy in this case will reveal the diagnosis. This would save her the potentially disastrous consequences of immunosupression.

Question 257 of 277

A 46 year old Indian gentleman who moved to the UK four years previously presents to the Emergency Department complaining of a numb left foot. He has a background history of type 2 diabetes mellitus, hypertension and gastro-oesophageal reflux disease. His latest haemoglobin A1c (HbA1c) is 6.4%. On examination he has reduced sensation over the left heel and plantar aspect of the foot and six hypoesthesic, hypopigmented patches over both legs.

What is the most appropriate management?

A. Referral to diabetes specialist clinic for management of peripheral neuropathy
B. Dapsone, clofazimine
C. Rifamipicin, clofazimine, isoniazid
D. Rifamipicin, dapsone, clofazimine
E. Dapsone, terbinafine, rifampicin

D. Rifamipicin, dapsone, clofazimine

The travel history, the distribution of sensory peripheral loss and the pattern of hypoesthesic skin patches are the clues to this patient's diagnosis. Mycobacterium leprae is one of the most common causes of peripheral neuropathy worldwide and has a vast spectrum of presentations from the typical skin manifestations described here to systemic involvement involving the respiratory tract, kidneys, testes and bones.

When there is neurological involvement, the posterior tibial nerve is most commonly affected, (the pattern of sensory loss being described here) however there may equally be involvement of other nerves eg. ulnar, median, lateral popliteal and facial.

Although he may have some underlying diabetic peripheral neuropathy, the pattern of sensory loss would be symmetrical and therefore targeting treatment towards his diabetes will not necessarily help here.

For the treatment of multibacillary leprosy, the WHO have recommended a multi-drug therapy regimen of dapsone, rifampicin and clofazimine for a two year period.

Question 258 of 277

A 36-year-old Sri-Lankan woman presents to the GP with a malar rash. On examination she has a erythematous rash that is warm to touch with some underlying oedema over both cheeks and the bridge of her nose.

She reports feeling low in energy over several months and describes a feeling of numbness in her feet and hands.

Investigations:

haemoglobin	125 g/L (115-165)
white cell count	9.4 Ã— 109/L (4.0-11.0)
platelet count	220 Ã— 109/L (150-400)
erythrocyte sedimentation rate	50 mm/1st h (<30)
serum urea	7.0 mmol/L (2.5-7.0)
serum creatinine	105 mol/L (60-110)
serum alanine aminotransferase	17 U/L (5-35)
serum aspartate aminotransferase	26 U/L (1-31)
serum complement C3	80 mg/dL (65-190)
serum complement C4	45 mg/dL (15-50)
serum C-reactive protein	145 mg/L (<10)
anti-double-stranded DNA antibodies	negative
c-ANCA	negative
p-ANCA	negative
antinuclear antibodies	1:20 (negative at 1:20 dilution)

An outpatient rheumatology appointment is arranged and she is started on a course of steroids in the interim. Her symptoms rapidly improve and the rash almost completely resolves however she is left with persistent numbness that appears to be worsening.

What is the most likely underlying diagnosis?

A. Granuloma annulare
B. Annular psoriasis
C. Systemic lupus erythematosus
D. Leprosy
E. Cutaneous leishmaniasis

D. Leprosy

The diagnosis here is leprosy. Leprosy can present along a spectrum from borderline to leprotamous and can often be mistaken for conditions like psoriasis, SLE and granuloma annulare.

The key distinguishing feature is the presence of anaesthetic patches that are present in leprosy but none of the other condition. A full clinical examination is not complete until sensation has been checked over the skin lesions with a microfilament.

The presence of anaesthetic patches should prompt you to look for other hallmarks of disease such as thickened nerves (often easiest to feel are the median nerve in the wrist the common peroneal nerve around the lateral head of the fibula and the ulnar nerve at the elbow.) the loss of hair (in and around lesions and often in the eyebrows) and the presence of neuropathy. Diagnosis is made by demonstrating acid fast bacilli within a cutaneous nerve on microscopy.

The severe skin changes seen with leprosy are not caused by the bacteria themselves but the bodys own immune response towards the bacilli. As a result steroids would improve the physical appearance of skin lesions but at the same time accelerate disease as the bacteria proliferate unhindered. This corresponds to the case outlined above where the patients neurological symptoms worsen yet the skin disease improves on starting steroids.

Question 259 of 277

A 34-year-old man presents to the emergency department with three days of fever, muscle ache, retro-orbital headache and a rash. He has returned from Honduras 5 days ago. He has no past medical history and does not take any regular medications.

Observations:

- Heart rate 101 beats/min
- Oxygen saturations 97% on room air
- Respiratory rate 20 breaths/min
- Temperature 38.5ºC
- Blood pressure 124/82 mmHg

On examination, his face appears flushed. There is a maculopapular rash covering most of his body. There is no splenomegaly. There is no synovitis.

Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	89 * 10 /L ^{9}	(150 - 400)
WBC	4.4 * 10 /L ^{9}	(4.0 - 11.0)
Na$^+$	137 mmol/L	(135 - 145)
K$^+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	22 mg/L	(< 5)
Bilirubin	14 µmol/L	(3 - 17)
ALP	111 u/L	(30 - 100)
ALT	143 u/L	(3 - 40)
Albumin	34 g/L	(35 - 50)

What is the most likely diagnosis?

A. Chikungunya
B. Dengue
C. Malaria
D. Typhoid
E. Zika

B. Dengue

Retro-orbital headache, fever, facial flushing, rash, thrombocytopenia in returning traveller → ?dengue

Dengue is the correct answer. Dengue virus is transmitted by the Aedes mosquito. It is endemic to Honduras. Facial flushing and a retro-orbital headache are characteristic along with severe myalgia (i.e 'breakbone fever'). Thrombocytopenia and deranged liver function tests are also common.

Chikungunya is incorrect. This can cause fever in the returning traveller and is another virus transmitted by the Aedes mosquito that is found in Honduras. While this condition can cause fever and myalgia, arthralgia and arthritis are almost ubiquitous in this condition and their absence makes this much less likely.

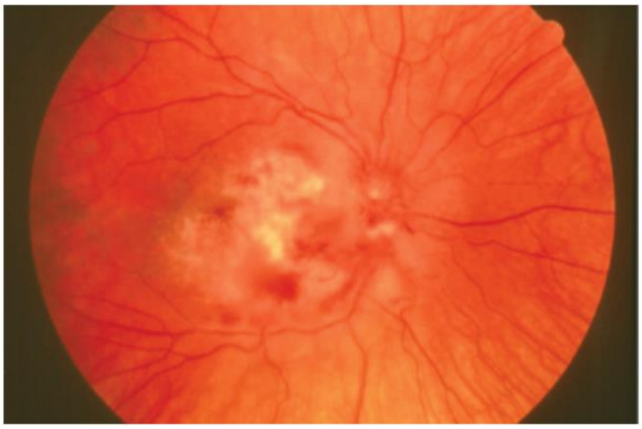
Malaria is incorrect. Malaria is present in Honduras and can cause fever and thrombocytopenia. However, malaria is typically not associated with a maculopapular rash and facial flushing and therefore dengue is more likely.

Typhoid is incorrect. This is another common cause of fever in the returning traveller. This can cause fever, thrombocytopenia and deranged liver function tests. However, it is often associated with abdominal pain and constipation. Additionally, the rash is typically described as 'rose spots' occurring on the lower chest and abdomen rather than a diffuse maculopapular rash and facial flushing. Severe myalgia is also less common. Therefore, dengue is more likely.

Zika is incorrect. This is another virus transmitted by the Aedes mosquito. However, it is not typically associated with a high fever (usually <38ºC) and is often associated with conjunctivitis and itching, which are absent in this case. Dengue is, therefore, more likely.

Question 260 of 277

A 42-year-old man who has recently emigrated to the UK is seen in the HIV clinic. He was diagnosed with HIV 5 years ago and has only sporadically taken anti-retroviral therapy during that period. He complains of blurred vision. Fundoscopy shows the following:



What is the most appropriate treatment?

A. Intravenous ganciclovir
B. Oral pyrimethamine and sulfadiazine, plus folinic acid
C. Intravenous methylprednisolone
D. Oral mebendazole
E. Oral co-trimoxazole

A. Intravenous ganciclovir

The fundoscopic image shows changes consistent with cytomegalovirus retinitis.

Question 261 of 277

A 35 year old known HIV positive patient presents with a gradual deterioration in his vision. He states that this has happened over the course of a few weeks. You note from his previous records that he is known to be poorly compliant with his antiretroviral therapy. His most recent CD4 count is 177 cells/mm3.

Given the most likely diagnosis, what would be the initial management strategy?

A. Oral aciclovir
B. Intravenous pentamidine

C. Oral pyrimethamine and sulfadiazine, plus folinic acid
D. Intravenous ganciclovir
E. Oral co-trimoxazole

D. Intravenous ganciclovir

This gentleman has developed cytomegalovirus retinitis treatment of which should be with intravenous ganciclovir or its prodrug oral valganciclovir.

CMV retinitis:

- Presents in those who are HIV +ve with CD4 counts typically <200 cells/mm3.
- Patients may be asymptomatic initially, but tend to present with a gradual deterioration in their visual acuity and visual blurring.
- Typical fundoscopic features described include the 'pizza pie' fundus. Flame hemorrhages may also be seen.
- Treatment is with intravenous ganciclovir or its prodrug oral valganciclovir.

Intravenous pentamidine and oral co-trimoxazole are used to treat *Pneumocystis jirovecii* (formely known as *Pneumocystis carinii*.

Oral pyrimethamine and sulfadiazine, plus folinic acid is used to treat toxoplasmosis.

Question 262 of 277

A 44-year-old woman presents to the emergency department with cough, haemoptysis, and episodes of epistaxis. Additionally, she reports a two week history of fatigue, fever and muscle aches.

On examination, she appears icteric. Coarse crackles are heard on her chest and she has right upper quadrant tenderness. There is tenderness in both her calves and in her lower back.

She is usually fit and well, working as a vet in a nearby town. She is a non-smoker and consumes around 20 units of alcohol a week. At home, she has a pet cat.

Which of the following is most appropriate for this patient?

A. Advise her to isolate for the course of her infection as she is at risk of transmission to others
B. Advise serology testing is most likely to confirm the diagnosis
C. After recovery she should be offered a vaccine as she has occupational risk
D. Offer a short course of oral ciprofloxacin
E. She should be warned that her cat was likely the source of her infection

B. Advise serology testing is most likely to confirm the diagnosis

Serology is the most commonly used test for the diagnosis of leptospirosis, however, antibodies may not be present until after 7 days

This patient has occupational and social history that increase the risk of zoonotic infections. She has presented with a febrile illness with components which include liver involvement and a coagulopathy. Together with myalgia classically affecting the calves and lower back this is suggestive of leptospirosis.

The diagnosis is most commonly made by serological testing for specific antibodies. It is difficult to isolate the organism by culture. The greatest diagnostic yield for culture is if it is done in the first 10 days of the illness. After this point, the organisms are only intermittently present in the blood. This patient has had symptoms for at least 2 weeks and therefore culture pick-up rates are now even lower.

An infected individual will shed leptospires in their urine for the period of the illness and for a time afterwards. Hence there is in theory a transmittable route to others but only in a specific way. Respiratory droplet transmission does not occur and so normal social interactions are safe.

There is no vaccine against leptospirosis available. Therefore, hand hygiene is important in those with occupational risk.

Most cases of leptospirosis are mild and self-resolve without pharmacological management. Where antibiotics are employed, doxycycline or azithromycin are often used. Amoxicillin is also effective.

Leptospirosis is classically associated with rats, which are the most common source of transmission, but other sources include dogs, cattle and pigs.

Question 263 of 277

A 24-year-old female presented to clinic with symptoms of dysuria and new vaginal discharge. She has been having unprotected sexual intercourse with a new male partner over the past eight weeks. Her nuclear acid amplification (NAAT) test was positive for *Chlamydia* and negative for gonorrhoea infection. She is currently menstruating.

What is the first-line treatment of choice for this infection?

A. Amoxicillin
B. Azithromycin
C. Ceftriaxone
D. Doxycycline
E. Erythromycin

D. Doxycycline

Chlamydia - treat with doxycycline

This patient has a *Chlamydia* infection. We know she is not pregnant as she is currently menstruating. The first-line treatment for *Chlamydia* infection is a 7-day course of doxycycline. Azithromycin was previously preferred as a first-line treatment as it can be given as a one-off dose, which increases compliance. However, recent evidence has raised concern for co-infection with *Chlamydia* and *Mycoplasma genitalium*, with growing resistance to macrolides. Therefore, doxycycline is now recommended as first-line treatment in non-pregnant patients.

Amoxicillin may be considered as a treatment for *Chlamydia* in pregnant patients. However, is not the first-line in this case.

Azithromycin is no longer considered first-line due to growing concerns around resistance. Azithromycin is also considered as a treatment option in pregnant patients with chlamydia infection.

Ceftriaxone is the first-line treatment for patients with *Gonorrhoea*, rather than *Chlamydia* infection. This patient was negative for *Gonorrhoea* infection on NAAT.

Erythromycin may also be considered as a treatment for *Chlamydia* in pregnant patients. However, is not the first-line in this case.

Question 264 of 277

A 23-year-old man presents to a sexual health clinic with a five-day history of dysuria, purulent urethral discharge and urinary frequency. He reports having a long-term partner. He has never previously had a sexual health screening. The patient has no known allergies.

A urine sample is sent for Nucleic Acid Amplification Testing (NAAT) which is negative for chlamydia and gonorrhoea. A urethral swab shows leucocytes. Blood-borne virus testing is negative and cultures of rectal and oral swabs are negative.

What is the most appropriate treatment?

A. Antibiotics not indicated
B. Intramuscular ceftriaxone
C. Oral aciclovir
D. Oral doxycycline
E. Oral metronidazole

D. Oral doxycycline

Urethritis in a male, negative for Gonorrhoea and Chlamydia →?Mycoplasma genitalium

Oral doxycycline is the correct answer. This patient has non-gonococcal urethritis (NGU) which can be caused, by organisms including *Chlamydia trachomatis* and *Mycoplasma genitalium*. NICE recommends doxycycline 100 mg twice a day for 7 days as first-line treatment. If a *Mycoplasma genitalium* NAAT is positive, BASHH recommends oral doxycycline 100mg bd for seven days followed by azithromycin 1g orally as a single dose then 500mg orally once daily for 2 days, where the organism is known to be macrolide-sensitive or where resistance status is unknown.

Antibiotics not indicated is the incorrect answer. Although NAAT testing for chlamydia and gonorrhoea is negative, this patient is symptomatic and requires treatment for urethritis.

Intramuscular ceftriaxone is the incorrect answer. This is the treatment for gonorrhoea and the patient has had a negative gonorrhoea NAAT.

Oral aciclovir is the incorrect answer. This is used to treat herpes simplex virus infection. There is no genital ulceration to suggest herpes infection.

Oral metronidazole is the incorrect answer. This would be the appropriate treatment if *Trichomonas vaginalis* is isolated, which is a cause of NGU. However, metronidazole would not be given first-line for a non-specified NGU.

Question 265 of 277

A 35-year-old woman presents to the acute medical unit with a 1-week history of worsening headache and fever. Her past medical history is unremarkable. On examination, you note nuchal rigidity and photophobia. A neurological examination is entirely normal. Observations are as follows: heart rate 115 beats per minute, blood pressure 125/75 mmHg, respiratory rate 16 breaths per minute, SpO2 96% (on air), and temperature 38.5ºC.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	168 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	2.4 mmol/L	(2.0 - 7.0)
Creatinine	52 µmol/L	(55 - 120)
CRP	78 mg/L	(< 5)
Glucose	7.8 mmol/L	(0.7-1.0)

HIV testing	HIV-1 antibody detected
HIV viral load	240,890 copies/mL

A lumbar puncture is performed:

Opening pressure	44 cm H2O	(7-18)
WBC count	250 cells/µL (90% lymphocytes)	(0-5)
Glucose	1.8 mmol/L	(0.7-1.0)
Protein	220 mg/dL	(<45)

What is the most likely diagnosis?

A. Bacterial meningitis
B. CNS lymphoma
C. Cerebral toxoplasmosis
D. Cryptococcal meningitis
E. TB meningitis

D. Cryptococcal meningitis

In cryptococcal meningitis, CSF shows high opening pressure and elevated protein. The white cell count may vary according to HIV status

It is important to note that this patient has a new diagnosis of HIV given the positive HIV-1 antibody result.

Cryptococcal meningitis is correct. Cryptococcal meningitis is the most common fungal CNS infection in patients with HIV. The lymphocytic pleocytosis, low glucose, raised protein, and markedly elevated opening pressure is characteristic of cryptococcal meningitis.

Bacterial meningitis is incorrect. The classic CSF results in bacterial meningitis is a high WBC count with a predominance of neutrophils (>90%).

CNS lymphoma is incorrect. This condition behaves as a space-occupying lesion which would usually be associated with focal neurology.

Cerebral toxoplasmosis is incorrect. Cerebral toxoplasmosis mostly presents as cerebral mass lesions with headache, confusion, fever, lethargy, seizures, cranial nerve palsies, psychomotor changes, hemiparesis and/or ataxia. The absence of neurological symptoms makes this a less likely diagnosis.

TB meningitis is incorrect. Distinguishing TB meningitis from cryptococcal meningitis based on clinical and laboratory features can be a real challenge. TB meningitis also results in a WBC pleocytosis (early neutrophils then lymphocytes), low glucose, and elevated protein. However, in this case, the markedly raised opening pressure favours the diagnosis of cryptococcal meningitis.

Question 266 of 277

A 49-year-old man presents to the emergency department with fever and dry cough for the last week. He also complains of myalgia and headaches which have been hampering his work on his farm. These headaches are variable in location, but usually worse behind his eyes. He is an exsmoker, with a 15 pack-year history. His alcohol intake is minimal and he has no significant past medical history of note.

On examination, he has coarse crackles in his right lung base. His abdomen is soft and non-tender. There is no rash. Heart sounds are normal, with no murmurs heard.

Initial investigations are done and a chest x-ray is requested.

Hb	146 g/L	Male: (135-180)Female: (115 - 160)
Platelets	452 * 10 /L 9	(150 - 400)
WBC	14.8 * 10 /L 9	(4.0 - 11.0)

Na +	138 mmol/L	(135 - 145)
K +	4.7 mmol/L	(3.5 - 5.0)
Urea	6.9 mmol/L	(2.0 - 7.0)
Creatinine	118 µmol/L	(55 - 120)
CRP	83 mg/L	(< 5)
Bilirubin	17 µmol/L	(3 - 17)
ALP	122 u/L	(30 - 100)
ALT	84 u/L	(3 - 40)
Î³GT	66 u/L	(8 - 60)
Albumin	39 g/L	(35 - 50)

What is the most appropriate treatment option?

A. Albendazole
B. Amoxicillin
C. Azithromycin
D. Co-trimoxazole
E. Doxycycline

E. Doxycycline

Farmer, fever, transaminitis ?Q fever

This patient is a farmer who has presented with evidence of pneumonia combined with a transaminitis. His occupation should make you think about potential zoonotic infections, which cause this presentation. Some examples of zoonotic infections include brucellosis, cryptosporidiosis, orf and Q fever.

Q fever is caused by *Coxiella burnetii*, a rickettsia. The source of infection is typically an abattoir (cattle/sheep). It may be inhaled from infected dust. It's features include a prodromal illness, atypical pneumonia and a transaminitis, as in this case. Treatment is most effective if given early, and doxycycline is the antibiotic of choice.

Amoxicillin may be used in cases of community-acquired pneumonia to cover typical organisms. However the transaminitis and occupation in the question point to a more atypical presentation.

Azithromycin is a potential treatment option for typhoid fever, which is more common in returning travellers from Asia. It often causes a prodromal illness and can affect the liver. In this case, there is no mention of travel and other features of typhoid such as a 'rose-spots' rash and bradycardia are absent.

Co-trimoxazole is a combination antibiotic, consisting of trimethoprim and sulfamethoxazole. It is the treatment of choice for pneumocystis pneumonia. However, this is rare in immunocompetent patients, classically occurring in those with HIV and a CD4 count below 200 cells/mm .

Question 267 of 277

Raymond is a 35-year-old man presenting with fevers. He had just returned from his overseas trip 7 days ago and he started experiencing fevers 3 days after his return. This was accompanied by joint pain along his wrists and ankles. The pain was so severe that he struggled to walk and lift objects with his hands due to the pain. Paracetamol and ibuprofen did not help the pain. He also felt generally fatigues over this time.

Raymond has recently travelled to Africa and India over the last 2 months. He states that he had gotten all of the recommended vaccinations before travelling. He notes that he had taken Malarone as his malaria prophylaxis throughout the trip. He had applied mosquito repellent during the 1st month of the trip but had forgotten to replenish this during the 2nd month of the trip.

Examination revealed swollen joints that were hot to touch but not overtly erythematous over both his wrist and ankle. An erythematous rash is also noted across the body with no clear discrete lesions identified. This was not pruritic in nature. Pyrexia was noted at 38.4ºC.

Blood tests results were as follow:

Hb	130 g/L	Male: (135-180)Female: (115 - 160)
Platelets	90 * 10 /L 9	(150 - 400)
WBC	5.0 * 10 /L 9	(4.0 - 11.0)
Neuts	3.7 * 10 /L 9	(2.0 - 7.0)
Lymphs	0.7 * 10 /L 9	(1.0 - 3.5)
Mono	0.5 * 10 /L 9	(0.2 - 0.8)
Eosin	0.1 * 10 /L 9	(0.0 - 0.4)

Na +	137 mmol/L	(135 - 145)
K +	4.0 mmol/L	(3.5 - 5.0)
Urea	6.0 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
Bilirubin	10 µmol/L	(3 - 17)
ALP	50 u/L	(30 - 100)
ALT	23 u/L	(3 - 40)
Î³GT	56 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

Three thick and thin blood films were negative. \

What is the likely cause for his fevers?

A. Chikungunya fever
B. Dengue fever
C. Leptospirosis
D. Malaria
E. Yellow fever

A. Chikungunya fever

Chikungunya can present with debilitating joint pain

The history of travel to Africa and India with hints that the patient may not have engaged with adequate mosquito protection places him at risk for mosquito-borne illness. The combination of rash, fevers and significant joint pains makes chikungunya fever the most likely culprit. Its vector is the *Aedes* mosquito and is endemic within Africa and Asia. It can cause issues like lymphopenia and thrombocytopenia on blood tests. Treatment is supportive.

Dengue fever is less likely as it is not commonly associated with significant joint pains. Instead, it is usually associated with myalgic pains. It will also cause a circulatory collapse in its severe presentation, which is not common in chikungunya.

Yellow fever is also predominantly endemic in Africa. It is less likely in this case given the absence of any significant liver abnormalities. Also, hepatomegaly can be picked up during examination in these patients.

Leptospirosis is predominantly spread by rodents. There is no clear risk of exposure to its vector and it is also not usually associated with joint pains. It is more commonly seen with myalgia and as the disease progresses, liver and renal involvement start to become a prominent feature.

Lastly, malaria is a common disease in both these countries. However, anaemia and jaundice would be expected. Besides, the 3x negative blood films are reassuring and useful to rule out malaria as the underlying cause.

Q

Question 268 of 277

A previously well 28-year-old man presents with shortness of breath and abdominal discomfort. He reports a dry cough for the previous 10 days. He works full time as a management consultant. He is a non-smoker and drinks approximately 20 units of alcohol a week. He went on a stag-do to Prague with a bunch of friends 2 weeks ago. In the last few days, he has noticed a widespread skin rash which he describes as lots of pink rings around a pale centre.

Bloods on admission:

Na +	128 mmol/l
K +	3.7 mmol/l
Urea	8.2 mmol/l
Creatinine	150 µmol/l

Chest x-ray: Diffuse reticular infiltrates and small right-sided pleural effusion.

What is the most likely causative organism?

A. Staphylococcus aureus
B. Pneumocystis jirovecii
C. Mycoplasma pneumoniae
D. Streptococcus pneumoniae
E. Haemophilus influenzae

C. Mycoplasma pneumoniae

Stereotypical history of mycoplasma pneumonia: worsening flu-like symptoms and a dry cough. Erythema multiforme is noted on examination

This patient has community-acquired pneumonia. Whilst *Streptococcus pneumoniae* and *Haemophilus influenzae* are the commonest causative organisms they tend to present with a shorter history. The longer duration of symptoms and unusual features of abdominal pain, dry cough and hyponatraemia should alert you to an atypical organism of which *Mycoplasma pneumoniae* is one of the commonest. The patient also describes erythema multiforme which is seen with *Mycoplasma pneumonia*.

Mycoplasma pneumoniae occurs in epidemics every three to four years and typically affects younger people. It tends to have an insidious onset with flu-like symptoms and atypical features. Hyponatraemia is often seen. Cold agglutinins can cause an autoimmune haemolytic anaemia. Diagnosis is confined with Mycoplasma serology. Treatment is with clarithromycin or a tetracycline or fluoroquinolone.

Staphylococcal pneumonia may complicate influenza infection and is seen most frequently in the elderly and in intravenous drug users or patients with underlying disease. It can result in a cavitating pneumonia.

Pneumocystis jirovecii is seen in immunocompromised patients. It typically presents with exertional breathlessness and patients are seen to desaturate on walking. Whilst a HIV test should be considered in the diagnostic workup of this patient, it is not the most likely diagnosis in this case.

Question 269 of 277

A 45-year-old man attends the general outpatient clinic having recently returned from hiking holiday in the Highlands of Scotland. Following his return, he describes how he has been feeling a bit unwell. He states that he has been experiencing general muscle aches, fatigue and a mild headache. On examination, they have a red papule on the posterior aspect of their calf with a patch of clear skin and a further red ring. It is non-tender and there is no warmth.

Further examination is unremarkable.

What is the most appropriate initial action?

A. Discharge with reassurance and worsening advice
B. ELISA antibody test B. Burgdorferi
C. Oral doxycycline
D. PCR test
E. Skin biopsy

C. Oral doxycycline

Lyme disease can be diagnosed clinically if erythema migrans is present → give antibiotics

The best initial option is to treat them empirically for Lyme disease. They have been out walking in an endemic area for Lyme disease and have features of early disease (erythema migrans and nonspecific viral features). Early treatment for suspected Lyme disease is appropriate in people who present with erythema migrans and other features of infection. Specific investigations for Lyme disease may be appropriate if the clinical presentation is delayed.

There is no requirement for further investigations as they have features of Lyme disease so a skin biopsy, ELISA PCR test is inappropriate as these would not change the management. Similarly, as they have presented with erythema migrans and there is good reason to suspect Lyme disease, discharging with no treatment is also inappropriate.

Question 270 of 277

A 30-year-old female presented to the emergency department with a 5-day history of fever, malaise, myalgia, joint pains, and headache. She thought she was recovering but over the past 2 days, her eyes had started to turn yellow. She had no past medical history and was on no regular medications. She had recently returned from Brazil 8 days ago where she had spent 2 weeks participating in many outdoor sporting events, including a forest marathon and wild swimming in lakes. She denied having a regular partner but reported that she had unprotected sexual intercourse on her last night in Brazil. She does not remember being bitten by insects.

On examination, she looked unwell.

Her observations were as follows:

- temperature 39.1ºC
- respiratory rate 22/min
- heart rate 109bpm
- blood pressure 105/67mmHg
- SpO2 98% on room air

She had scleral icterus and mild tender hepatomegaly. A faint petechial rash could be seen on her torso, hands, and feet. Blood tests results were as follows:

Hb	101 g/L	Male: (135-180)Female: (115 - 160)
Platelets	83 * 10 /L 9	(150 - 400)
WBC	15 * 10 /L 9	(4.0 - 11.0)
Neuts	11 * 10 /L 9	(2.0 - 7.0)
Lymphs	3 * 10 /L 9	(1.0 - 3.5)
Mono	0.6 * 10 /L 9	(0.2 - 0.8)
Eosin	0.4 * 10 /L 9	(0.0 - 0.4)
Bilirubin	80 µmol/L	(3 - 17)
ALP	231 u/L	(30 - 100)
ALT	265 u/L	(3 - 40)
AST	524 u/L	(5 - 40)

HBsAg - negative

Anti-HBs - positive

Anti-HBc - positive

Which test is most likely to reveal the diagnosis?

A. Skin scrapings for Leishmania braziliensis culture and PCR
B. Serum measurement of HBeAg
C. Urine microscopy for detection of Schistosoma haematobium
D. Treponema pallidum particle agglutination (TPPA) assay
E. Leptospira interrogans serum serology

E. Leptospira interrogans serum serology

Serology is the most commonly used test for the diagnosis of leptospirosis, however, antibodies may not be present until after 7 days

Leptospirosis is caused by zoonotic spirochete bacteria, spread via contact with infected animal urine. Animals such as rodents act as reservoirs of infection, shedding the bacteria in their urine which subsequently enter mucous membranes and broken skin. Freshwater swimming and other watersports are associated with leptospirosis infection. After an incubation period of 7 - 14 days, the disease presents in a biphasic fashion: acute fever, malaise, headache, and abdominal pain followed by severe systemic upset such as renal failure, pulmonary haemorrhage, and hepatic failure. Thrombocytopenia is also seen (suggested mechanisms include poor production by bone marrow and immune-mediated platelet destruction). Serology is the most commonly used test for the diagnosis of leptospirosis, however, antibodies may not be present until after 7 days.

Leishmania brasiliensis is the unicellular parasite responsible for cutaneous and mucosal leishmaniasis. Endemic in South America, this disease presents with skin and mucosal ulcerative lesions and is spread by the sandfly. Leishmaniasis is diagnosed by detecting Leishmania parasites (or DNA) in tissue specimens. This patient had no such skin lesions and no history of insect bites.

This patient's hepatitis serology demonstrates that she has been exposed to hepatitis B (positive anti-HBc and anti-HBs) but has cleared the virus (negative HBsAg). Hepatitis B e antigen (HBeAg) is an indicator of viral replication and correlates with hepatitis B virus infectivity. This would typically be measured if the patient had active hepatitis B. As this patient is HepBsAg negative, this test is not necessary.

Schistosoma haematobium is a parasitic fluke endemic to areas of Africa. The intermediate host is the freshwater snail; transmission risk is increased by swimming in such bodies of water. Whilst acute infection can cause a transient febrile illness (Katayama syndrome) the history typically includes pruritis (swimmers itch) with eosinophilia. Schistosomiasis is primarily a chronic disease with *Schistosoma haematobium* causing urological manifestations such as cystitis or obstructive uropathy. Examination of the urine for ova is the primary method used to diagnose suspected *Schistosoma haematobium* infections.

Treponema pallidum a sexually transmitted bacterial spirochete responsible for causing syphilis.

Primary syphilis is characterised by a painless self-limiting genital ulcer (chancre) and lymphadenopathy occurring 10-90 days after sexual transmission. Secondary syphilis occurs following the haematogenous spread of the bacteria and can present with a variety of symptoms including a widespread rash, adenopathy, arthralgia, hepatitis, and alopecia. This classically presents 4-8 weeks after the presentation of the chancre. Whilst this diagnosis should be considered given the patient's sexual history, there is no mention of a genital lesion in the question stem, and the very short period between the sexual encounter (8 days prior) and the onset of her symptoms is not typical of secondary syphilis. The Treponema pallidum particle agglutination (TPPA) assay is one of many tests that may be used to detect specific antitreponemal antibodies in serum. This is usually only requested after a positive non-treponemal screening test in the diagnostic workup of syphilis.

Question 271 of 277

A 25-year-old sexually active woman presents with abnormal vaginal discharge and burning during urination. A nucleic acid amplification test (NAAT) for sexually transmitted infections is performed.

NAAT	positive for *Chlamydia trachomatis*

She has no allergies, is using oral contraceptives, and is not pregnant or breastfeeding.

What antibiotic is most appropriate in this case?

A. Azithromycin
B. Ceftriaxone
C. Doxycycline
D. Erythromycin
E. Trimethoprim

C. Doxycycline

Chlamydia - treat with doxycycline

National Institute for Health and Care Excellence (NICE) guidance states that **doxycycline** is now the first-line treatment for anyone over the age of 13 diagnosed with *Chlamydia* who is not pregnant or breastfeeding. This is therefore the correct answer.

Azithromycin is the second-line treatment recommended by NICE for treating *Chlamydia* in patients for whom doxycycline is contraindicated or not tolerated.

Ceftriaxone is used in the treatment of *Gonorrhoea* but is not recommended for treating *Chlamydia*.

Erythromycin is a third-line agent recommended by NICE for treating *Chlamydia* in patients for whom both doxycycline and azithromycin are contraindicated or not tolerated.

Trimethoprim is indicated in treating urinary tract infections in some populations however is not used in the treatment of *Chlamydia*.

Question 272 of 277

A 47-year-old male presents to the emergency department with joint pains and rash developing over 48 hours. He describes feeling weak and tired with headaches, myalgia, and lumbar back pain.

Examination reveals painful tender distal inter-phalangeal (DIP) joints and tender wrists in a symmetric distribution. He tells you the pain is worse in the morning and improves throughout the day. He has an erythematous maculopapular rash involving his torso and upper limbs with multiple insect bites. During your assessment, he develops a fever of 39.7°C. His chest is clear on auscultation. There is no palpable lymphadenopathy. He denies any nausea, vomiting, or diarrhoea.

His medical history includes asthma, obstructive sleep apnoea, and depression. He tells you he returned from a family holiday in Mexico 5 days earlier.

Blood tests:

Hb	148g/L	Male: (135-180)Female: (115 - 160)
Platelets	98* 10 /L $_9$	(150 - 400)
WBC	7.8* 10 /L $_9$	(4.0 - 11.0)
Neuts	6.8* 10 /L $_9$	(2.0 - 7.0)
Lymphs	0.2* 10 /L $_9$	(1.0 - 3.5)
Mono	0.6* 10 /L $_9$	(0.2 - 0.8)
Eosin	0.2* 10 /L $_9$	(0.0 - 0.4)

Urea	6.8mmol/L	(2.0 - 7.0)
Creatinine	128 µmol/L	(55 - 120)
CRP	24mg/L	(< 5)

What is the most likely cause of this man's presentation?

A. Dengue
B. Rheumatoid arthritis
C. Malaria
D. Chikungunya
E. Psoriatic arthritis

D. Chikungunya

Chikungunya can present with debilitating joint pain

Chikungunya can present with debilitating joint pain. A rash develops in up to 75% of patients. The most common symptoms include fevers and malaise. It can be difficult to differentiate from dengue early in the disease. Two significant differences may help distinguish between them; 1) In chikungunya, rashes appear on the torso and the arms while in dengue, they appear on the arms and the face. 2) Joint pain in chikungunya is experienced in the hands, wrists, feet, and legs, while in dengue it is experienced in the shoulders and the knees.

Dengue is an important differential diagnosis. It is a mosquito-borne tropical disease caused by the dengue virus. Symptoms include a high fever, headache, vomiting, joint pains, and a characteristic skin rash. It may be indistinguishable from chikungunya early in the disease.

Rheumatoid arthritis is a symmetric polyarthritis involving large and small joints. This is unlikely given the acute presentation, and rheumatoid arthritis is not typically associated with fevers or rash.

Malaria should be considered in any patient with fevers and non-specific symptoms travelling from an endemic area. It may present with fevers, malaise, diaphoresis, headaches, cough, arthralgia. Chikungunya is more likely in our patient as it more commonly presents with joint pains and rash.

Psoriatic arthritis is associated with small joint involvement (DIPs) and a characteristic scaly rash. The acute presentation and fevers suggest an infectious cause.

Treatment: Relief of symptoms. No specific treatment.

Question 273 of 277

A 45-year-old man is known to be HIV positive but has a long history of poor compliance with anti-retroviral medication. He presents to the Emergency Department with a 4-day history of headache and vomiting. On examination, he has neck stiffness but no rash. He has a temperature of 38.6 ºC and is confused. A CT head is unremarkable. A lumbar puncture is performed. Examination of CSF with India ink is positive.

CD4 count	60 cells per mm 3	(500 - 1500)

What additional finding from the lumbar puncture would be most in keeping with the diagnosis?

A. Normal glucose
B. Normal protein
C. Opening pressure of 28 cm H2O
D. Presence of organism-specific antibodies in the CSF
E. Raised white cell count with predominantly neutrophils

C. Opening pressure of 28 cm H2O

In cryptococcal meningitis, CSF shows high opening pressure and elevated protein. The white cell count may vary according to HIV status

This patient has cryptococcal meningitis. *Cryptococcus neoformans* is an encapsulated yeast that is found in the environment and is a common cause of meningitis in patients with HIV with a CD4 count of less than 100. Examination of the CSF with India ink is positive in 70-90% of cases of HIVrelated cryptococcal meningitis.

Opening pressure of 28 cm H2O is correct. All patients with suspected cryptococcal meningitis should have manometry performed as intracranial pressure is often significantly raised. Patients can require serial lumbar punctures to lower intracranial pressure, or may even require neurosurgical devices such as extra-ventricular drains or ventriculoperitoneal shunts to manage their intracranial pressure.

Normal glucose is incorrect. CSF glucose is generally low in cryptococcal meningitis, although it can sometimes be normal.

Normal protein is incorrect. CSF protein is usually elevated in cryptococcal meningitis.

Presence of organism-specific antibodies in the CSF is incorrect. Antibodies to *Cryptococcus neoformans* are not used in diagnosis, either in the blood or CSF. Cryptococcal antigen (CrAg), however, is a useful test and can be carried out on both blood and CSF. A positive CSF CrAg has a 98% sensitivity for cryptococcal meningitis. High CSF CrAg is a poor prognostic marker.

Raised white cell count with predominantly neutrophils is incorrect. The white cell count is usually elevated, but the predominant cell type would be lymphocytes. Patients with HIV may not have an elevated CSF white cell count, and this is a poor prognostic marker.

Question 274 of 277

A 27-year-old male attends the emergency department with a 5-day history of fevers, myalgia, and headaches. He is a non-smoker and has no previous medical history.

On examination he appears dyspnoeic, his oxygen saturations are 92% with a respiratory rate of 24/minute. Heart sounds are normal and the abdomen is soft,non-tender with no organomegaly.

A chest x-ray reveals subtle bilateral interstitial infiltrates.

Blood tests:

Hb 153g/L Male: (135-180)

Female: (115 - 160)

Platelets 380* 10 /L (150 - 400)

WBC 15.1* 10 /L (4.0 - 11.0)

Na 138mmol/L (135 - 145)

K 4.1mmol/L (3.5 - 5.0)

Urea 6.7mmol/L (2.0 - 7.0)

Creatinine 96 µmol/L (55 - 120)

Bilirubin 12 µmol/L (3 - 17)

ALP 2721u/L (30 - 100)

ALT 354u/L (3 - 40)

Î³GT 468u/L (8 - 60)

Albumin 37g/L (35 - 50)

He works on a dairy farm with his father, who was recently treated in hospital for pneumonia. His father tested negative for *COVID19* while in hospital. He tells you he has had limited social contacts in the last number of weeks to protect his ageing father from COVID19.

Which of the following is the most likely cause for his presentation?

A. Q fever
B. Mycoplasma pneumonia
C. COVID19
D. Brucellosis
E. Psittacosis

A. Q fever

Farmer, fever, transaminitis ?Q fever

Q fever is the correct answer. Q fever *(Coxiella Burnetti)* is a zoonotic infection most commonly found in farmers and abattoir workers. It presents as a non-specific flu-like illness with fevers, headaches, fatigue, and myalgia. Q fever may present as pneumonia and is commonly associated with transaminitis. Occasionally it may present with endocarditis or other localized infections such as bone and joint infections or vascular infections (infected aneurysm). Q fever should be suspected in patients who present with symptoms and have risk factors (working closely with animals, exposure to infected dust, lab work).

Mycoplasma pneumonia may cause a similar presentation. Mycoplasma pneumonia is characterized by a non-specific flu-like illness with patchy infiltrates on chest x-ray, However, mycoplasma pneumonia is rarely associated with significant transaminitis and an alternative diagnosis should be considered.

COVID19 is less likely as he denies any potential exposure.

Brucellosis is incorrect. Brucellosis is associated with dairy farming and may have a similar presentation to q fever. However, brucellosis is more frequently associated with international travel. A minority of cases are transmitted within the UK and Ireland.

Psittacosis is typically associated with transmission from infected birds ('Parrot fever'). Transmission from dairy cattle has been reported but this is a much less likely occurrence. This patient does not disclose any contact with infected birds.

Question 275 of 277

A 45-year-old man presents with a 5-day history of fever and headache, followed by the onset of rash and drowsiness on the day of presentation. He has been working as a counsellor in a refugee camp in Ethiopia and returned to the UK 7 days ago. The camp is over capacity and the living conditions are very crowded. The facilities in the camp for personal hygiene and washing clothes are severely limited for both volunteers and residents. There are reports that many people in the camp have also become unwell.

On examination, he is mildly confused and drowsy with a Glasgow Coma Score of 13 (eyes 3, voice 4, motor 6.) He is visibly jaundiced with a palpable liver edge. He has a maculopapular rash on his trunk. A chest x-ray reveals bilateral patchy pulmonary infiltrates.

What antibiotic would be the first line in the management of this patient?

A. Benzylpenicillin
B. Ciprofloxacin
C. Doxycycline
D. Metronidazole
E. Rifampicin

C. Doxycycline

Doxycycline is typically used in the management of typhus

This patient has epidemic typhus, which is caused by *Rickettsia prowazekii*, which is a small bacterium transmitted by the bites of the human body louse. Epidemic typhus mainly occurs in outbreaks in conditions of severe upheaval and overcrowding, such as in conflict situations or after natural disasters. It is the most severe infection of the typhus group and has a mortality of 20-50% if untreated. It presents with abrupt onset of headache and fever, followed by the development of rash at day 5, and is commonly complicated by neurological symptoms or multi-organ failure.

The first-line treatment for all rickettsial infections is **doxycycline** . This includes infections in both the spotted fever group and the typhus group. Other management in the outbreak setting would include doxycycline prophylaxis for healthcare workers and mass delousing.

Benzylpenicillin is incorrect. Beta-lactam-based antibiotics are not effective against rickettsial infections. Benzylpenicillin can be used for bacterial meningitis, but this diagnosis is less likely in this patient who also has liver and respiratory involvement.

Ciprofloxacin is incorrect. Ciprofloxacin is not routinely used for the treatment of typhus. It could be considered for treating severe cholera, but this is unlikely in this patient given the lack of diarrhoea. (Doxycycline can also be used to treat cholera in addition to typhus).

Metronidazole is incorrect. Metronidazole is active against anaerobes but does not have any activity against rickettsia.

Rifampicin is incorrect. Rifampicin has some activity against rickettsia, but outcomes are significantly worse than with doxycycline so it is therefore not used in treatment.

Question 76 of 277

A 35-year-old farmer presents to the Emergency Department with a one week history of lethargy and subjective pyrexia. Over the past 24 hours he has developed right sided pleuritic chest pain which brought him to hospital.

He denies any past medical history and had been systemically well prior to this. He denies any recent overseas travel.

Examination reveals right sided coarse crackles in the lungs, there is no abnormality heard in the left side of the lung.

His observations revealed heart rate 105 beats per minute, oxygen saturation 96% in room air, temperature 38.1ºC, respiratory rate 18 breaths per minute, blood pressure 145/95 mmHg.

An ECG was performed which revealed sinus tachycardia and his chest radiograph revealed right sided consolidation.

His blood results taken on admission were as follows:

Hb	140 g/L	Male: (135-180)Female: (115 - 160)
Platelets	500 * 10 /L 9	(150 - 400)
WBC	16 * 10 /L 9	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	4 mmol/L	(3.5 - 5.0)
Urea	6 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
CRP	159 mg/L	(< 5)

Bilirubin	16 µmol/L	(3 - 17)
ALP	78 u/L	(30 - 100)
ALT	80 u/L	(3 - 40)
Î³GT	55 u/L	(8 - 60)
Albumin	40 g/L	(35 - 50)

What is the most likely diagnosis?

A. Mycoplasma pneumoniae
B. Influenza
C. Legionnaires disease
D. Pulmonary embolism
E. Q fever

E. Q fever

Farmer, fever, transaminitis ?Q fever

This patient has Q fever. His possible exposure to sheep given that he is a farmer, pneumonia and mild transaminitis point towards Q fever as a diagnosis.

Influenza is a possibility as it may present with pyrexia and tachycardia along with respiratory symptoms, the clue in this history if that the patient is a farmer, thereby making Q fever more likely.

Legionnaires disease is usually spread through infected air conditioning units in aeroplanes or hotels. This patient has no history of travel.

Mycoplasma would classically present with hyponatraemia in the context of pneumonia, it is not usually caused by exposure to sheep or cattle. which this patients has most likely been exposed to.

A pulmonary embolism could be a differential with pleuritic chest pain and tachycardia, however the likely exposure to sheep, high temperature and consolidation on the chest radiograph makes Q fever more likely.

Question 42 of 277

A returning traveller presents to the emergency department with a 10 day history of fever, cough and abdominal pain. He has spent the last 2 weeks in Jakarta, Indonesia. His vital signs are: temperature: 40.1ºC, heart rate 85 beats/minute, blood pressure 120/80 mmHg

On examination his spleen is enlarged and there is a rose spot rash over the chest. Blood culture grows salmonella typhi and the on-call doctor diagnoses enteric fever (typhoid).

If left untreated, what is the most important and serious complication that can occur within the following 2 weeks?

A. Chronic carriage within gallbladder
B. Bowel perforation and haemorrhage
C. Splenic infarction and rupture
D. Acute liver failure
E. Bacterial meningitis

B. Bowel perforation and haemorrhage

The most serious and frequent complications of Typhoid are bowel perforation and haemorrhage. This is caused by bacterial destruction of the Peyer's patches in the small intestine and classically occurs late in the second week of illness or early in the third week. Other complications include myocarditis and endocarditis.

Chronic bacterial carriage in the gall bladder does occur, but this is not the most serious complication. It renders the patient chronically infective and capable of transmitting the disease. Acute liver failure does not occur, but mild jaundice may result from cholecystitis or hepatitis. Bacterial meningitis is a very rare complication not often reported.

passmedicine PART 2

ONCOLOGY

2024

A 20-year-old asymptomatic woman is referred to the genetics clinic. Her grandmother died of breast cancer aged 54 and her mother and older sister have both recently been diagnosed with the disease.

Breast examination does not reveal any lumps and her recent ultrasound of the breasts did not reveal any suspicious lesions.

What should she be told about her breast cancer risk?

- ○ Her chance of having a BRCA1 mutation is 55-65%
- ○ Her chance of having a BRCA2 mutation is 55-65%
- ○ If BRCA1 positive, she has a 55-65% chance of developing breast cancer
- ○ If BRCA2 positive, she has a 55-65% chance of developing breast cancer
- ○ Given her family history, she has a 55-65% chance of developing breast cancer

Back to top

A 20-year-old asymptomatic woman is referred to the genetics clinic. Her grandmother died of breast cancer aged 54 and her mother and older sister have both recently been diagnosed with the disease.

Breast examination does not reveal any lumps and her recent ultrasound of the breasts did not reveal any suspicious lesions.

What should she be told about her breast cancer risk?

Her chance of having a BRCA1 mutation is 55-65%	7%
Her chance of having a BRCA2 mutation is 55-65%	3%
🟩 If BRCA1 positive, she has a 55-65% chance of developing breast cancer	49%
If BRCA2 positive, she has a 55-65% chance of developing breast cancer	15%
🟥 Given her family history, she has a 55-65% chance of developing breast cancer	25%

The BRCA1 and BRCA2 genes are tumour suppressor genes involved in DNA repair. Familial mutations in these genes are associated with an increased risk of breast and ovarian cancer. Carriers tend to develop these cancers at a younger age as they have an inherited germline mutation of one copy of the gene so only require a 'second hit' of damage to the second copy to inactivate it. BRCA mutations account for 20-25% of hereditary breast cancers and 5-10% of all breast cancer cases, They also account for 15% of all ovarian cancer.

If a woman with at least a 10% risk of breast or ovarian cancer (approximated from family history) will be offered genetic screening. This requires genetic counselling and living relative whose DNA can also be tested for the mutation, otherwise, the chance of identifying the mutation is too low. This has important ethical considerations with regard to consent.

The percentage risk of developing breast cancer by age 70 is 55-65% for BRCA1 and 45% for BRCA2 mutations.

The percentage risk of developing ovarian cancer by age 70 is 40% for BRCA1 and 15% for BRCA2 mutations.

Because of the high risks involved, women with a positive test result may choose to have enhanced screening for these cancers, prophylactic surgery (bilateral mastectomy and/or bilateral salpingo-oophorectomy) or chemoprevention with hormonal drugs.

Breast cancer: risk factors ★

Predisposing factors

- BRCA1, BRCA2 genes - 40% lifetime risk of breast/ovarian cancer
- 1st degree relative premenopausal relative with breast cancer (e.g. mother)
- nulliparity, 1st pregnancy > 30 yrs (twice risk of women having 1st child < 25 yrs)
- early menarche, late menopause
- combined hormone replacement therapy (relative risk increase * 1.023/year of use), combined oral contraceptive use
- past breast cancer
- not breastfeeding
- ionising radiation
- p53 gene mutations
- obesity
- previous surgery for benign disease (?more follow-up, scar hides lump)

You are working as a registrar on the palliative care ward. A 58-year-old lady is admitted for symptom control. She has a past medical history of metastatic pancreatic cancer and diabetic nephropathy. She has been suffering from severe abdominal pain which has been unresponsive to titration of morphine, gabapentin and duloxetine.

Blood results are as follows:

Hb	75 g/l	Na^+	138 mmol/l
Platelets	$224 * 10^9/l$	K^+	3.8 mmol/l
WBC	$14.9 * 10^9/l$	Urea	18.6 mmol/l
Neuts	$12.9 * 10^9/l$	Creatinine	288 µmol/l
eGFR	22 mL/min		

You decide to start an opioid which acts as a neuropathic agent by NMDA antagonism. What analgesic is most appropriate?

○ Methadone

○ Oxycodone

○ Buprenorphine

○ Paracetamol

○ Venlafaxine

Question 2 of 43 ✗

You are working as a registrar on the palliative care ward. A 58-year-old lady is admitted for symptom control. She has a past medical history of metastatic pancreatic cancer and diabetic nephropathy. She has been suffering from severe abdominal pain which has been unresponsive to titration of morphine, gabapentin and duloxetine.

Blood results are as follows:

Hb	75 g/l	Na^+	138 mmol/l
Platelets	224 * 10^9/l	K^+	3.8 mmol/l
WBC	14.9 * 10^9/l	Urea	18.6 mmol/l
Neuts	12.9 * 10^9/l	Creatinine	288 µmol/l
eGFR	22 mL/min		

You decide to start an opioid which acts as a neuropathic agent by NMDA antagonism. What analgesic is most appropriate?

Methadone ✓	33%
Oxycodone	15%
Buprenorphine	40%
Paracetamol	0%
Venlafaxine ✗	12%

Methadone can be used as a third line opioid for patients with complex pain that is poorly responsive to other opioids and adjuvants

Important for me Less important

Methadone can be used as a third line opioid for patients with complex pain that is poorly responsive to other opioids and adjuvants. The patients pain has not responded to titration of morphine, combined with two neuropathic adjuvants. Methadone should therefore be considered.

The patients eGFR is les than 30 which also strengthens the decision to start methadone. Opioids which are safe in CKD 4 and 5 include fentanyl, buprenorphine and methadone.

Paracetamol and venlafaxine are not opioids.

Next question >

Palliative care prescribing: pain ★

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment
- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points
- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
  - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
  - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however,

should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	**To**	**Conversion factor**
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	**To**	**Conversion factor**
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations
- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 3 of 43

You are asked to provide advice on a patient who has metastatic renal cell carcinoma with pulmonary and bone metastases. They are being managed in their own home with community palliative care input, but their swallow has started to deteriorate. It is now felt that they are approaching the terminal phase of their illness and a decision has been made to start a syringe driver. They report good pain control with their current analgesia regime.

Their current analgesia regime is 60mg oxycodone modified release capsules twice a day with oxycodone instant release, taken as required. The oxycodone modified release is converted into the equivalent subcutaneous dose for an oxycodone syringe driver.

What would be the most appropriate dose of breakthrough analgesia to prescribe based on the current syringe driver dose?

- ○ Oxycodone I/R oral solution 20mg
- ○ Oxycodone I/R oral solution 10mg
- ○ Oxycodone subcutaneous injection 10mg
- ○ Morphine sulphate for injection 10mg
- ○ Morphine sulphate injection 20mg

You are asked to provide advice on a patient who has metastatic renal cell carcinoma with pulmonary and bone metastases. They are being managed in their own home with community palliative care input, but their swallow has started to deteriorate. It is now felt that they are approaching the terminal phase of their illness and a decision has been made to start a syringe driver. They report good pain control with their current analgesia regime.

Their current analgesia regime is 60mg oxycodone modified release capsules twice a day with oxycodone instant release, taken as required. The oxycodone modified release is converted into the equivalent subcutaneous dose for an oxycodone syringe driver.

What would be the most appropriate dose of breakthrough analgesia to prescribe based on the current syringe driver dose?

Oxycodone I/R oral solution 20mg	33%
Oxycodone I/R oral solution 10mg	10%
Oxycodone subcutaneous injection 10mg	42%
Morphine sulphate for injection 10mg	9%
Morphine sulphate injection 20mg	7%

Breakthrough dose = 1/6th of daily morphine dose

Important for me   Less important

The breakthrough dose for analgesia should be one sixth of the total dose administered within 24 hours. If there are no changes to the total dose of oxycodone and it is converted to subcutaneous then the total dose is halved (120mg to 60mg). This is because the subcutaneous strength is twice that of oral oxycodone. The drug choice for breakthrough should match what is in the syringe driver as much as possible (stick with oxycodone) and the breakthrough should be a sixth of the total dose. Given that they need a syringe driver which is made up of oxycodone, the most appropriate drug choice would be subcutaneous oxycodone. Therefore, the breakthrough dose would be a sixth of 60mg= 10mg.

You are looking after a 65-year-old man with a background of high-grade lymphoma who she is currently receiving R-CHOP chemotherapy for. She developed neutropaenic sepsis yesterday for which she was started on piperacillin/tazobactam, and gentamicin. She has been persistently pyrexial for the past 24 hours.

She has a background of complex pain for which she uses a 25micrograms/hour fentanyl patch. You are asked to review her due to confusion and visual hallucinations. On examination, she has pinpoint pupils, GCS 14 (M6, V4, E4), and you note myoclonic jerks.

Na^+	136 mmol/L	(135 - 145)
K^+	3.8 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	130 µmol/L	(55 - 120)

Bilirubin	14 µmol/L	(3 - 17)
ALP	95 u/L	(30 - 100)
ALT	82 u/L	(3 - 40)
Î³GT	86 u/L	(8 - 60)
Albumin	35 g/L	(35 - 50)

You suspect opioid toxicity. What is the most likely explanation for this?

○ Acidosis

○ Fentanyl and piperacillin/tazobactam drug interaction

○ Increased fentanyl absorption due to pyrexia

○ Liver dysfunction

○ Renal dysfunction

Question 4 of 43 ✗

You are looking after a 65-year-old man with a background of high-grade lymphoma who she is currently receiving R-CHOP chemotherapy for. She developed neutropaenic sepsis yesterday for which she was started on piperacillin/tazobactam, and gentamicin. She has been persistently pyrexial for the past 24 hours.

She has a background of complex pain for which she uses a 25micrograms/hour fentanyl patch. You are asked to review her due to confusion and visual hallucinations. On examination, she has pinpoint pupils, GCS 14 (M6, V4, E4), and you note myoclonic jerks.

Na^+	136 mmol/L	(135 - 145)
K^+	3.8 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	7.2 mmol/L	(2.0 - 7.0)
Creatinine	130 µmol/L	(55 - 120)

Bilirubin	14 µmol/L	(3 - 17)
ALP	95 u/L	(30 - 100)
ALT	82 u/L	(3 - 40)
Î³GT	86 u/L	(8 - 60)
Albumin	35 g/L	(35 - 50)

You suspect opioid toxicity. What is the most likely explanation for this?

Acidosis	6%
Fentanyl and piperacillin/tazobactam drug interaction	11%
Increased fentanyl absorption due to pyrexia	56%
Liver dysfunction	12%
Renal dysfunction	15%

Transdermal fentanyl absorption is increased by heat (e.g. hot water bottle) or pyrexia, potentially leading to opioid toxicity

Important for me Less important

Transdermal fentanyl absorption is increased by heat or pyrexia (which results in vasodilation and increased blood flow), potentially leading to opioid toxicity. This is therefore the correct option.

Acidosis is incorrect. Acidosis is not known to exacerbate opioid toxicity.

Renal dysfunction is incorrect. Fentanyl is hepatically metabolised by CYP450 3A4 with no active metabolites. Therefore it is the opioid of choice in renal failure.

Liver dysfunction is incorrect. Although the patient has a mild transaminitis, their synthetic liver function is normal, making it an unlikely contributing factor.

Piperacillin/tazobactam is incorrect. Fentanyl has no known interactions with piperacillin/tazobactam.

- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
    - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
    - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	Usually persistent
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 5 of 43

A 63-year-old woman presents with unrelenting thoracic back pain. She finds that the pain is debilitating, especially as she helps look after her grandchildren. She has a past medical history of breast cancer diagnosed two years ago, for which she underwent a mastectomy with reconstruction. She also had postoperative radiotherapy and endocrine therapy. As she was found to be BRCA1 positive, she underwent a hysterectomy with bilateral oophorectomy as well. On examination, she is tender over the spine at T4, but neurological examination is unremarkable. What is the most appropriate imaging investigation for her back pain?

- ○ MRI of the whole spine within 7 days
- ○ MRI of the thoracic spine within 7 days
- ○ MRI of the whole spine within 24 hours
- ○ MRI of the thoracic spine within 24 hours
- ○ Bone scan of the whole body within 7 days

A 63-year-old woman presents with unrelenting thoracic back pain. She finds that the pain is debilitating, especially as she helps look after her grandchildren. She has a past medical history of breast cancer diagnosed two years ago, for which she underwent a mastectomy with reconstruction. She also had postoperative radiotherapy and endocrine therapy. As she was found to be BRCA1 positive, she underwent a hysterectomy with bilateral oophorectomy as well. On examination, she is tender over the spine at T4, but neurological examination is unremarkable. What is the most appropriate imaging investigation for her back pain?

MRI of the whole spine within 7 days	40%
MRI of the thoracic spine within 7 days	6%
MRI of the whole spine within 24 hours	45%
MRI of the thoracic spine within 24 hours	5%
Bone scan of the whole body within 7 days	4%

The correct answer is MRI whole spine within 7 days. This is a patient with known cancer presenting with highly suspicious back pain but no evidence of spinal cord compression. The most appropriate modality is MRI which can not only detect metastasis but also demonstrate patency or compression of the spinal cord. The whole spine should be scanned as to exclude further metastasis as 30-50% of patients have multi-level involvement by the time of presentation. The timing of the scan depends on suspicion of cord compression. For this patient, there is no evidence of neurological compromise and therefore the scan does not have to occur within 24 hours.

Discuss (4) | Improve

Next question >

Spinal metastases ★

Patients may present with spinal metastases before developing metastatic spinal cord compression. It is, therefore, important to detect these patients early before any neurological compromise develops.

Symptoms and findings

- Unrelenting lumbar back pain
- Any thoracic or cervical back pain
- Worse with sneezing, coughing or straining
- Nocturnal
- Associated with tenderness

If any neurological features are present then spinal cord compression must be suspected and acted on promptly. Without neurological features, a whole spine MRI should be completed within one week. The whole spine should be imaged as patients commonly present with multi-level disease.

Question 6 of 43

You are looking after a 68-year-old man with aggressive multiple myeloma. He has intractable vomiting which has not improved with regular subcutaneous metoclopramide.

Blood results are as follows:

Calcium	4.2 mmol/L	(2.1-2.6)

You decide to start him on a syringe driver. What would be your anti-emetic of choice?

○ Aprepitant

○ Cyclizine

○ Levomepromazine

○ Nabilone

○ Ondansetron

You are looking after a 68-year-old man with aggressive multiple myeloma. He has intractable vomiting which has not improved with regular subcutaneous metoclopramide.

Blood results are as follows:

Calcium	4.2 mmol/L	(2.1-2.6)

You decide to start him on a syringe driver. What would be your anti-emetic of choice?

Aprepitant	9%
Cyclizine	13%
🟩 Levomepromazine	46%
Nabilone	1%
🟥 Ondansetron	31%

Metabolic causes of nausea and vomiting, for example uraemia and hypercalcaemia, cause nausea and vomiting by stimulating dopamine type 2 (D2) receptors on the chemoreceptor trigger zone. This pathway is most effectively blocked by using a central dopamine antagonist such as haloperidol

Important for me   Less important

Metabolic causes of nausea and vomiting (e.g. hypercalcaemia) are particularly sensitive to central dopamine antagonists such as **levomepromazine** making this the favoured choice.

Levomepromazine is a very broad spectrum anti-emetic that acts as an antagonist to multiple receptors including histamine type 1, muscarinic-cholinergic, dopaminergic 2, alpha-1 adrenoceptor, and 5HT-2 receptors. Thus it is a powerful anti-emetic that can be used in many scenarios.

Aprepitant is a substance P/neurokinin 1 receptor antagonist used to prevent chemotherapy-induced and postoperative nausea and vomiting. The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Cyclizine is a histamine H1-receptor antagonist which may have effects directly on the vestibular system and on the chemoreceptor trigger zone. It also exerts a central anticholinergic action The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Ondansetron is a specific 5HT3-receptor antagonist which blocks 5HT3 receptors in the gastrointestinal tract and in the CNS. The patient in this clinical case has nausea secondary to a metabolic abnormality, and thus a dopamine antagonist is the preferred choice.

Nabilone is a synthetic cannabinoid which is used to treat nausea and vomiting caused by cytotoxic chemotherapy, which is unresponsive to conventional antiemetics.

Syringe drivers ★

A syringe driver should be considered in the palliative care setting when a patient is unable to take oral medication due to nausea, dysphagia, intestinal obstruction, weakness or coma. In the UK there are two main types of syringe driver:
- Graseby MS16A (blue): the delivery rate is given in mm per hour
- Graseby MS26 (green): the delivery rate is given in mm per 24 hours

The majority of drugs are compatible with water for injection although for the following drugs sodium chloride 0.9% is recommended:
- granisetron
- ketamine
- ketorolac
- octreotide
- ondansetron

Commonly used drugs
- nausea and vomiting: cyclizine, levomepromazine, haloperidol, metoclopramide
- respiratory secretions/bowel colic: hyoscine hydrobromide, hyoscine butylbromide, or glycopyrronium bromide.
- agitation/restlessness: midazolam, haloperidol, levomepromazine
- pain: diamorphine is the preferred opioid

Mixing and compatibility issues
- diamorphine is compatible with the majority of other drugs used including dexamethasone, haloperidol, hyoscine butylbromide, hyoscine hydrobromide, levomepromazine, metoclopramide, midazolam
    - cyclizine may precipitate with diamorphine when given at higher doses

- cyclizine is incompatible with a number of drugs including clonidine, dexamethasone, hyoscine butylbromide (occasional), ketamine, ketorolac, metoclopramide, midazolam, octreotide, sodium chloride 0.9%

Question 7 of 43

A 54-year-old-man with a history of granulomatosis with polyangiitis attends for his annual review in the rheumatology clinic. He was diagnosed at age 35 where he presented with rapidly progressive glomerulonephritis and pulmonary haemorrhage and was treated with cyclophosphamide and steroids. He required a period of haemofiltration on the intensive care unit but has remained well since.

Today, he feels well after recently quitting smoking but reports occasional blood in his urine. On examination, his abdomen is soft and non tender, there is no pallor or oedema and his chest is clear. His investigations are below and his urine appears clear.

Hb	105 g/l
Platelets	300* 10^9/l
WBC	5* 10^9/l
Urinalysis	blood 3+ protein -
Na$^+$	139 mmol/l
K$^+$	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	98 µmol/l

What is his likely diagnosis?

○ Recurrence of glomerulonephritis

○ Transitional cell carcinoma

○ Renal calculi

○ Faulty urinalysis recording

○ Rhabdomyolysis

Submit answer

He was diagnosed at age 35 where he presented with rapidly progressive glomerulonephritis and pulmonary haemorrhage and was treated with cyclophosphamide and steroids. He required a period of haemofiltration on the intensive care unit but has remained well since.

Today, he feels well after recently quitting smoking but reports occasional blood in his urine. On examination, his abdomen is soft and non tender, there is no pallor or oedema and his chest is clear. His investigations are below and his urine appears clear.

Hb	105 g/l
Platelets	300* 10^9/l
WBC	5* 10^9/l
Urinalysis	blood 3+ protein -
Na^+	139 mmol/l
K^+	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	98 µmol/l

What is his likely diagnosis?

Recurrence of glomerulonephritis	12%
Transitional cell carcinoma	79%
Renal calculi	4%
Faulty urinalysis recording	3%
Rhabdomyolysis	2%

Use of cyclophosphamide in granulomatosis with polyangiitis is associated with increased risk of bladder cancer

Important for me Less important

The use of cyclophosphamide is linked to transitional cell carcinoma in patients with vasculitis. Given that his U&Es are normal, a recurrence of glomerulonephritis is unlikely. Renal calculi would cause loin to groin pain. Haematuria can often not be visible to the eye even when present. While rhabdomyolysis could give a positive dipstick, there are no other features to suggest this

Discuss (3) | Improve

Next question

Cyclophosphamide

Cyclophosphamide is an alkylating agent used in the management of cancer and autoimmune conditions. It works by causing cross-linking of DNA

Adverse effects

- haemorrhagic cystitis: incidence reduced by the use of hydration and mesna
- myelosuppression
- transitional cell carcinoma

Mesna

- 2-**me**rcaptoethane **s**ulfonate **Na**
- a metabolite of cyclophosphamide called acrolein is toxic to urothelium
- mesna binds to and inactivates acrolein helping to prevent haemorrhagic cystitis

A 68-year-old man is admitted to the unit with an exacerbation of severe pain around his abdomen. He describes it as a tight band like pain which is burning in character. He has a past medical history of metastatic prostate cancer. His drug history includes morphine modified release (100mg, twice daily), duloxetine (60mg, twice daily), pregabalin (200mg, three times per day). He states that the pain initially responded well to the analgesics he is on however over the past few weeks it has got progressively worse and culminated in a severe attack of pain today.

You suspect that he has got severe neuropathic pain secondary to spinal metastases. The pain is now poorly controlled with a large dose of opioids and two neuropathic agents. Your consultant decides to start him on ketamine.

What acute complication is it important to monitor for?

- ○ Bladder dysfunction
- ○ Liver dysfunction
- ○ Raised intracranial pressure
- ○ Cardiomyopathy
- ○ Pulmonary fibrosis

He states that the pain initially responded well to the analgesics he is on however over the past few weeks it has got progressively worse and culminated in a severe attack of pain today.

You suspect that he has got severe neuropathic pain secondary to spinal metastases. The pain is now poorly controlled with a large dose of opioids and two neuropathic agents. Your consultant decides to start him on ketamine.

What acute complication is it important to monitor for?

Bladder dysfunction	27%
Liver dysfunction	20%
🟩 Raised intracranial pressure	42%
Cardiomyopathy	9%
🟥 Pulmonary fibrosis	2%

Ketamine can cause raised intracranial pressure. It is important to monitor for side effects such as headache, papilloedema, and vomiting

Important for me Less important

Ketamine can be used for neuropathic pain poorly responsive to titrated opioids and oral adjuvant analgesics (e.g. antidepressant and/or anticonvulsant) particularly when there is abnormal pain sensitivity (e.g. allodynia, hyperalgesia or hyperpathia). Ketamine is an NMDA receptor antagonists. Side effects to be aware of include hypertension, raised intracranial pressure and hallucinations.

Bladder and liver dysfunction can occur with long term use of ketamine. Therefore, if a patient is anticipated to have a reasonably good prognosis, alternative options should be considered to replace the ketamine, for example lidocaine infusions.

Question 9 of 43

A medical consult was sought from the nursing staff concerning a 68-year-old gentleman admitted with a urinary tract infection. He was diagnosed with terminal adenocarcinoma of the pancreas six months ago. He had complained of increasing severe abdominal pain for the last few weeks for which his GP commenced and then titrated morphine sulphate tablets (MST) achieving a temporary analgesic effect with each increment. By the time of admission he had been using 150mg BD and was unable to tolerate any further dose increases owing to drowsiness.

His drug history comprised of ciprofloxacin 250mg BD started four days ago for the management of urinary tract infection, paracetamol 1g QDS, tramadol 100mg QDS, MST 150mg BD, senna 2 tabs ON & Movicol one sachet BD.

In view of the continuing abdominal pain investigations were organised by the inpatient team revealing the following findings:

Hb	135 g/l
Platelets	224 * 10^9/l
WBC	11.2 * 10^9/l

Bilirubin	23 µmol/l
ALP	189 u/l
ALT	326 u/l
γGT	178 u/l
Albumin	34 g/l

Chest x-ray: Normal heart borders and lung fields, no evidence of subdiaphragmatic air.
Abdominal x-ray: presence of faeces, no evidence of dilatation.
USS abdomen: multiple hypoechoic lesions within the liver, nil else abnormal noted.

What is the next most appropriate management option?

- ○ Commence syringe driver containing diamorphine ×
- ○ Refer for immediate surgical consult ×
- ○ Refer for palliative radiotherapy ×
- ○ Convert MST to fentanyl ×

○ Commence trial with dexamethasone ×

A medical consult was sought from the nursing staff concerning a 68-year-old gentleman admitted with a urinary tract infection. He was diagnosed with terminal adenocarcinoma of the pancreas six months ago. He had complained of increasing severe abdominal pain for the last few weeks for which his GP commenced and then titrated morphine sulphate tablets (MST) achieving a temporary analgesic effect with each increment. By the time of admission he had been using 150mg BD and was unable to tolerate any further dose increases owing to drowsiness.

His drug history comprised of ciprofloxacin 250mg BD started four days ago for the management of urinary tract infection, paracetamol 1g QDS, tramadol 100mg QDS, MST 150mg BD, senna 2 tabs ON & Movicol one sachet BD.

In view of the continuing abdominal pain investigations were organised by the inpatient team revealing the following findings:

Hb	135 g/l
Platelets	224 * 10^9/l
WBC	11.2 * 10^9/l

Bilirubin	23 µmol/l
ALP	189 u/l
ALT	326 u/l
γGT	178 u/l
Albumin	34 g/l

Chest x-ray: Normal heart borders and lung fields, no evidence of subdiaphragmatic air.
Abdominal x-ray: presence of faeces, no evidence of dilatation.
USS abdomen: multiple hypoechoic lesions within the liver, nil else abnormal noted.

What is the next most appropriate management option?

Commence syringe driver containing diamorphine	20%
Refer for immediate surgical consult	4%
Refer for palliative radiotherapy	10%
Convert MST to fentanyl	19%

Commence trial with dexamethasone 47%

This gentleman has evidence of extensive hepatic metastases most probably arising from known adenocarcinoma of the pancreas. Despite an escalating opiate regimen he is unable to obtain satisfactory pain relief. One of the sources of pain associated with liver metastases is due to stretching and irritation of the liver capsule for which a trial of dexamethasone may provide an analgesic effect. Option 5 is, therefore, the most suitable option.

There is no evidence of obstruction or perforation and thus a surgical consult is not warranted, and palliative radiotherapy is not specifically indicated here (in contrast with bone metastases).

Switching to fentanyl will probably not provide any additional benefit in terms of tolerance compared with MST; it is however indicated in patients with poor renal failure owing to its predominant hepatic route of metabolism. For further information:

http://www.ruh.nhs.uk/ForClinicians/departmentsruh/PalliativeCare/documents/palliativecarehandbook.pd provides a helpful guide for prescribing in palliative settings.

Next question >

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment
- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
    - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
    - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	**To**	**Conversion factor**
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Back to top

A medical consult was sought regarding a 58-year-old gentleman admitted with pneumonia complaining of relentless hiccups. He was diagnosed with hepatocellular carcinoma six months ago and was deemed not for curative treatment owing to the extent of the disease. He was initially comfortable with no discernible symptoms but over the last four weeks developed hiccups. In conjunction with the palliative care nurse his GP had initially trialled domperidone and then haloperidol but with no improvement in his symptoms. He denied the presence of any other symptoms other than fatigue, and upon questioning denied the presence of abdominal pain, heartburn or early satiety.

His past medical history was comprised of alcohol dependence syndrome, chronic liver disease, hypertension and hypercholesterolaemia for which he was prescribed thiamine 100mg TDS, lactulose 10mls BD, spironolactone 100mg OD, propranolol 40mg OD, simvastatin 20mg OD as well as intravenous co-amoxiclav 625mg TDS for the treatment of his pneumonia.
Examination revealed the presence of a cachectic male. His blood pressure was 108/58 mmHg, heart rate 78 bpm, respiratory rate 18/min and temperature 36.6ºC. Examination of his gastrointestinal system revealed the presence of a palpable mass in the right upper quadrant inferior to the right sterna edge and ascites with no tenderness. Examination of his neurological system revealed the absence of any focal neurological symptoms; likewise, examination of cardiovascular and respiratory systems was unremarkable.

Recent investigations revealed the following results:

Bilirubin	22 µmol/l
ALP	221 u/l
ALT	278 u/l
Protein	62 g/l
Albumin	18 g/l

Chest x-ray: normal heart borders and lung fields

Surveillance upper GI endoscopy four months ago: normal stomach mucosal surface, no evidence of portal hypertension

Which of the following options is the best option with a view to managing his hiccups?

○ Commence treatment with proton pump inhibitor ×

○ Commence treatment with levomepromazine ×

○ Commence treatment with dexamethasone ×

○ Commence treatment with midazolam infusion ×

○ Commence treatment with baclofen ×

Question 10 of 43 ✗

A medical consult was sought regarding a 58-year-old gentleman admitted with pneumonia complaining of relentless hiccups. He was diagnosed with hepatocellular carcinoma six months ago and was deemed not for curative treatment owing to the extent of the disease. He was initially comfortable with no discernible symptoms but over the last four weeks developed hiccups. In conjunction with the palliative care nurse his GP had initially trialled domperidone and then haloperidol but with no improvement in his symptoms. He denied the presence of any other symptoms other than fatigue, and upon questioning denied the presence of abdominal pain, heartburn or early satiety.

His past medical history was comprised of alcohol dependence syndrome, chronic liver disease, hypertension and hypercholesterolaemia for which he was prescribed thiamine 100mg TDS, lactulose 10mls BD, spironolactone 100mg OD, propranolol 40mg OD, simvastatin 20mg OD as well as intravenous co-amoxiclav 625mg TDS for the treatment of his pneumonia.
Examination revealed the presence of a cachectic male. His blood pressure was 108/58 mmHg, heart rate 78 bpm, respiratory rate 18/min and temperature 36.6ºC. Examination of his gastrointestinal system revealed the presence of a palpable mass in the right upper quadrant inferior to the right sterna edge and ascites with no tenderness. Examination of his neurological system revealed the absence of any focal neurological symptoms; likewise, examination of cardiovascular and respiratory systems was unremarkable.

Recent investigations revealed the following results:

Bilirubin	22 µmol/l
ALP	221 u/l
ALT	278 u/l
Protein	62 g/l
Albumin	18 g/l

Chest x-ray: normal heart borders and lung fields

Surveillance upper GI endoscopy four months ago: normal stomach mucosal surface, no evidence of portal hypertension

Which of the following options is the best option with a view to managing his hiccups?

Commence treatment with proton pump inhibitor	2%
Commence treatment with levomepromazine	38%

Commence treatment with dexamethasone	36%
Commence treatment with midazolam infusion	3%
Commence treatment with baclofen	22%

This gentleman has known advanced hepatocellular carcinoma and is complaining of distressing hiccups. He does not have any sign of gastro-oesophageal reflux and therefore a trial of proton pump inhibitor is unlikely to be of benefit. In the presence of hepatic or cerebral cancer a trial of dexamethasone may induce some remission and is therefore suggested as an appropriate next line given he has already had a trial of treatment with a prokinetic and a typical antipsychotic with no remission; see http://www.palliativecareguidelines.scot.nhs.uk/guidelines/symptom-control/Hiccups.aspx for further information. There is also limited evidence for treatment with baclofen and levomepromazine; subcutaneous midazolam should be reserved if all else proves futile. Note also the BNF has a very useful section regarding prescribing in palliative care scenarios; in this instance it also suggests the use of antacids or nifedipine in addition to the above options.

Discuss (6) Improve

Next question

Palliative care prescribing: hiccups

Management of hiccups

- chlorpromazine is licensed for the treatment of intractable hiccups
- haloperidol, gabapentin are also used
- dexamethasone is also used, particularly if there are hepatic lesions

A 47-year-old woman presents to the emergency department with sudden onset of shortness of breath and pleuritic chest pain. Observations demonstrate marked hypoxia and she is given oxygen and analgesia and undergoes a chest X-ray followed by a CT pulmonary angiogram which shows a pulmonary embolism. There is also an incidental finding of a nodule suspicious of metastatic disease.

She is started on a treatment dose of low molecular weight heparin and admitted under the medical team for further assessment. During a more detailed history, she explains that she has lost one stone in weight over two months and been feeling progressively more tired as well. She denies any other symptoms. She has a past medical history of asthma and also underwent a caesarean section three years ago. She has two children, of which she breastfed both, and has a long history of use of oral contraceptive use. She is an ex-smoker of 5 pack-years and has minimal alcohol intake. Her grandfather died of prostate cancer, and her sister developed breast cancer at the age of 52.

A complete further examination was completed and no abnormalities were found. Routine blood tests are currently pending, and a flexible bronchoscopy for biopsy of the lung nodule has been arranged. How should this patient be further investigated?

○ Tumour markers AFP and hCG, and mammography

○ CT abdomen and pelvis, tumour markers AFP and hCG, and a myeloma screen

○ Ultrasound abdomen and pelvis, and tumours marker AFP and hCG

○ CT abdomen and pelvis, and tumour markers AFP and hCG

○ CT abdomen and pelvis, myeloma screen, and colonoscopy

She has a past medical history of asthma and also underwent a caesarean section three years ago. She has two children, of which she breastfed both, and has a long history of use of oral contraceptive use. She is an ex-smoker of 5 pack-years and has minimal alcohol intake. Her grandfather died of prostate cancer, and her sister developed breast cancer at the age of 52.

A complete further examination was completed and no abnormalities were found. Routine blood tests are currently pending, and a flexible bronchoscopy for biopsy of the lung nodule has been arranged. How should this patient be further investigated?

Tumour markers AFP and hCG, and mammography	22%
CT abdomen and pelvis, tumour markers AFP and hCG, and a myeloma screen	21%
Ultrasound abdomen and pelvis, and tumours marker AFP and hCG	5%
CT abdomen and pelvis, and tumour markers AFP and hCG	46%
CT abdomen and pelvis, myeloma screen, and colonoscopy	7%

The correct answer is CT abdomen and pelvis, and tumour markers AFP and hCG. These investigations complete all those recommended by NICE for an unknown primary. This question highlights how to investigate a malignancy of unknown origin. This patient has a likely metastatic disease causing a pulmonary embolism with unclear clinical findings as to the location of the primary malignancy.

NICE recommends the following investigations for all patients:

- FBC, U&E, LFT, calcium, urinalysis, LDH
- Chest X-ray
- CT of chest, abdomen and pelvis
- AFP and hCG

NICE recommends the following investigations for specific patients:
- Myeloma screen (if lytic bone lesions)
- Endoscopy (directed towards symptoms)
- PSA (men)
- CA 125 (women with peritoneal malignancy or ascites)
- Testicular US (in men with germ cell tumours)
- Mammography (in women with clinical or pathological features compatible with breast cancer)

A is incorrect because it does not include CT scanning of the abdomen and pelvis. Mammography is tempting but NICE does not recommend it without any clinical findings which are suggestive of a breast malignancy. B and E are incorrect because a myeloma screen is not indicated without lytic bone lesions. E is also incorrect as colonoscopy should be symptom directed. C is incorrect as US is not an appropriate investigation.

Question 12 of 43

A 62-year-old lady with metastatic breast cancer is admitted with a general decline. She is found to have a pneumonia and treated with IV fluids and antibiotics. She makes limited improvement with these and antibiotics are stopped. The decision is made to focus on control of her symptoms.

She is started on a syringe driver of morphine sulphate to treat breathlessness and pain related to liver metastases. She then develops nausea and hiccups.

Which medication is the best choice to add to the syringe driver?

○ Cyclizine

○ Domperidone

○ Midazolam

○ Metoclopramide

○ Ondansetron

Question 12 of 43

A 62-year-old lady with metastatic breast cancer is admitted with a general decline. She is found to have a pneumonia and treated with IV fluids and antibiotics. She makes limited improvement with these and antibiotics are stopped. The decision is made to focus on control of her symptoms.

She is started on a syringe driver of morphine sulphate to treat breathlessness and pain related to liver metastases. She then develops nausea and hiccups.

Which medication is the best choice to add to the syringe driver?

Cyclizine	16%
Domperidone	16%
Midazolam	14%
Metoclopramide	40%
Ondansetron	15%

Cyclizine, domperidone and ondansetron are anti-emetics, though domperidone does not come in a subcutaneous preparation for syringe driver. Midazolam is an anxiolytic.

Metoclopramide is the first choice to treat hiccup as well as nausea. Other options include baclofen, nifedipine and chlorpromazine.

Question 13 of 43

A 60-year-old man has been admitted under urology with difficulty passing urine and back pain. A post-void bladder scan shows 980mls in his bladder. He was catheterised by the admitting doctor and now has haematuria.

He has a background of metastatic prostate cancer, atrial fibrillation, previous NSTEMI, hypertension, hypercholesterolaemia and hypothyroidism. His medications include warfarin and modified-release morphine 30mg every 12 hours.

He has been seen by the urology consultant who has said to put a 3-way catheter in if the haematuria does not settle and refer to the palliative care team for pain management. The palliative care specialist advised increasing the modified release morphine to 45mg every 12 hours.

What dose of immediate-release morphine should the patient be prescribed for breakthrough pain?

- ○ 5mg
- ○ 7.5mg
- ○ 10mg
- ○ 15mg
- ○ 20mg

Question 13 of 43

A 60-year-old man has been admitted under urology with difficulty passing urine and back pain. A post-void bladder scan shows 980mls in his bladder. He was catheterised by the admitting doctor and now has haematuria.

He has a background of metastatic prostate cancer, atrial fibrillation, previous NSTEMI, hypertension, hypercholesterolaemia and hypothyroidism. His medications include warfarin and modified-release morphine 30mg every 12 hours.

He has been seen by the urology consultant who has said to put a 3-way catheter in if the haematuria does not settle and refer to the palliative care team for pain management. The palliative care specialist advised increasing the modified release morphine to 45mg every 12 hours.

What dose of immediate-release morphine should the patient be prescribed for breakthrough pain?

5mg	3%
7.5mg	6%
10mg	10%
15mg	80%
20mg	2%

Breakthrough dose = 1/6th of daily morphine dose

Important for me Less important

To answer this question, you need to calculate the total daily dose of morphine. The amount of immediate-release morphine for breakthrough pain should be one-sixth (1/6) of the total daily dose.

The patient was previously on 60mg of morphine per day. One-sixth of this would be 10mg of immediate-release morphine for breakthrough pain.

The modified release morphine has now been up titrated to 90mg per day. Whenever background morphine is increased, it is important to calculate the new breakthrough pain dosage for patients to receive the maximal benefit. In this case, one-sixth of 90 is 15mg. Therefore the correct answer is 15mg of immediate-release morphine.

👍 👎 Discuss (1) Improve

Next question ›

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment

- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
  - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
  - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however,

should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	**To**	**Conversion factor**
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	**To**	**Conversion factor**
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

You are looking after an 82-year-old man with a background of metastatic colorectal carcinoma. He is in significant pain and is on a syringe driver containing 6mg of alfentanil. He has end-stage renal failure.

What breakthrough analgesic will you prescribe?

1mg subcutaneous alfentanil	74%
25mg subcutaneous morphine	4%
25mg subcutaneous oxycodone	12%
2mg subcutaneous alfentanil	7%
50mg subcutaneous oxycodone	2%

Breakthrough dose = 1/6th of daily morphine dose

Important for me Less important

Palliative care guidelines recommend using 1/6 of the daily dose as a breakthrough. Alfentanil is a potent drug and is particularly useful in renal failure as it is metabolised by the liver, has no active metabolites, and has a very short half-life.

Next question >

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment

- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
    - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
    - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 15 of 43

An 82-year-old man is reviewed by the palliative care team on the ward. He has a past medical history of metastatic lung cancer. He is not for any further chemotherapy, surgery or radiotherapy. He has deteriorated rapidly in the prior few days and is considered to be in the last days of life. He is suffering from intractable nausea, the cause of which is not clear.

What is the most appropriate medication to manage his symptoms?

- ○ Buscopan
- ○ Levomepromazine
- ○ Metoclopramide
- ○ Morphine
- ○ Ondansetron

Question 15 of 43

An 82-year-old man is reviewed by the palliative care team on the ward. He has a past medical history of metastatic lung cancer. He is not for any further chemotherapy, surgery or radiotherapy. He has deteriorated rapidly in the prior few days and is considered to be in the last days of life. He is suffering from intractable nausea, the cause of which is not clear.

What is the most appropriate medication to manage his symptoms?

Buscopan	1%
Levomepromazine	55%
Metoclopramide	18%
Morphine	3%
Ondansetron	22%

Levomepromazine is a 'dirty drug' which blocks lots of different receptors (e.g. ACh, DA, 5HT). It is therefore a broad spectrum anti-emetic. It is first line in the last days of life.

Levomepromazine is correct. This is a broad-spectrum anti-emetic - a 'dirty drug' targeting many receptors. It is therefore the most suitable choice where the cause of nausea is unknown and in the last days of life.

Buscopan is incorrect. This is indicated in palliative care for excess secretions rather than nausea.

Metoclopramide is incorrect. This would be a rational choice for nausea due to gastric stasis. However, where the cause is unknown and in the last days of life, a more broad spectrum anti-emetic is preferred. Therefore, levomepromazine is preferable.

Morphine is incorrect. This is indicated in palliative care for breathlessness and pain rather than nausea.

Ondansetron is incorrect. This is a rational choice for chemotherapy or post-operative related nausea. However, it is a specific serotonin 5-HT3 receptor antagonist, with a low affinity for dopamine receptors and therefore has a more narrow spectrum of action than levomepromazine and is, therefore, less preferable in this circumstance.

Discuss (1) Improve

Next question

Syringe drivers

A syringe driver should be considered in the palliative care setting when a patient is unable to take oral medication due to nausea, dysphagia, intestinal obstruction, weakness or coma. In the UK there are two main types of syringe driver:

- Graseby MS16A (blue): the delivery rate is given in mm per hour
- Graseby MS26 (green): the delivery rate is given in mm per 24 hours

The majority of drugs are compatible with water for injection although for the following drugs sodium chloride 0.9% is recommended:

- granisetron
- ketamine
- ketorolac
- octreotide
- ondansetron

Commonly used drugs

- nausea and vomiting: cyclizine, levomepromazine, haloperidol, metoclopramide
- respiratory secretions/bowel colic: hyoscine hydrobromide, hyoscine butylbromide, or glycopyrronium bromide.
- agitation/restlessness: midazolam, haloperidol, levomepromazine
- pain: diamorphine is the preferred opioid

Mixing and compatibility issues

- diamorphine is compatible with the majority of other drugs used including dexamethasone, haloperidol, hyoscine butylbromide, hyoscine hydrobromide, levomepromazine, metoclopramide, midazolam
    - cyclizine may precipitate with diamorphine when given at higher doses
- cyclizine is incompatible with a number of drugs including clonidine, dexamethasone, hyoscine butylbromide (occasional), ketamine, ketorolac, metoclopramide, midazolam, octreotide, sodium chloride 0.9%

Question 16 of 43

A 65-year-old woman presents to the emergency department with reduced consciousness. Her husband reports that she has been unwell for the past 3 days with coryzal symptoms. She has a past medical history of hypertension and metastatic pancreatic cancer for which she is under the palliative care team. Her regular medications include amlodipine, bisoprolol, paracetamol and a fentanyl patch for pain.

On examination, her temperature is 38.1ºC with a heart rate of 101 beats/min and a blood pressure of 118/66mmHg. Auscultation of the chest is clear with a respiratory rate of 8 breaths/min and oxygen saturations of 92% on air. Her abdomen is soft and non-tender and she is visibly jaundiced. She has a GCS of 11/15 (E2V4M5).

What is the most likely cause of this patient's reduced consciousness?

- ○ Delirium ×
- ○ Hepatic encephalopathy ×
- ○ Hypoglycaemia ×
- ○ Meningitis ×
- ○ Opioid toxicity ×

Her regular medications include amlodipine, bisoprolol, paracetamol and a fentanyl patch for pain.

On examination, her temperature is 38.1ºC with a heart rate of 101 beats/min and a blood pressure of 118/66mmHg. Auscultation of the chest is clear with a respiratory rate of 8 breaths/min and oxygen saturations of 92% on air. Her abdomen is soft and non-tender and she is visibly jaundiced. She has a GCS of 11/15 (E2V4M5).

What is the most likely cause of this patient's reduced consciousness?

Delirium	8%
Hepatic encephalopathy	16%
Hypoglycaemia	2%
Meningitis	3%
Opioid toxicity	72%

Transdermal fentanyl absorption is increased by heat (e.g. hot water bottle) or pyrexia, potentially leading to opioid toxicity

Important for me Less important

Opioid toxicity is correct. This patient has signs of opioid toxicity including drowsiness and a slow respiratory rate. There are multiple differential diagnoses for an acutely unresponsive patient and, therefore, it is key to take a thorough history and examination. From this patient's collateral history it is learned that she uses a fentanyl patch for pain control. It is important to note that transdermal fentanyl absorption is increased by heat whether that be secondary to the application of a hot water bottle or pyrexia. This patient has a fever of 38.1ºC which is a likely contributing factor to her toxicity.

Delirium is incorrect. This is a very reasonable differential diagnosis given the history of fever in a patient with a frail comorbid status. However, delirium is less likely to cause this patient's reduced respiratory rate compared to opioid toxicity. Generally, fever is associated with tachypnoea and the opposite response should raise suspicion.

Hepatic encephalopathy is incorrect. Although this patient is jaundiced, it is likely to be cholestatic jaundice secondary to the underlying malignancy rather than decompensated liver disease. Furthermore, the acute onset of symptoms and lack of signs of hepatic encephalopathy makes the diagnosis less likely.

Hypoglycaemia is incorrect. This is an important differential diagnosis given the history of advanced malignancy and the likelihood of reduced oral intake. However, the presence of bradypnoea and opioid use makes opioid toxicity more likely.

Meningitis is incorrect. Fever and reduced consciousness are features of meningitis. However, the presence of bradypnoea and the use of strong opioid analgesics make opioid toxicity more likely.

Question 17 of 43

A 56-year-old man with metastatic small cell lung carcinoma is admitted to hospital with vomiting, ankle swelling and pruritus. He recently completed a course of palliative chemotherapy. He has a background of chronic obstructive pulmonary disease and hypertension and takes morphine sulphate (MST) for pain relief.

On examination, he is cachectic with peripheral oedema and skin excoriations. Heart rate is 96 beats per minute and blood pressure is 140/85 mmHg.

Tests show:

Hb	134 g/l
Platelets	185 * 10^9/l
WBC	5.5 * 10^9/l

Na^+	146 mmol/l
K^+	5.4 mmol/l
Urea	23 mmol/l
Creatinine	420 µmol/l

Urine dip:	Blood +
Urine osmolality	350 mOsm/L
Urinary sodium	45 mEqL
Microscopy:	red cells; casts.

What is the most appropriate pain relief for this patient?

- ○ Fentanyl patch ×
- ○ Diamorphine ×
- ○ Oxycodone ×
- ○ Pregabalin ×
- ○ Tramadol ×

Submit answer

He has a background of chronic obstructive pulmonary disease and hypertension and takes morphine sulphate (MST) for pain relief.

On examination, he is cachectic with peripheral oedema and skin excoriations. Heart rate is 96 beats per minute and blood pressure is 140/85 mmHg.

Tests show:

Hb	134 g/l
Platelets	185 * 10^9/l
WBC	5.5 * 10^9/l

Na^+	146 mmol/l
K^+	5.4 mmol/l
Urea	23 mmol/l
Creatinine	420 µmol/l

Urine dip:	Blood +
Urine osmolality	350 mOsm/L
Urinary sodium	45 mEqL
Microscopy:	red cells; casts.

What is the most appropriate pain relief for this patient?

Fentanyl patch	56%
Diamorphine	5%
Oxycodone	36%
Pregabalin	1%
Tramadol	1%

This patient has an acute kidney injury secondary to cisplatin chemotherapy. As a result, he needs adjustments to his pain relief. He is on regular, long-acting MST, so the most appropriate substitution is a fentanyl patch.

Oxycodone can be used in moderate renal failure, but only as breakthrough pain relief. Modified release preparations should be avoided. Diamorphine and tramadol should be avoided in renal failure. Pregabalin can be administered at reduced dose, but would not be an appropriate first-line substitution for MST.

Alfentanil and methadone are safe even in severe renal impairment and are administered subcutaneously. Alfentanil would be appropriate for this patient if he had unstable pain and required dose titration.

Question 18 of 43

A 69-year-old male patient presents with worsening mouth soreness and painful swallowing, progressively getting worse over the last week. He started radical radiotherapy for a base of mouth squamous cell cancer three weeks ago. He also has a PEG in situ. He was recently seen by the dietician and is now having fluid and Ensure nutritional supplements via his PEG. He had been given soluble paracetamol by the specialist nurse, but this has failed to control his pain.

On examination, his oral cavity appears inflamed with multiple small ulcers posterior to his lower lip. There are no patches or plaques inside. You change the paracetamol to liquid co-codamol and give him a topical lidocaine gel at 2% strength. What is the most appropriate next step in management to control his symptoms?

- ○ Benzydamine mouthwash
- ○ Menthol mouthwash
- ○ Chlorhexidine mouthwash
- ○ Fluconazole
- ○ Metronidazole

He had been given soluble paracetamol by the specialist nurse, but this has failed to control his pain.

On examination, his oral cavity appears inflamed with multiple small ulcers posterior to his lower lip. There are no patches or plaques inside. You change the paracetamol to liquid co-codamol and give him a topical lidocaine gel at 2% strength. What is the most appropriate next step in management to control his symptoms?

Benzydamine mouthwash	60%
Menthol mouthwash	2%
Chlorhexidine mouthwash	31%
Fluconazole	6%
Metronidazole	1%

The correct answer is benzydamine mouthwash. This gentleman is suffering from radiotherapy-induced mucositis. Given the location of his tumour and the high dose of radiotherapy necessary for curative therapy, mucositis is not an uncommon side effect. Many of these patients will have a PEG inserted prophylactically in anticipation of the difficulties in maintaining an oral diet with mucositis and oesophageal involvement. For this patient, already on co-codamol, benzydamine mouthwash can be very helpful in treating his symptoms. Menthol and chlorhexidine mouthwashes, often bought over the counter, would increase oral irritation. There is no evidence of fungal or bacterial infection currently.

Discuss (6) Improve

Next question

Radiotherapy-induced mucositis

Many patients will suffer from mucositis following radiotherapy to the head and neck. Often these patients will have a PEG tube inserted prior to treatment to help maintain oral intake. Management of pain involves topical treatment such as local anaesthetic gels and benzydamine mouthwashes. Standard WHO based pain ladder should be followed, but medications should be in liquid form.

Question 19 of 43

A 75-year-old man is admitted to the palliative care unit for end of life care. He has a past medical history of metastatic prostate cancer. His drug history includes a syringe driver with morphine, levomepromazine and midazolam. During personal care the nurses have stated that he suffers excruciating pain when being turned onto his side. His pain throughout the day is otherwise well controlled.

What is the most appropriate way to manage his pain?

- ○ Titrate the syringe driver morphine ×
- ○ Morphine sulphate modified release tablets ×
- ○ Oxycodone modified release tablets ×
- ○ Morphine sulphate immediate release liquid ×
- ○ Paracetamol ×

A 75-year-old man is admitted to the palliative care unit for end of life care. He has a past medical history of metastatic prostate cancer. His drug history includes a syringe driver with morphine, levomepromazine and midazolam. During personal care the nurses have stated that he suffers excruciating pain when being turned onto his side. His pain throughout the day is otherwise well controlled.

What is the most appropriate way to manage his pain?

Titrate the syringe driver morphine	15%
Morphine sulphate modified release tablets	7%
Oxycodone modified release tablets	2%
Morphine sulphate immediate release liquid	74%
Paracetamol	2%

Incident pain is defined as pain which comes on as a result of an action or activity, for example during personal care. Sublingual fentanyl has rapid onset and is a short-acting opioid, and is therefore a good choice for treating this type of pain

Important for me Less important

Incident pain is defined as pain which comes on as a result of an action or activity, for example during personal care. Sublingual fentanyl has rapid onset and is a short-acting opioid, and is therefore a good choice for treating this type of pain. Similarly, morphine sulphate immediate release liquid is also suitable.

The patients pain during the day is otherwise well controlled therefore titrating up the syringe driver with more morphine is not appropriate. Not only will this not be particularly effective at treating the incident pain, it will also give rise to unnecessary side effects such as sedation and constipation.

Similarly, morphine sulphate modified release tablets have an action time of approximately 12 hours so they are therefore inappropriate for breakthrough pain as they will cause accumulation of morphine in the system predisposing to toxicity.

Discuss (4) Improve

Next question ›

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment

- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
    - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
    - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	**To**	**Conversion factor**
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	**To**	**Conversion factor**
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	**To**	**Conversion factor**
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 20 of 43

A 64-year-old cachectic lady presents to the emergency department with difficulty in breathing. She reports smoking since she was 14 years old. Chest X-Ray reveals a large right sided pleural effusion. A sample is obtained under ultrasound-guidance for evaluation. CT does not identify a cause. The results of the pleural aspiration demonstrate an exudative effusion and histology is suggestive of an adenocarcinoma with positive TTF-1 stain. What is the most likely cause for the effusion?

- ○ Non-small cell lung cancer ×
- ○ Small cell lung cancer ×
- ○ Ovarian carcinoma ×
- ○ Breast carcinoma ×
- ○ Mesothelioma ×

Question 20 of 43 ✗

A 64-year-old cachectic lady presents to the emergency department with difficulty in breathing. She reports smoking since she was 14 years old. Chest X-Ray reveals a large right sided pleural effusion. A sample is obtained under ultrasound-guidance for evaluation. CT does not identify a cause. The results of the pleural aspiration demonstrate an exudative effusion and histology is suggestive of an adenocarcinoma with positive TTF-1 stain. What is the most likely cause for the effusion?

Non-small cell lung cancer	43%
Small cell lung cancer	17%
Ovarian carcinoma	24%
Breast carcinoma	5%
Mesothelioma	10%

TTF-1 (thyroid transcription factor 1) is a protein which regulates the transcription of genes specific for the thyroid and lung. Lung adenocarcinomas and small cell carcinomas are usually TTF-1 positive. The histology in the above example is suggestive of an adenocarcinoma and therefore this is mostly likely a lung primary given the TTF-1 stain and history of smoking.

Non-small cell lung cancers include adenocarcinoma, large cell and squamous cell carcinoma.

Next question >

Lung cancer: non-small cell

There are three main subtypes of non-small cell lung cancer:

Squamous cell cancer

- typically central
- associated with parathyroid hormone-related protein (PTHrP) secretion → hypercalcaemia
- strongly associated with finger clubbing
- cavitating lesions are more common than other types
- hypertrophic pulmonary osteoarthropathy (HPOA)

Adenocarcinoma

- typically peripheral
- most common type of lung cancer in non-smokers, although the majority of patients who develop lung adenocarcinoma are smokers

Large cell lung carcinoma

- typically peripheral
- anaplastic, poorly differentiated tumours with a poor prognosis
- may secrete β-hCG

Question 21 of 43

A 76-year-old woman with metastatic transitional cell carcinoma of the bladder is admitted to hospice with a 3-day history of hallucinations, confusion and pruritus. Her only other symptoms are intermittent vomiting and pelvic discomfort. She has a past medical history of hypertension and has recently completed a course of radiotherapy for bone metastases. She takes paracetamol, morphine sulphate, cyclizine, dexamethasone and a herbal flower remedy for anxiety.

On examination, she is cachectic and frail. The lungs are clear and heart sounds are normal. Pulse rate is 85 beats per minute and blood pressure 130/80mmHg. She is afebrile.

Neurological examination reveals myoclonus. She is mildly hypotonic and all reflexes are diminished. There is miosis on cranial nerve examination.

Blood tests show:

Hb	12.1 g/dl
Platelets	250 * 10^9/l
WBC	12 * 10^9/l

Na^+	135 mmol/l
K^+	4.3 mmol/l
Urea	5 mmol/l
Creatinine	80 µmol/l
Calcium (unadjusted)	2.1 mmol/l

Bilirubin	15 µmol/l
ALP	45 u/l
ALT	15 u/l
AST	20 u/l
Albumin	28 g/l

Urine dip: no abnormality

What is the most likely diagnosis?

○ Hypercalcaemia

○ Opioid toxicity

○ Sepsis

○ Corticosteroid psychosis

○ Brain metastases

A 76-year-old woman with metastatic transitional cell carcinoma of the bladder is admitted to hospice with a 3-day history of hallucinations, confusion and pruritus. Her only other symptoms are intermittent vomiting and pelvic discomfort. She has a past medical history of hypertension and has recently completed a course of radiotherapy for bone metastases. She takes paracetamol, morphine sulphate, cyclizine, dexamethasone and a herbal flower remedy for anxiety.

On examination, she is cachectic and frail. The lungs are clear and heart sounds are normal. Pulse rate is 85 beats per minute and blood pressure 130/80mmHg. She is afebrile.

Neurological examination reveals myoclonus. She is mildly hypotonic and all reflexes are diminished. There is miosis on cranial nerve examination.

Blood tests show:

Hb	12.1 g/dl
Platelets	250 * 10^9/l
WBC	12 * 10^9/l

Na^+	135 mmol/l
K^+	4.3 mmol/l
Urea	5 mmol/l
Creatinine	80 µmol/l
Calcium (unadjusted)	2.1 mmol/l

Bilirubin	15 µmol/l
ALP	45 u/l
ALT	15 u/l
AST	20 u/l
Albumin	28 g/l

Urine dip: no abnormality

What is the most likely diagnosis?

Hypercalcaemia 8%

Opioid toxicity	60%
Sepsis	1%
Corticosteroid psychosis	16%
Brain metastases	15%

This lady is presenting with opioid toxicity. She has vomiting, confusion, hallucinations and pruritus. Her symptoms have been precipitated by a reduction in her opioid requirement. This is a common occurrence in patients who have radiotherapy for bone metastases if their medication dose is not adjusted.

Hypercalcaemia could cause a similar presentation, but the corrected calcium is 2.4 mmol/L. This lady is hypoalbuminaemic due to her advanced cancer. The patient no symptoms of infection. She is apyrexial and her slightly raised white cell count is due to her advanced disease and dexamethasone treatment. Corticosteroid psychosis is possible, but would not cause the neurological signs or pruritus. Transitional cell carcinomas of the urothelial tract only rarely metastasise to the brain; the neurological signs suggest opioid toxicity rather than a focal lesion.

A 65-year-old man is referred to the oncology team after presenting to the emergency department. The patient described a three-week history of progressive thoracic back pain. The pain was localised to a point between the patient's shoulder blades, and was exacerbated by movement and coughing.

In addition, over the previous 6 hours, the patient reported that he had been struggling to stand up unassisted, and was having difficultly walking. The sudden change in his mobility had been the event that had prompted his attendance at hospital. When questioned directly, the patient described intermittent tingling sensations in his lower legs, but denied any loss of sensation. There had been no dysfunction of his bladder or bowels.

The patient had been diagnosed with prostate cancer five years previously. This had been treated with a radical prostatectomy and hormone therapy. The patient had moved area two years previously, and had subsequently been lost to urological follow-up. Despite his previous cancer treatment, the patient stated that he was very fit and active, playing golf three times a week and taking an active role in the care of his grandchildren.

Peripheral nerve examination of lower limbs: tone generally increased bilaterally; power generally slightly reduced (4+/5) bilaterally; normal coordination; no impairment of light touch or sharp touch sensation; knee and ankle jerks brisk bilaterally, plantar responses up going bilaterally.

Digital rectal examination: preserved peri-anal sensation and normal tone.

Bed-side bladder scan: 50 ml

MRI whole spine: metastatic invasion and collapse of T10 vertebral with spinal cord compression.

The patient was treated with analgesia and dexamethasone while definitive treatment was planned.

What is most appropriate first-line treatment of patient's spinal cord compression?

- ○ Surgical tumour resection and spinal cord stabilisation with adjuvant radiotherapy ×
- ○ Radiotherapy: single dose 8 Gy ×
- ○ Chemotherapy: docetaxel ×
- ○ Best supportive care ×

○ Chemotherapy: cabazitaxel ×

A 65-year-old man is referred to the oncology team after presenting to the emergency department. The patient described a three-week history of progressive thoracic back pain. The pain was localised to a point between the patient's shoulder blades, and was exacerbated by movement and coughing.

In addition, over the previous 6 hours, the patient reported that he had been struggling to stand up unassisted, and was having difficultly walking. The sudden change in his mobility had been the event that had prompted his attendance at hospital. When questioned directly, the patient described intermittent tingling sensations in his lower legs, but denied any loss of sensation. There had been no dysfunction of his bladder or bowels.

The patient had been diagnosed with prostate cancer five years previously. This had been treated with a radical prostatectomy and hormone therapy. The patient had moved area two years previously, and had subsequently been lost to urological follow-up. Despite his previous cancer treatment, the patient stated that he was very fit and active, playing golf three times a week and taking an active role in the care of his grandchildren.

Peripheral nerve examination of lower limbs: tone generally increased bilaterally; power generally slightly reduced (4+/5) bilaterally; normal coordination; no impairment of light touch or sharp touch sensation; knee and ankle jerks brisk bilaterally, plantar responses up going bilaterally.

Digital rectal examination: preserved peri-anal sensation and normal tone.

Bed-side bladder scan: 50 ml

MRI whole spine: metastatic invasion and collapse of T10 vertebral with spinal cord compression.

The patient was treated with analgesia and dexamethasone while definitive treatment was planned.

What is most appropriate first-line treatment of patient's spinal cord compression?

Surgical tumour resection and spinal cord stabilisation with adjuvant radiotherapy	55%
Radiotherapy: single dose 8 Gy	39%
Chemotherapy: docetaxel	2%
Best supportive care	4%

Chemotherapy: cabazitaxel 1%

The best predictor of neurological outcome with treatment in metastatic spinal cord compression is neurological status at the initiation of treatment. The patient in the question has presented very promptly and has only limited neurological compromise. Therefore, it is imperative that definitive treatment is provided promptly (ideally, within 24 hours) to optimise long-term outcome.

Definite treatment of metastatic spinal cord compression can include any combination of radiotherapy, surgery and chemotherapy. Recent evidence indicates that surgery is superior to radiotherapy in retaining or regaining neurological function and relieving pain. In the case of this patient, who has an excellent performance status, surgery followed by radiotherapy would likely offer a better outcome than radiotherapy alone.

Radiotherapy may be considered as first-line treatment in some circumstances. Recommended regimen vary, for example 20 Gy in five daily fractions. The radiotherapy regime offered as a answer to the question would be appropriate as palliative treatment for pain-control, making it an incorrect answer for this patient.

Chemotherapy have a role in the management of spinal-cord compression secondary to chemo-sensitive malignancies (for example, small-cell lung cancer or germ cell tumours), but would not be optimal treatment for this patient.

Al-Qurainy, Collis E. Metastatic spinal cord compression: diagnosis and management. BMJ 2016;353:i2539.

Next question

Neoplastic spinal cord compression

Spinal cord compression is an oncological emergency and affects up to 5% of cancer patients. Extradural compression accounts for the majority of cases, usually due to vertebral body metastases. It is more common in patients with lung, breast and prostate cancer

Features

- back pain
    - the earliest and most common symptom
    - may be worse on lying down and coughing
- lower limb weakness
- sensory changes: sensory loss and numbness
- neurological signs depend on the level of the lesion. Lesions above L1 usually result in upper motor neuron signs in the legs and a sensory level. Lesions below L1 usually cause lower

motor neuron signs in the legs and perianal numbness. Tendon reflexes tend to be increased below the level of the lesion and absent at the level of the lesion

Investigation

- urgent MRI: the 2019 NICE guidelines recommend a whole MRI spine within 24 hours of presentation

Management

- high-dose oral dexamethasone
- urgent oncological assessment for consideration of radiotherapy or surgery

Back to top

A 56-year-old patient presents to hospital with confusion. He is a long-term smoker. He has a past-medical history of chronic obstructive pulmonary disease, hypertension, bipolar disease and long-term muscular back pain.

On examination he is confused with a Glasgow Coma Scale score of 14 out of 15. He has a pulse rate of 97 beats per minute with a blood pressure of 145/97 mmHg. Respiratory rate is 14 per minute with oxygen saturations of 95% on room air. He has bilateral vesicular breath sounds on auscultation with normal percussion. His abdomen is soft and non-tender with no masses. He has no focal neurology.

Investigations

Hb	102 g/dL
WCC	8.2 *10^9/l
Platelets	133 *10^9/l

Na+	146 mmol/L
K+	5.4 mmol/L
Cr	132 µmol/L
Ur	10.1 mmol/L

Albumin	26 g/L
Adjusted Calcium	3.78 mmol/L
Alkaline Phosphatase	76 IU/L
PTH	Undetectable
Serum ACE	45U/L (10-50)
Serum Electrophoresis	IgG 18 g/L (5-13 g/L) - Polyclonal
Urinary Electrophoresis	Undetectable

Chest X-ray	Right parahilar opacification 3x4cm
Lumbar Spine X-ray	Normal

What is the likely underlying diagnosis?

○ Squamous Cell Carcinoma ×

○ Multiple Myeloma ×

○ Sarcoidosis ×

○ Drug induced hypercalcaemia ×

○ Prostate carcinoma ×

On examination he is confused with a Glasgow Coma Scale score of 14 out of 15. He has a pulse rate of 97 beats per minute with a blood pressure of 145/97 mmHg. Respiratory rate is 14 per minute with oxygen saturations of 95% on room air. He has bilateral vesicular breath sounds on auscultation with normal percussion. His abdomen is soft and non-tender with no masses. He has no focal neurology.

Investigations

Hb	102 g/dL
WCC	8.2 *10^9/l
Platelets	133 *10^9/l

Na+	146 mmol/L
K+	5.4 mmol/L
Cr	132 µmol/L
Ur	10.1 mmol/L

Albumin	26 g/L
Adjusted Calcium	3.78 mmol/L
Alkaline Phosphatase	76 IU/L
PTH	Undetectable
Serum ACE	45U/L (10-50)
Serum Electrophoresis	IgG 18 g/L (5-13 g/L) - Polyclonal
Urinary Electrophoresis	Undetectable

Chest X-ray	Right parahilar opacification 3x4cm
Lumbar Spine X-ray	Normal

What is the likely underlying diagnosis?

Squamous Cell Carcinoma	63%
Multiple Myeloma	22%
Sarcoidosis	13%
Drug induced hypercalcaemia	1%
Prostate carcinoma	1%

The patient has severe hypercalcaemia. The commonest causes are hyperparathyroidism and cancer. The patient has a normal alkaline phosphatase without evidence of fracture or bone disease making bone metastases unlikely. The patient has a normal serum ACE with an atypical chest X-ray for sarcoidosis, although unilateral chest findings are possible.

The patient has features of multiple myeloma including anaemia, renal insufficiency and hypercalcaemia. However, there is a polyclonal, rather than a monoclonal increase in paraprotein.

The chest x-ray findings with a background of smoking suggest an underlying respiratory malignancy. This patient has squamous cell carcinoma of the lung with parathyroid related protein secretion causing hypercalcaemia. PrPTH is not deteced on a PTH assay. Hypercalcaemia can induce confusion and renal impairment.

👍 👎 Discuss (9) Improve

Next question >

Lung cancer: non-small cell ★

There are three main subtypes of non-small cell lung cancer:

Squamous cell cancer
- typically central
- associated with parathyroid hormone-related protein (PTHrP) secretion → hypercalcaemia
- strongly associated with finger clubbing
- cavitating lesions are more common than other types
- hypertrophic pulmonary osteoarthropathy (HPOA)

Adenocarcinoma
- typically peripheral
- most common type of lung cancer in non-smokers, although the majority of patients who develop lung adenocarcinoma are smokers

Large cell lung carcinoma

- typically peripheral
- anaplastic, poorly differentiated tumours with a poor prognosis
- may secrete β-hCG

A 65-year-old man with metastatic squamous cell lung cancer is admitted to the Acute Medical Unit for the management of hypercalcaemia. He is currently taking slow-release morphine sulphate (MST) 90mg bd to control his pain along with regular naproxen and paracetamol. During his admission he complains of pain in his right arm which is the site of a known skeletal metastasis. What is the most appropriate medication to prescribe to treat his acute pain?

- ○ Oral morphine solution 30mg
- ○ Oral morphine solution 15mg
- ○ Oral morphine solution 10mg
- ○ Add alendronate 70mg weekly
- ○ Tramadol 50mg

Question 24 of 43 ✗

A 65-year-old man with metastatic squamous cell lung cancer is admitted to the Acute Medical Unit for the management of hypercalcaemia. He is currently taking slow-release morphine sulphate (MST) 90mg bd to control his pain along with regular naproxen and paracetamol. During his admission he complains of pain in his right arm which is the site of a known skeletal metastasis. What is the most appropriate medication to prescribe to treat his acute pain?

Oral morphine solution 30mg	63%
Oral morphine solution 15mg	13%
Oral morphine solution 10mg	2%
Add alendronate 70mg weekly	19%
Tramadol 50mg	2%

This patient is describing break-through pain. Whilst bisphosphonates have a role in bone metastases they are not suitable for acute pain. A suitable break-through dose is therefore 1/6th of the total daily morphine dose i.e. 1/6th of 180mg = 30mg.

Discuss (2) Improve

Next question ›

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment

- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine

solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points
- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
  - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
  - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations
- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 25 of 43

A 77-year-old female is electively admitted for investigation of bilateral lower limb swelling onset over the past 3 years associated with limitation of exercise as a result. Her past medical history includes bilateral pulmonary emboli in 2010 and type 2 diabetes mellitus. On examination, non-pitting bilateral lower limb oedema is noted to the high thighs without abdominal involvement. Her heart sounds are normal with no added sounds, her chest is clear. Her abdomen is soft and non-tender without ascites or superficial swelling. A transthoracic echocardiogram demonstrates normal left ventricular function but was unable to produce good views of the right heart. A CT pulmonary angiogram demonstrates no embolus, a ventilation-perfusion scan demonstrates a low probability of pulmonary emboli. Ultrasound abdomen is unremarkable. The patient undergoes a right heart catheter, demonstrating a mean pulmonary arterial pressure of 14mmHg. What is the likely cause of her lower limb swelling?

- ○ Left heart failure ×
- ○ Idiopathic pulmonary arterial hypertension ×
- ○ Right heart failure ×
- ○ Pelvic malignancy ×
- ○ Lymphoedema ×

A 77-year-old female is electively admitted for investigation of bilateral lower limb swelling onset over the past 3 years associated with limitation of exercise as a result. Her past medical history includes bilateral pulmonary emboli in 2010 and type 2 diabetes mellitus. On examination, non-pitting bilateral lower limb oedema is noted to the high thighs without abdominal involvement. Her heart sounds are normal with no added sounds, her chest is clear. Her abdomen is soft and non-tender without ascites or superficial swelling. A transthoracic echocardiogram demonstrates normal left ventricular function but was unable to produce good views of the right heart. A CT pulmonary angiogram demonstrates no embolus, a ventilation-perfusion scan demonstrates a low probability of pulmonary emboli. Ultrasound abdomen is unremarkable. The patient undergoes a right heart catheter, demonstrating a mean pulmonary arterial pressure of 14mmHg. What is the likely cause of her lower limb swelling?

Left heart failure	1%
Idiopathic pulmonary arterial hypertension	7%
Right heart failure	14%
Pelvic malignancy	22%
Lymphoedema	56%

Interpretation of the various investigations this patient has undertaken allows lymphoedema as a diagnosis of exclusion. The patient would have been referred to this standard set of investigations for pulmonary hypertension after clinically presenting as progressive exercise limitation and peripheral oedema, with the primary concern being right heart failure secondary to an increased pressure within the pulmonary vasculature.

Most importantly, the pulmonary arterial pressure is normal on the right heart catheter, ruling idiopathic pulmonary hypertension. Left heart dysfunction is excluded by a normal echocardiogram evaluation of the left ventricular function. CTPA and normal abdominal ultrasound, predominantly investigating the portal circulation, rule out causes of pulmonary hypertension. Lastly, the non-pitting nature of the oedema suggests a non-cardiac cause, making lymphoedema the most likely cause of lower limb swelling.

Discuss (7) | Improve

Next question

Lymphoedema

Causes of lymphoedema include:

- primary: inherited
- secondary e.g. surgery, radiation, infection (classically filariasis) or injury resulting in damage to the lymphatic system

Question 26 of 43

A 65-year-old man is admitted to the hospital for palliative radiotherapy. He has a squamous cell carcinoma of the tongue that has metastasized to his neck and surrounds the carotid artery. There are no surgical options to treat his disease.

On day 2 of the admission, he experiences a catastrophic bleed from his neck.

What is the most appropriate medication to administer in this circumstance?

- ○ Buscopan
- ○ Chlorpromazine
- ○ Haloperidol
- ○ Midazolam
- ○ Morphine

Question 26 of 43 ✗

A 65-year-old man is admitted to the hospital for palliative radiotherapy. He has a squamous cell carcinoma of the tongue that has metastasized to his neck and surrounds the carotid artery. There are no surgical options to treat his disease.

On day 2 of the admission, he experiences a catastrophic bleed from his neck.

What is the most appropriate medication to administer in this circumstance?

Buscopan	4%
Chlorpromazine	3%
Haloperidol	4%
Midazolam	79%
Morphine	10%

In a massive terminal haemorrhage, a large dose of midazolam (10mg) can be given as part of 'crisis management' to relieve distress. Red or green towels or blankets should be available to soak up and mask the colour of blood

Important for me Less important

Midazolam is the correct answer. The patient has experienced a terminal haemorrhage as a consequence of his tumour eroding through the carotid artery. Given the lack of surgical options available to treat his condition, urgent symptom control is warranted to manage this distressing event. Intravenous midazolam is indicated in this horrific situation as a consequence of its anxiolytic and sedative effects, along with the rapidity of its onset.

Haloperidol is incorrect. This can be used to treat agitation in palliative care. However, intravenous midazolam is preferred in this catastrophic situation due to its rapidity of onset.

Morphine is incorrect. This is typically used to treat pain and breathlessness in a palliative care setting, rather than agitation.

Chlorpromazine is incorrect. This can also be used to treat agitation in a palliative care setting. However, midazolam is preferred in terminal haemorrhages.

Buscopan is incorrect. This is used to decrease the burden of secretions in palliative care. It is not used to treat agitation.

Discuss (3) | Improve

Next question ›

Palliative care prescribing: agitation and confusion

Underlying causes of confusion need to be looked for and treated as appropriate, for example hypercalcaemia, infection, urinary retention and medication. If specific treatments fail then the following may be tried:

- first choice: haloperidol
- other options: chlorpromazine, levomepromazine

In the terminal phase of the illness then agitation or restlessness is best treated with midazolam

A 64-year-old Nepalese woman who emigrated to the United Kingdom six months prior arrives to her GP. She has known multinodular goitre which has been untreated. However, her daughter who translates for her reports that she has noticed a tight sensation like she is being strangled. This is worse in the mornings and her daughter has noticed that her face does appear puffy. She has no weight loss, fevers or night sweats. She is otherwise well and has never smoked.

On examination, there is a large multinodular goitre that occupies a large part of the neck and measures 15-20cm in width. There is no audible stridor but there are several neck veins visible. You ask her to stretch out her hands up high to observe for a tremor and she starts to complain of the tightness. becoming worse. Her chest sounds are quiet and her chest is clear. There is dull percussion under the top third of the sternum.

TSH	0.07 mU/L (normal range 0.05-5.0)
T4	10 pmol/L (normal range 9-50)
T3	4.0 pmol/L (normal range 3.5-7.8)
D-dimer	0.15 (normal range 0-0.25)
Chest x-ray	Widened mediastinum, no focal lung lesion

What is the underlying cause of these new symptoms?

○ Multinodular goitre ×

○ Lymphoma ×

○ Thoracic artery aneurysm ×

○ Lung carcinoma ×

○ Superior vena cava thrombus ×

Question 27 of 43 ✗

A 64-year-old Nepalese woman who emigrated to the United Kingdom six months prior arrives to her GP. She has known multinodular goitre which has been untreated. However, her daughter who translates for her reports that she has noticed a tight sensation like she is being strangled. This is worse in the mornings and her daughter has noticed that her face does appear puffy. She has no weight loss, fevers or night sweats. She is otherwise well and has never smoked.

On examination, there is a large multinodular goitre that occupies a large part of the neck and measures 15-20cm in width. There is no audible stridor but there are several neck veins visible. You ask her to stretch out her hands up high to observe for a tremor and she starts to complain of the tightness. becoming worse. Her chest sounds are quiet and her chest is clear. There is dull percussion under the top third of the sternum.

TSH	0.07 mU/L (normal range 0.05-5.0)
T4	10 pmol/L (normal range 9-50)
T3	4.0 pmol/L (normal range 3.5-7.8)
D-dimer	0.15 (normal range 0-0.25)
Chest x-ray	Widened mediastinum, no focal lung lesion

What is the underlying cause of these new symptoms?

Multinodular goitre	28%
Lymphoma	13%
Thoracic artery aneurysm	4%
Lung carcinoma	4%
Superior vena cava thrombus	50%

Enlarged goitre can be a rare cause of SVC obstruction

Important for me Less important

This presentation is classical for superior vena cava obstruction and the worsening of her symptoms when she lifts her hands up is Pemberton's test which is positive in this case. The next decision is to seek the cause. The obvious cause here is a huge goitre which is recognised as a rare cause of superior cava obstruction. Lung carcinoma is possible but this lady is a non smoker and there is no cough or weight loss. Thoracic artery aneurysm would show a widened mediastinum but there would often be a history of connective tissue disease or uncontrolled hypertension. Lymphoma causing SVC obstruction would typically have mediastinal lymphadenopathy on chest x-ray. SVC thrombus would be unlikely given that the D-dimer is negative

Discuss (8) | Improve

Next question

Superior vena cava obstruction

Superior vena cava (SVC) obstruction is an oncological emergency caused by compression of the SVC. It is most commonly associated with lung cancer.

Features
- dyspnoea is the most common symptom
- swelling of the face, neck and arms - conjunctival and periorbital oedema may be seen
- headache: often worse in the mornings
- visual disturbance
- pulseless jugular venous distension

Causes
- common malignancies: small cell lung cancer, lymphoma
- other malignancies: metastatic seminoma, Kaposi's sarcoma, breast cancer
- aortic aneurysm
- mediastinal fibrosis
- goitre
- SVC thrombosis

Management is dependant on the individual patient and malignancy and advice should be taken from the oncology team. Options include:
- endovascular stenting is often the treatment of choice to provide symptom relief
- certain malignancies such as lymphoma, small cell lung cancer may benefit from radical chemotherapy or chemo-radiotherapy rather than stenting
- the evidence base supporting the use of glucocorticoids is weak but they are often given

A 78-year-old gentleman with known metastatic prostate cancer is admitted due to lower back pain that is worse on sitting upright. He denies any sensory changes or weakness but is woken at night and cannot sleep. He takes aspirin, paracetamol and bicalutamide regularly.

On examination, he has normal tone, full power and downgoing plantars in both lower legs. He is exquisitely tender in the midline at L2 and L3.

Bilirubin	34 µmol/l
ALP	450 u/l
ALT	56 u/l
Albumin	32 g/l
Calcium	3.1mmol/l
MRI spine	sclerotic lesions seen in T9, L2 and L3

What medical therapy would offer greatest benefit to him?

- ○ Intravenous fluids ×
- ○ Denosumab ×
- ○ Spinal decompressive surgery ×
- ○ Omeprazole ×
- ○ Transcutaneous electrical nerve stimulation (TENS) ×

Question 28 of 43 ✗

A 78-year-old gentleman with known metastatic prostate cancer is admitted due to lower back pain that is worse on sitting upright. He denies any sensory changes or weakness but is woken at night and cannot sleep. He takes aspirin, paracetamol and bicalutamide regularly.

On examination, he has normal tone, full power and downgoing plantars in both lower legs. He is exquisitely tender in the midline at L2 and L3.

Bilirubin	34 µmol/l
ALP	450 u/l
ALT	56 u/l
Albumin	32 g/l
Calcium	3.1mmol/l
MRI spine	sclerotic lesions seen in T9, L2 and L3

What medical therapy would offer greatest benefit to him?

Intravenous fluids	13%
Denosumab	62%
Spinal decompressive surgery	19%
Omeprazole	0%
Transcutaneous electrical nerve stimulation (TENS)	6%

Denosumab is an unlicensed medication for bony metastasis pain

Important for me   Less important

This gentleman has bony pain associated with bony metastases. This is a key question in identifying the problem and how to help him. There is no sign of nerve compression so spinal surgery will not benefit him. He is asymptomatic from his hypercalcaemia so IV fluids would not benefit. Omeprazole will help protect his stomach from ulceration. For bony pain, NSAIDs usually are a good first line. Bisphosphonates and radiotherapy help but are not an answer. Denosumab is a third line when the above fail. TENS can be useful for all pains but is not evidence based for bony pain.

Palliative care prescribing: pain ★

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment

- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
    - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
    - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however,

should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	Usually persistent
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations
- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

Question 29 of 43

You are fast-bleeped to the oncology ward to review a 72-year-old man with a background of metastatic, fungating buccal cancer. During initial MDT, it was deemed inoperable due to carotid artery involvement. He was initially admitted with hypercalcaemia but has deteriorated during his admission and is on the end-of-life pathway.

On your arrival, you note a large amount of blood around the patient with staff using towels and applying pressure to the neck. Nursing staff report that there was a sudden 'pop' and large volume bleeding began at the site of the fungating cancer. They state that bleeding has occurred before but not to this extent.

What is the most appropriate next step in management?

- ○ Adrenaline ×
- ○ Midazolam ×
- ○ Morphine ×
- ○ Terlipressin ×
- ○ Vascular surgery opinion ×

You are fast-bleeped to the oncology ward to review a 72-year-old man with a background of metastatic, fungating buccal cancer. During initial MDT, it was deemed inoperable due to carotid artery involvement. He was initially admitted with hypercalcaemia but has deteriorated during his admission and is on the end-of-life pathway.

On your arrival, you note a large amount of blood around the patient with staff using towels and applying pressure to the neck. Nursing staff report that there was a sudden 'pop' and large volume bleeding began at the site of the fungating cancer. They state that bleeding has occurred before but not to this extent.

What is the most appropriate next step in management?

Adrenaline	8%
Midazolam	74%
Morphine	5%
Terlipressin	6%
Vascular surgery opinion	7%

In a massive terminal haemorrhage, a large dose of midazolam (10mg) can be given as part of 'crisis management' to relieve distress. Red or green towels or blankets should be available to soak up and mask the colour of blood

Important for me Less important

This is an example of a catastrophic, terminal haemorrhage likely arising from carotid artery involvement. In these circumstances, patients can become very distressed and unfortunately, often there is very little that can be done. To aid in relieving stress it is advised to use red or green towels to help soak up blood as well as obscuring the colour of the blood, as well as giving a large dose of midazolam for relaxation.

Adrenaline can be used in specific circumstances of major haemorrhage but is not used in terminal haemorrhage. Given that the history explains that the patient is on the end of life pathway and that he is not for surgical intervention, adrenaline is not appropriate.

Morphine can be used for pain and breathlessness in palliative care but is not used in terminal haemorrhages.

Terlipressin can be used for major haemorrhage, particularly of gastrointestinal bleeding, however again, this is not appropriate in terminal haemorrhages.

The MDT has already decided that surgical intervention is not appropriate and therefore a vascular surgery opinion at this time would not be appropriate.

Next question

Palliative care prescribing: agitation and confusion

Underlying causes of confusion need to be looked for and treated as appropriate, for example hypercalcaemia, infection, urinary retention and medication. If specific treatments fail then the following may be tried:

- first choice: haloperidol
- other options: chlorpromazine, levomepromazine

In the terminal phase of the illness then agitation or restlessness is best treated with midazolam

Question 30 of 43

A 60-year-old woman presented to the emergency department with recurrent episodes of severe headache and vomiting over past 3-4 days. She was known to have underlying metastatic breast cancer for which she was receiving palliative chemotherapy. She was also known to have underlying type 2 diabetes mellitus and osteoarthritis of bilateral knee joints.

On examination, her pulse rate was 105/min, respiratory rate was 16/min, blood pressure was 120/80 mmHg. Fundoscopy revealed early papilloedema.

A contrast enhanced CT brain was done which showed a solitary mass of 3 cm in the left cerebral hemisphere.

What is the next appropriate management?

○ Start 16 mg of i.v dexamethasone and prophylactic anticonvulsants

○ Start 16 mg of dexamethasone and arrange urgent MRI brain

○ Refer to neurosurgery for biopsy of the brain lesion

○ Refer to radiation oncologist for Whole brain radiotherapy

○ Stereotactic radiosurgery

She was also known to have underlying type 2 diabetes mellitus and osteoarthritis of bilateral knee joints.

On examination, her pulse rate was 105/min, respiratory rate was 16/min, blood pressure was 120/80 mmHg. Fundoscopy revealed early papilloedema.

A contrast enhanced CT brain was done which showed a solitary mass of 3 cm in the left cerebral hemisphere.

What is the next appropriate management?

Start 16 mg of i.v dexamethasone and prophylactic anticonvulsants	37%
Start 16 mg of dexamethasone and arrange urgent MRI brain	57%
Refer to neurosurgery for biopsy of the brain lesion	1%
Refer to radiation oncologist for Whole brain radiotherapy	2%
Stereotactic radiosurgery	2%

High dose dexamethasone is the mainstay of immediate management of brain metastasis. For lesions identified as solitary on contrast enhanced CT brain, MRI with gadolinium is indicated to assess the extent of intracranial disease. Patients presenting with seizure activity should be given anticonvulsant therapy. Patients with limited number of lesions(<4) can be considered for more aggressive treatment like neurosurgery or stereotactic radiotherapy but not the immediate step. Biopsy of the lesion is indicated if primary is unknown.Whole brain radiotherapy is indicated for multiple brain metastasis (>4).

Next question

Breast cancer: management

The management of breast cancer depends on the staging, tumour type and patient background. It may involve any of the following:

- surgery
- radiotherapy
- hormone therapy
- biological therapy
- chemotherapy

Surgery

The vast majority of patients who have breast cancer diagnosed will be offered surgery. An exception may be a very frail, elderly lady with metastatic disease who may be better managed with hormonal therapy.

Prior to surgery, the presence/absence of axillary lymphadenopathy determines management:

- women with no palpable axillary lymphadenopathy at presentation should have a pre-operative axillary ultrasound before their primary surgery
    - if negative then they should have a sentinel node biopsy to assess the nodal burden
- in patients with breast cancer who present with clinically palpable lymphadenopathy, axillary node clearance is indicated at primary surgery
    - this may lead to arm lymphedema and functional arm impairment

Depending on the characteristics of the tumour women either have a wide-local excision or a mastectomy. Around two-thirds of tumours can be removed with a wide-local excision. The table below lists some of the factors determining which operation is offered:

Mastectomy	**Wide Local Excision**
Multifocal tumour	Solitary lesion
Central tumour	Peripheral tumour
Large lesion in small breast	Small lesion in large breast
DCIS > 4cm	DCIS < 4cm

Women should be offered breast reconstruction to achieve a cosmetically suitable result regardless of the type of operation they have. For women who've had a mastectomy this may be done at the initial operation or at a later date.

Radiotherapy

Whole breast radiotherapy is recommended after a woman has had a wide-local excision as this may reduce the risk of recurrence by around two-thirds. For women who've had a mastectomy radiotherapy is offered for T3-T4 tumours and for those with four or more positive axillary nodes

Hormonal therapy

Adjuvant hormonal therapy is offered if tumours are positive for hormone receptors. For many years this was done using tamoxifen for 5 years after diagnosis. Tamoxifen is still used in pre- and peri-menopausal women. In post-menopausal women, aromatase inhibitors such as anastrozole are used for this purpose*. This is important as aromatisation accounts for the majority of oestrogen production in post-menopausal women and therefore anastrozole is used for ER +ve breast cancer in this group.

Important side effects of tamoxifen include an increased risk of endometrial cancer, venous thromboembolism and menopausal symptoms.

Biological therapy

The most common type of biological therapy used for breast cancer is trastuzumab (Herceptin). It is only useful in the 20-25% of tumours that are HER2 positive.

Trastuzumab cannot be used in patients with a history of heart disorders.

Chemotherapy

Cytotoxic therapy may be used either prior to surgery ('neoadjuvanant' chemotherapy) to downstage a primary lesion or after surgery depending on the stage of the tumour, for example, if there is axillary node disease - FEC-D is used in this situation.

Question 31 of 43

A 48-year-old woman is currently undergoing various cycles of chemotherapy for breast cancer. She asks the oncology team for advice as, 2-3 days post-chemotherapy, she experiences severe nausea and vomiting that lasts for several days. This is debilitating, despite taking antiemetics during the chemotherapy and afterward.

What is the most appropriate drug to prevent this delayed reaction?

- ○ Dexamethasone
- ○ Levopromazine
- ○ Lorazepam
- ○ Metoclopramide
- ○ Ondansetron

A 48-year-old woman is currently undergoing various cycles of chemotherapy for breast cancer. She asks the oncology team for advice as, 2-3 days post-chemotherapy, she experiences severe nausea and vomiting that lasts for several days. This is debilitating, despite taking antiemetics during the chemotherapy and afterward.

What is the most appropriate drug to prevent this delayed reaction?

Dexamethasone	42%
Levopromazine	12%
Lorazepam	2%
Metoclopramide	8%
Ondansetron	36%

Dexamethasone is the most useful agent in preventing the delayed phase of chemotherapy-induced emesis

Important for me Less important

Dexamethasone has been shown by numerous trials to be the most effective agent in preventing delayed nausea and vomiting. As opposed to more immediate nausea and vomiting, for which antiemetics are useful, the delayed reaction (between 24 hours and 1-week post-chemotherapy) is not as effectively reduced by antiemetics.

Levopromazine is a 'dirty drug', acting at multiple receptor sites. It is a useful antiemetic, particularly parenterally, but sedates patients quite significantly and is generally reserved for palliative care and intractable symptoms.

Lorazepam, a benzodiazepine, has mild antiemetic properties and is not considered effective at reducing the delayed phase. It is generally used for its anti-anxiolytic properties.

Metoclopramide is a dopamine antagonist and an effective antiemetic. It may be used first-line for immediate nausea and vomiting. However, in the context of the delayed phase, dexamethasone is more useful.

Ondansetron is a serotonin receptor antagonist and another effective antiemetic used for chemotherapy-induced nausea and vomiting. With regards to the delayed phase, however, dexamethasone is the most effective agent.

Discuss (1) Improve

Next question >

Chemotherapy side-effects: nausea and vomiting

Nausea and vomiting are common side-effects of chemotherapy. Risk factors for the development of symptoms include:

- anxiety
- age less than 50 years old
- concurrent use of opioids
- the type of chemotherapy used

For patients at low-risk of symptoms then drugs such as metoclopramide may be used first-line. For high-risk patients then 5HT3 receptor antagonists such as ondansetron are often effective, especially if combined with dexamethasone

Question 32 of 43

A 68-year-old man with metastatic prostate cancer is due to go for radiotherapy in an hour. The nurses tell you that he complained of pain during the transfer yesterday. His pain has been otherwise well controlled on a total of 60mg morphine daily. How is it best to manage his pain control for the transfer today?

○ Nothing as it is only temporary pain

○ An additional dose of 10mg morphine 30 minutes prior to his transfer

○ An additional dose of 15mg morphine 1 hour prior to his transfer

○ An additional dose of 10mg morphine 1 hour prior to his transfer

○ An additional dose of 15mg morphine 30 minutes prior to his transfer

Question 32 of 43

A 68-year-old man with metastatic prostate cancer is due to go for radiotherapy in an hour. The nurses tell you that he complained of pain during the transfer yesterday. His pain has been otherwise well controlled on a total of 60mg morphine daily. How is it best to manage his pain control for the transfer today?

Nothing as it is only temporary pain	2%
An additional dose of 10mg morphine 30 minutes prior to his transfer	68%
An additional dose of 15mg morphine 1 hour prior to his transfer	3%
An additional dose of 10mg morphine 1 hour prior to his transfer	22%
An additional dose of 15mg morphine 30 minutes prior to his transfer	4%

A breakthrough dose of morphine should be given 30 minutes prior to his transfer as indicated in the BNF. 1 hour is too long prior as it should last him the transfer back and 30 minutes prior is enough for the morphine to have the desired effect. A breakthrough dose should be 1/6th of his total daily dose which in this case is 10mg. Therefore, 15mg is too high a dose for this patient.

Although it is temporary pain, it should still be treated as the patient's comfort and quality of life are important aspects of his care.

Next question

Palliative care prescribing: pain

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment
- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient

preference), with oral immediate-release morphine for breakthrough pain

- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points

- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease
  - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
  - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	**Usually persistent**
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	To	Conversion factor
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

A 72-year-old man presents to the emergency department with shortness of breath. He describes his breathlessness has progressively become worse over the last two weeks and is especially troublesome when leaning forward. His wife has commented that his appearance has changed too, with his face becoming more swollen and different in colour. He has a past medical history of right-sided heart failure, myocardial infarction, type two diabetes, COPD and small cell lung cancer diagnosed three months ago. He is an ex-smoker of 20 pack-years and drinks moderate amounts of alcohol.

On examination, he appears settled at rest. His face is swollen and slightly purple. His neck veins are distended and his JVP is markedly elevated to 4cm. Auscultation reveals bibasal crepitations. There is pitting oedema at the ankles. A chest X-ray demonstrates a widened mediastinum. What investigation is most appropriate to establish the diagnosis?

- ○ ECG
- ○ Trans-thoracic echocardiogram
- ○ Trans-oesophageal echocardiogram
- ○ Bronchoscopy
- ○ CT chest

His wife has commented that his appearance has changed too, with his face becoming more swollen and different in colour. He has a past medical history of right-sided heart failure, myocardial infarction, type two diabetes, COPD and small cell lung cancer diagnosed three months ago. He is an ex-smoker of 20 pack-years and drinks moderate amounts of alcohol.

On examination, he appears settled at rest. His face is swollen and slightly purple. His neck veins are distended and his JVP is markedly elevated to 4cm. Auscultation reveals bibasal crepitations. There is pitting oedema at the ankles. A chest X-ray demonstrates a widened mediastinum. What investigation is most appropriate to establish the diagnosis?

ECG	1%
Trans-thoracic echocardiogram	11%
Trans-oesophageal echocardiogram	7%
Bronchoscopy	3%
CT chest	78%

The correct answer is CT chest as the patient has a clinical history consistent with obstruction of the superior vena cava (SVC). There are several symptoms and signs consistent with SVC obstruction, including breathlessness worse, leaning forward, distended neck veins and a swollen face. This, in combination with known lung cancer, suggests progression of the primary malignancy or lymph nodes compressing the SVC. Whilst some of the finds could be suggestive of acute pulmonary oedema, the chest X-ray is consistent with SVC obstruction. As a cardiac cause is unlikely, an echocardiogram or ECG is unlikely to be diagnostic. A bronchoscopy is a possible approach for obtaining a biopsy if an SVC obstruction is diagnosed and the source of the obstruction is unclear, but as this patient is known to have lung cancer this is not going to be helpful for this patient.

Next question

Superior vena cava obstruction

Superior vena cava (SVC) obstruction is an oncological emergency caused by compression of the SVC. It is most commonly associated with lung cancer.

Features
- dyspnoea is the most common symptom
- swelling of the face, neck and arms - conjunctival and periorbital oedema may be seen
- headache: often worse in the mornings
- visual disturbance
- pulseless jugular venous distension

Causes
- common malignancies: small cell lung cancer, lymphoma
- other malignancies: metastatic seminoma, Kaposi's sarcoma, breast cancer
- aortic aneurysm
- mediastinal fibrosis
- goitre
- SVC thrombosis

Management is dependant on the individual patient and malignancy and advice should be taken from the oncology team. Options include:
- endovascular stenting is often the treatment of choice to provide symptom relief
- certain malignancies such as lymphoma, small cell lung cancer may benefit from radical chemotherapy or chemo-radiotherapy rather than stenting
- the evidence base supporting the use of glucocorticoids is weak but they are often given

A 40-year-old man is seen in the Emergency Department with breathlessness.

He was diagnosed with non-Hodgkin lymphoma 6 months ago and has been receiving chemotherapy. He is awaiting an appointment in haematology outpatients to assess his response to chemotherapy.

He describes becoming more breathless over the last week and feeling that his arms and face are puffy. He has had no chest pain, cough or fevers.

On examination his oxygen saturations are 92% on air and his heart rare is 112 beats per minute. His chest is clear and he is unable to lay flat for his abdomen to be examined due to is breathlessness. His face appears flushed and he has oedema of the arms and hands. His neck veins appear engorged.

Chest x-ray shows a widened mediastinum with extensive lymphadenopathy.

A CT scan of the thorax confirms superior vena cava obstruction (SVCO). The scan is reviewed by the haematology team who explain to him that his lymphoma has progressed despite chemotherapy.

He is started on steroids and a proton pump inhibitor.

What is the next step in the management of this gentleman's SVCO?

- ○ Chemotherapy
- ○ Observation
- ○ Radiotherapy
- ○ Stent insertion
- ○ Surgery

A 40-year-old man is seen in the Emergency Department with breathlessness.

He was diagnosed with non-Hodgkin lymphoma 6 months ago and has been receiving chemotherapy. He is awaiting an appointment in haematology outpatients to assess his response to chemotherapy.

He describes becoming more breathless over the last week and feeling that his arms and face are puffy. He has had no chest pain, cough or fevers.

On examination his oxygen saturations are 92% on air and his heart rare is 112 beats per minute. His chest is clear and he is unable to lay flat for his abdomen to be examined due to is breathlessness. His face appears flushed and he has oedema of the arms and hands. His neck veins appear engorged.

Chest x-ray shows a widened mediastinum with extensive lymphadenopathy.

A CT scan of the thorax confirms superior vena cava obstruction (SVCO). The scan is reviewed by the haematology team who explain to him that his lymphoma has progressed despite chemotherapy.

He is started on steroids and a proton pump inhibitor.

What is the next step in the management of this gentleman's SVCO?

Chemotherapy	3%
Observation	1%
Radiotherapy	21%
Stent insertion	71%
Surgery	3%

SVCO is an oncological emergency and is most common in lung cancer and lymphomas. The immediate management is steroids with proton pump inhibitor cover for gastric protection.

Further options include stent insertion, radiotherapy and chemotherapy.

This gentleman is unable to lay flat so would not be able to tolerate radiotherapy. Radiotherapy also has the disadvantage of causing increased swelling acutely before it causes long term shrinkage.

Lymphomas are highly chemotherapy responsive tumours and this gentleman has only had first-line chemotherapy, therefore second-line chemotherapy should be planned in order to shrink his mediastinal disease.

Stent insertion is the most immediate management for relieving SVCO until chemotherapy can take effect. The patient's haemoglobin, platelets and clotting must be checked and optimised. In patients with end-stage disease, stents can still become blocked.

Surgery is not generally part of the management for SVCO.

Question 35 of 43

A 71-year-old woman is referred by her GP to the rapid access chest clinic with progressive shortness of breath and reduced exercise tolerance over 3 months and a chronic productive cough. When asked about her past medical history she states that she has had some pain for the past month or so in her left shoulder, which has been present at a constant level. She has been taking paracetamol and codeine for the pain which helps slightly. Otherwise, the patient has moderate COPD, for which she taken ipratropium bromide and salmeterol and mechanical back pain. She has a 15 year pack-history and drinks 1-2 units of alcohol per day.

Examination reveals some wasting of the hypothenar eminence of the left hand, although the chest sounds clear bilaterally with no added sounds. Heart sounds 1 and 2 are present with no murmurs.

What would be the most useful investigation following a chest x-ray?

- ○ Electromyogram studies
- ○ Computed tomography of the thorax
- ○ Bronchoscopy
- ○ Myeloma screen
- ○ Sputum microscopy, culture and sensitivity

Question 35 of 43

A 71-year-old woman is referred by her GP to the rapid access chest clinic with progressive shortness of breath and reduced exercise tolerance over 3 months and a chronic productive cough. When asked about her past medical history she states that she has had some pain for the past month or so in her left shoulder, which has been present at a constant level. She has been taking paracetamol and codeine for the pain which helps slightly. Otherwise, the patient has moderate COPD, for which she taken ipratropium bromide and salmeterol and mechanical back pain. She has a 15 year pack-history and drinks 1-2 units of alcohol per day.

Examination reveals some wasting of the hypothenar eminence of the left hand, although the chest sounds clear bilaterally with no added sounds. Heart sounds 1 and 2 are present with no murmurs.

What would be the most useful investigation following a chest x-ray?

Electromyogram studies	6%
Computed tomography of the thorax	81%
Bronchoscopy	5%
Myeloma screen	6%
Sputum microscopy, culture and sensitivity	2%

The most likely diagnosis in this case is lung malignancy, in particular a Pancoast tumour, given this patient's wasting of the hypothenar eminence, shortness of breath and cough. The most useful investigation is a CT of the thorax - bronchoscopy is not as useful as the cancer is often too peripheral.

Discuss (3) Improve

Next question

Lung cancer: non-small cell

There are three main subtypes of non-small cell lung cancer:

Squamous cell cancer

- typically central
- associated with parathyroid hormone-related protein (PTHrP) secretion → hypercalcaemia
- strongly associated with finger clubbing
- cavitating lesions are more common than other types
- hypertrophic pulmonary osteoarthropathy (HPOA)

Adenocarcinoma

- typically peripheral
- most common type of lung cancer in non-smokers, although the majority of patients who develop lung adenocarcinoma are smokers

Large cell lung carcinoma

- typically peripheral
- anaplastic, poorly differentiated tumours with a poor prognosis
- may secrete β-hCG

You are asked to review a 67-year-old gentleman who was admitted to the medical emergency unit with pneumonia. He had been diagnosed with terminal small cell cancer of the lung which had extensively metastasised to his liver, thoracic vertebrae and femur bones. His past medical history was comprised of ischaemic heart disease, hypertension, hypercholesterolaemia and COPD.

His main complaint was of progressively worsening pain in his spine and legs. This was particularly bothersome at night; a trial of bisphosphonate therapy and radiotherapy did not provide any symptomatic relief. He was commenced initially on oral morphine sulphate solution which was converted to morphine sulphate tablets (MST); he had been on 60mg BD but this was titrated by the palliative care community nurse to 70mg BD a couple of days prior to admission with excellent analgesic effect. He was also using Oramorph solution 10mg on average 5-6 times a day for breakthrough pain.

He had been accordingly treated with intravenous antibiotics whilst on the ward making a full recovery. Prior to discharge, he was very keen on commencing transdermal treatment so as to minimise the number of oral medications taken.

What is the most appropriate starting dose to commence, with a view to completely discontinuing all oral opiate medication?

○ Commence Fentanyl 12 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain

○ Commence Fentanyl 25 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain

○ Commence Fentanyl 50 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain

○ Commence Fentanyl 75 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain

○ Commence Fentanyl 100 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain

You are asked to review a 67-year-old gentleman who was admitted to the medical emergency unit with pneumonia. He had been diagnosed with terminal small cell cancer of the lung which had extensively metastasised to his liver, thoracic vertebrae and femur bones. His past medical history was comprised of ischaemic heart disease, hypertension, hypercholesterolaemia and COPD.

His main complaint was of progressively worsening pain in his spine and legs. This was particularly bothersome at night; a trial of bisphosphonate therapy and radiotherapy did not provide any symptomatic relief. He was commenced initially on oral morphine sulphate solution which was converted to morphine sulphate tablets (MST); he had been on 60mg BD but this was titrated by the palliative care community nurse to 70mg BD a couple of days prior to admission with excellent analgesic effect. He was also using Oramorph solution 10mg on average 5-6 times a day for breakthrough pain.

He had been accordingly treated with intravenous antibiotics whilst on the ward making a full recovery. Prior to discharge, he was very keen on commencing transdermal treatment so as to minimise the number of oral medications taken.

What is the most appropriate starting dose to commence, with a view to completely discontinuing all oral opiate medication?

- Commence Fentanyl 12 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain 9%
- Commence Fentanyl 25 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain 17%
- Commence Fentanyl 50 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain 30%
- Commence Fentanyl 75 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain 30%
- Commence Fentanyl 100 72 hr patch, paracetamol 1g QDS and oramorph solution PRN for breakthrough pain 13%

This gentleman was on a rather complicated opiate analgesia regimen and the key to this question is calculate the total daily dose of morphine salt, to then convert it to the appropriate amount of fentanyl.

His total morphine salt intake was thus:

MST 70mg BD = 140mg of morphine
Oramorph 10mg PRN = 50-60mg of morphine

Total = 190-200mg daily morphine salt intake

The BNF states that a fentanyl 75 patch is equivalent to 180mg daily intake of morphine salt whilst a fentanyl 100patch is equivalent to 240mg daily morphine salt intake. So as to avoid opiate toxicity the correct answer is thus to commence a fentanyl 75 patch and to supplement this with PRN Oramorph solution.

👍 👎 Discuss (6) Improve

Next question >

Palliative care prescribing: pain ★

NICE guidelines

In 2012 NICE published guidelines on the use of opioids in palliative care. Selected points are listed below. Please see the link for more details.

Starting treatment
- when starting treatment, offer patients with advanced and progressive disease regular oral modified-release (MR) or oral immediate-release morphine (depending on patient preference), with oral immediate-release morphine for breakthrough pain
- if no comorbidities use 20-30mg of MR a day with 5mg morphine for breakthrough pain. For example, 15mg modified-release morphine tablets twice a day with 5mg of oral morphine solution as required
- oral modified-release morphine should be used in preference to transdermal patches
- laxatives should be prescribed for all patients initiating strong opioids
- patients should be advised that nausea is often transient. If it persists then an antiemetic should be offered
- drowsiness is usually transient - if it does not settle then adjustment of the dose should be considered

SIGN guidelines

SIGN issued guidance on the control of pain in adults with cancer in 2008. Selected points
- the breakthrough dose of morphine is one-sixth the daily dose of morphine
- all patients who receive opioids should be prescribed a laxative
- opioids should be used with caution in patients with chronic kidney disease

  - oxycodone is preferred to morphine in palliative patients with mild-moderate renal impairment
  - if renal impairment is more severe, alfentanil, buprenorphine and fentanyl are preferred
- metastatic bone pain may respond to strong opioids, bisphosphonates or radiotherapy. The assertion that NSAIDs are particularly effective for metastatic bone pain is not supported by studies. Strong opioids have the lowest number needed to treat for relieving the pain and can provide quick relief, in contrast to radiotherapy and bisphosphonates*. All patients, however, should be considered for referral to a clinical oncologist for consideration of further treatments such as radiotherapy

Other points

When increasing the dose of opioids the next dose should be increased by 30-50%.

In addition to strong opioids, bisphosphonates and radiotherapy, denosumab may be used to treat metastatic bone pain.

Opioid side-effects

Usually transient	Usually persistent
Nausea Drowsiness	Constipation

Conversion between opioids

From	To	Conversion factor
Oral codeine	Oral morphine	Divide by 10
Oral tramadol	Oral morphine	Divide by 10**

Oxycodone generally causes less sedation, vomiting and pruritis than morphine but more constipation.

From	To	Conversion factor
Oral morphine	Oral oxycodone	Divide by 1.5-2***

The current BNF gives the following conversion factors for transdermal perparations

- a transdermal fentanyl 12 microgram patch equates to approximately 30 mg oral morphine daily
- a transdermal buprenorphine 10 microgram patch equates to approximately 24 mg oral morphine daily.

From	**To**	**Conversion factor**
Oral morphine	Subcutaneous morphine	Divide by 2
Oral morphine	Subcutaneous diamorphine	Divide by 3
Oral oxycodone	Subcutaneous diamorphine	Divide by 1.5

*BMJ 2015;350:h315 Cancer induced bone pain

**this has previously been stated as 5 but the current version of the BNF states a conversion of 10

***historically a conversion factor of 2 has been used (i.e. oral oxycodone is twice as strong as oral morphine). The current BNF however uses a conversion rate of 1.5

A 68-year-old man presents with a five-week history of lower back pain that is worse with coughing. He has noticed that he has been requiring more painkillers to the point where he is struggling to manage, especially at night. The pain is worse when straining to pass stool. He lost three kg over the last four months as well. He has a past medical history of COPD, hypertension, type two diabetes mellitus, and hypercholesterolemia. He has been admitted three times in the last year for exacerbations of COPD requiring the recurrent use of oral prednisolone. His regular medications include Symbicort, tiotropium, atorvastatin, metformin, paracetamol, codeine and Movicol. He is an ex-smoker with a 50 pack-year history and recently opted for early retirement from his job as an accountant as he was struggling with tiredness. On examination, he appears tired and his clothes appear loose fitting. Examination of his chest is unremarkable, but there is a 1cm swelling above his left clavicle. His abdomen is soft, there is no tenderness over his spine, and a neurological examination is unremarkable.

Observations:

Saturations	95%
Respiratory rate	15/min
Blood pressure	148/87mmHg
Heart rate	74/min
Temperature	37.4°C

Blood tests:

Hb	128 g/l
MCV	72 fl
Platelets	327 * 10^9/l
WBC	12.4 * 10^9/l
Na^+	136 mmol/l
K^+	4.2 mmol/l
Urea	4.1 mmol/l
Creatinine	77 µmol/l

What is the most likely diagnosis that explains his symptoms?

○ Osteoporotic vertebral collapse ×

○ Spinal cord metastasis ×

○ Myeloma ×

○ Degenerative changes ×

○ Discitis ×

Na^+	136 mmol/l
K^+	4.2 mmol/l
Urea	4.1 mmol/l
Creatinine	77 µmol/l

What is the most likely diagnosis that explains his symptoms?

Osteoporotic vertebral collapse 8%

Spinal cord metastasis 80%

Myeloma	7%
Degenerative changes	1%
Discitis	4%

The answer is spinal cord metastasis. This question highlights multiple subtle red flags in a history with back pain. He is over >55 and describes nocturnal and progressive pain worse with coughing and straining in the context of immunosuppression from repeated steroid use, weight loss, and increasing fatigue. Due to the high suspicion, the most diagnostic imaging investigation would be a whole spine MRI, which would differentiate between the above diagnoses. Osteoporotic fracture is suggested by the use of steroids but overall does not fit with the progressive nature and microcytic anaemia, nor do degenerative changes. There are very few symptoms to suggest infection such as fever and night sweats, but discitis cannot be fully excluded without imaging. Myeloma is a possible diagnosis, but so far there are no specific factors to suggest it, such as lytic bone lesions or deteriorating renal function.

Next question ›

Spinal metastases ★

Patients may present with spinal metastases before developing metastatic spinal cord compression. It is, therefore, important to detect these patients early before any neurological compromise develops.

Symptoms and findings
- Unrelenting lumbar back pain
- Any thoracic or cervical back pain
- Worse with sneezing, coughing or straining
- Nocturnal
- Associated with tenderness

If any neurological features are present then spinal cord compression must be suspected and acted on promptly. Without neurological features, a whole spine MRI should be completed within one week. The whole spine should be imaged as patients commonly present with multi-level disease.

A 56-year-old male with non-hodgkin's lymphoma is on his third cycle of R-CHOP chemotherapy. He has struggled previous times with nausea but is two days following the most recent cycle and attended hospital due to intractable vomiting.

He is vomiting 20+ times a day with green to clear fluid. He does not feel hungry and struggles to swallow water. He is not having diarrhoea. He takes regular indapamide and as required ondansetron and this has not helped him despite the oncologist suggesting he double his dose of ondansetron.

On examination, he looks pale and has dry mucosa. He is alert, has a clear chest and soft abdomen but begins to retch on sitting forward. He last passed urine 6 hours ago and his observations show a heart rate of 115 beats per minute and blood pressure 90/65mmHg. He is started on intravenous fluids by the emergency department.

Na^+	135 mmol/l
K^+	3.5 mmol/l
Urea	6.5 mmol/l
Creatinine	98 µmol/l

What medical intervention would offer greatest benefit?

- ○ Cyclizine
- ○ Potassium salt replacement
- ○ Elective terminal ileostomy
- ○ Dexamethasone
- ○ Delay next course of chemotherapy

Na^+	135 mmol/l
K^+	3.5 mmol/l
Urea	6.5 mmol/l
Creatinine	98 µmol/l

What medical intervention would offer greatest benefit?

Cyclizine	17%
Potassium salt replacement	2%
Elective terminal ileostomy	1%
Dexamethasone	76%
Delay next course of chemotherapy	5%

Dexamethasone with ondansetron is effective in refractory chemotherapy-induced vomiting

Important for me Less important

This gentleman has refractory vomiting despite ondansetron. He need assistance to ensure he can maintain fluids. Cyclizine is an antiemetic but bind histamine receptors so is most useful in labyrinthitis and motion sickness. Potassium salt replacement will probably make him vomit more but does replace his lost salts. Delaying the course of chemotherapy would be an option if nothing else could be offered. Surgery is not the way forward here. Dexamethasone is proven as an effective second line antiemetic in chemotherapy related nausea and vomiting. it is often given in lymphoma to prevent tumour lysis syndrome.

Discuss (6) Improve

Next question ›

Chemotherapy side-effects: nausea and vomiting ★

Nausea and vomiting are common side-effects of chemotherapy. Risk factors for the development of symptoms include:

- anxiety
- age less than 50 years old
- concurrent use of opioids
- the type of chemotherapy used

For patients at low-risk of symptoms then drugs such as metoclopramide may be used first-line. For high-risk patients then 5HT3 receptor antagonists such as ondansetron are often effective, especially if combined with dexamethasone

A 38-year-old man presents with increasing shortness of breath and ankle swelling. He reports he is more short of breath, especially on exertion, which is not being relieved by the use of his salbutamol inhaler. He has also noticed his ankles are swollen by the end of the day.

His past medical history includes asthma, which is usually well controlled, and lymphoma, which was treated with chemotherapy several years ago. His only medications are his beclometasone and salbutamol inhalers. The results of his blood tests are shown below:

Hb	140 g/L	(135-180)
Platelets	359 * 10^9/L	(150 - 400)
WBC	7.2 * 10^9/L	(4.0 - 11.0)
Na^+	137 mmol/L	(135 - 145)
K^+	4.3 mmol/L	(3.5 - 5.0)
Urea	5.9 mmol/L	(2.0 - 7.0)
Creatinine	119 µmol/L	(55 - 120)

His ECG showed sinus rhythm with left axis deviation. An echocardiogram was done which showed dilation of all four chambers of the heart and a left ventricular ejection fraction of 40%.

Which drug can be attributed to causing this man's presentation?

- ○ Cyclophosphamide
- ○ Vincristine
- ○ Doxorubicin
- ○ Docetaxel
- ○ Bleomycin

K^+	4.3 mmol/L	(3.5 - 5.0)
Urea	5.9 mmol/L	(2.0 - 7.0)
Creatinine	119 µmol/L	(55 - 120)

His ECG showed sinus rhythm with left axis deviation. An echocardiogram was done which showed dilation of all four chambers of the heart and a left ventricular ejection fraction of 40%.

Which drug can be attributed to causing this man's presentation?

Cyclophosphamide	1%
Vincristine	2%
Doxorubicin	88%
Docetaxel	4%
Bleomycin	5%

Anthracyclines (e.g. doxorubicin) may cause cardiomyopathy

Important for me Less important

This man is presenting with features of heart failure and the echocardiogram results would be in keeping with a diagnosis of dilated cardiomyopathy. Doxorubicin (an anthracycline) is used in the treatment of lymphoma and is known to be cardiotoxic.

Cyclophosphamide can also be used to treat lymphoma and other haematological conditions such as leukaemia. A well-known side effect is haemorrhagic cystitis.

Vincristine can be used with doxorubicin to treat lymphoma and is associated with peripheral neuropathy.

Docetaxel is often used in the management of breast and lung cancers and can cause neutropenia.

Bleomycin can be used as part of lymphoma management and is associated with the development of pulmonary fibrosis.

Next question >

Cytotoxic agents ★

The tables below summarises the mechanism of action and major adverse effects of commonly used cytotoxic agents.

Alkylating agents

Cytotoxic	**Mechanism of action**	**Adverse effects**
Cyclophosphamide	Alkylating agent - causes cross-linking in DNA	Haemorrhagic cystitis, myelosuppression, transitional cell carcinoma

Cytotoxic antibiotics

Cytotoxic	**Mechanism of action**	**Adverse effects**
Bleomycin	Degrades preformed DNA	Lung fibrosis
Anthracyclines (e.g doxorubicin)	Stabilizes DNA-topoisomerase II complex inhibits DNA & RNA synthesis	Cardiomyopathy

Antimetabolites

Cytotoxic	Mechanism of action	Adverse effects
Methotrexate	Inhibits dihydrofolate reductase and thymidylate synthesis	Myelosuppression, mucositis, liver fibrosis, lung fibrosis
Fluorouracil (5-FU)	Pyrimidine analogue inducing cell cycle arrest and apoptosis by blocking thymidylate synthase (works during S phase)	Myelosuppression, mucositis, dermatitis
6-mercaptopurine	Purine analogue that is activated by HGPRTase, decreasing purine synthesis	Myelosuppression
Cytarabine	Pyrimidine antagonist. Interferes with DNA synthesis specifically at the S-phase of the cell cycle and inhibits DNA polymerase	Myelosuppression, ataxia

Acts on microtubules

Cytotoxic	Mechanism of action	Adverse effects
Vincristine, vinblastine	Inhibits formation of microtubules	Vincristine: Peripheral neuropathy (reversible) , paralytic ileus Vinblastine: myelosuppression
Docetaxel	Prevents microtubule depolymerisation & disassembly, decreasing free tubulin	Neutropaenia

Topoisomerase Inhibitors

Cytotoxic	Mechanism of action	Adverse effects
Irinotecan	Inhibits topoisomerase I which prevents relaxation of supercoiled DNA	Myelosuppression

Other cytotoxic drugs

Cytotoxic	Mechanism of action	Adverse effects
Cisplatin	Causes cross-linking in DNA	Nephrotoxicity (the primary dose-limiting side effect), Ototoxicity, peripheral neuropathy, hypomagnesaemia
Hydroxyurea (hydroxycarbamide)	Inhibits ribonucleotide reductase, decreasing DNA synthesis	Myelosuppression

Question 40 of 43

You are reviewing a 65-year-old man who has recently started treatment for urological cancer with Nivolumab (Opdivo) a type of checkpoint inhibitor.

He has been having treatment for 1 month and has had no side effects so far. He would like to know what to expect from this treatment.

What is the most common side effect this patient is likely to experience?

- ○ Dry itchy skin and rashes
- ○ Depression and anxiety
- ○ Dry cough
- ○ Retinal damage
- ○ Skin discolouration

Question 40 of 43

You are reviewing a 65-year-old man who has recently started treatment for urological cancer with Nivolumab (Opdivo) a type of checkpoint inhibitor.

He has been having treatment for 1 month and has had no side effects so far. He would like to know what to expect from this treatment.

What is the most common side effect this patient is likely to experience?

Dry itchy skin and rashes	57%
Depression and anxiety	14%
Dry cough	8%
Retinal damage	9%
Skin discolouration	11%

The most common side effect of immune checkpoint inhibitors is dry itchy skin and rashes

Important for me Less important

Immune checkpoint inhibitors are a type of immunotherapy that are increasingly being used to treat certain types of cancer, as an alternative to cytotoxic chemotherapy. They are currently only used to treat solid tumours. They work by enhancing the bodies own T-cell population to destroy the cancer cells.

Their side effect profile reflects their mechanism of action and are, therefore, inflammatory and autoimmune in nature. They include:

- Dry, itchy skin and rashes (most commonly)
- Nausea and vomiting
- Decreased appetite
- Diarrhoea
- Tiredness and fatigue
- Shortness of breath and a dry cough.

Therefore, option one is the only correct answer.

Immune checkpoint inhibitors ★

Immune checkpoint inhibitors are a type of immunotherapy that are increasingly being used to treat certain types of cancer, as an alternative to cytotoxic chemotherapy. In contrast to therapies such as chemotherapy and tumour-targeted drugs that directly affect the growth and proliferation of tumour cells, these targeted treatments harness the body's natural anti-cancer immune response. They boost its ability to attack and destroy the cancer cells.

T-cells are an important part of our immune system which help destroy cancer cells. Some cancer cells make high levels of proteins that turn T-cells off. Checkpoint inhibitors block this process and reactivate and increase the body's own T-cell population, enhancing the immune systems own ability to recognise and fight cancer cells.

Types:

- Ipilimumab (Yervoy) is a checkpoint inhibitor that blocks CTLA-4 (cytotoxic T lymphocyte-associated protein 4). It is a treatment for advanced melanoma.
- Nivolumab (Opdivo) and pembrolizumab (Keytruda) blocks PD-1 (programmed cell death protein 1). These are treatments for melanoma, Hodgkin's lymphoma, non-small cell lung cancer and urological cancers.
- Atezolizumab, Avelumab and Durvalumab block PD-L1 and is used to treat lung cancer and urothelial cancer. It is also undergoing trials as a treatment for breast cancer.

The proteins CTLA-4 and PD-1 are found on T-cells and PD-L1 are found on cancer cells.

Administration

All CTLA-4 inhibitors and PD-1/PD-L1 inhibitors currently available are monoclonal antibodies (laboratory-produced molecules engineered to serve as substitute antibodies that each bind to a specific protein). They are all administered by injection/intravenous infusion. Mostly, they are given as a single-agent treatment but sometimes, they can be combined with chemotherapy or each other. For example, ipilimumab and nivolumab can be used in combination.

Side effects

This mechanism of action of these drugs can result in side effects termed 'Immune-related adverse events' that are inflammatory and autoimmune in nature. This is because all immune cells are boosted by these drugs, not just the ones that target cancer. The over-active T-cells can produce side effects such as:

- Dry, itchy skin and rashes (most commonly)
- Nausea and vomiting
- Decreased appetite
- Diarrhoea
- Tiredness and fatigue
- Shortness of breath and a dry cough.

Management of such side effects reflects the inflammatory nature, often involving corticosteroids.

It is important to monitor liver, kidney and thyroid function as these drugs can affect these organs.

The future

The early success of immune checkpoint inhibitors in solid tumours has generated a tremendous interest in further developing and exploring these strategies across the oncology disease spectrum. Their ongoing testing in clinical trials creates new hope for patients affected by other types of disease.

Question 41 of 43

A 54-year-old male presents to the emergency department with sudden onset palpitations and shortness of breath which began whilst he was watching television a few hours previously. He describes an odd fluttering sensation in his chest with mild dyspnoea but no chest pain. He denies having experienced this before. On systems review, he also complains of severe muscle cramps and a slight tremor in his hands over the last few days. His past medical history includes hypertension and gout for which he takes amlodipine and allopurinol. He denies any history of exertional dyspnoea but does occasionally get central chest pain on exertion for which he has not sought help. He has recently been diagnosed with small cell lung cancer and underwent his first round of chemotherapy last week; although he is unsure which drugs are being used. He used to smoke a pipe until his recent diagnosis of cancer and drinks a few measures of whisky most evenings.

On examination, his respiratory rate is 22 breaths/min and his oxygen saturations are 96% breathing two litres of oxygen. His heart rate is irregularly irregular and approximately 130 beats/min, his blood pressure is 152/78 mmHg. An ECG shows atrial fibrillation with no ischaemic changes.

What is the most likely cause for his new atrial fibrillation?

- ○ Ischaemic heart disease
- ○ Chemotherapy induced hypokalaemia
- ○ Chemotherapy induced hypomagnesaemia
- ○ Chemotherapy induced cardiomyopathy
- ○ Alcohol

A 54-year-old male presents to the emergency department with sudden onset palpitations and shortness of breath which began whilst he was watching television a few hours previously. He describes an odd fluttering sensation in his chest with mild dyspnoea but no chest pain. He denies having experienced this before. On systems review, he also complains of severe muscle cramps and a slight tremor in his hands over the last few days. His past medical history includes hypertension and gout for which he takes amlodipine and allopurinol. He denies any history of exertional dyspnoea but does occasionally get central chest pain on exertion for which he has not sought help. He has recently been diagnosed with small cell lung cancer and underwent his first round of chemotherapy last week; although he is unsure which drugs are being used. He used to smoke a pipe until his recent diagnosis of cancer and drinks a few measures of whisky most evenings.

On examination, his respiratory rate is 22 breaths/min and his oxygen saturations are 96% breathing two litres of oxygen. His heart rate is irregularly irregular and approximately 130 beats/min, his blood pressure is 152/78 mmHg. An ECG shows atrial fibrillation with no ischaemic changes.

What is the most likely cause for his new atrial fibrillation?

Ischaemic heart disease	2%
Chemotherapy induced hypokalaemia	14%
✓ Chemotherapy induced hypomagnesaemia	53%
Chemotherapy induced cardiomyopathy	25%
✗ Alcohol	6%

The most common chemotherapy regime for small cell lung cancer is etoposide and cisplatin. A common side effect of cisplatin is hypomagnesaemia which can result in muscle cramps, tremor, cardiac arrhythmias, confusion amongst other features. This gentleman appears to have angina and may well have some level of ischaemic heart disease in the background which would increase his risk of atrial fibrillation. However, it seems logical given the strong temporal relationship between the chemotherapy and the other symptoms of hypomagnesaemia that this is the cause.

Cytotoxic agents ★

The tables below summarises the mechanism of action and major adverse effects of commonly used cytotoxic agents.

Alkylating agents

Cytotoxic	**Mechanism of action**	**Adverse effects**
Cyclophosphamide	Alkylating agent - causes cross-linking in DNA	Haemorrhagic cystitis, myelosuppression, transitional cell carcinoma

Cytotoxic antibiotics

Cytotoxic	**Mechanism of action**	**Adverse effects**
Bleomycin	Degrades preformed DNA	Lung fibrosis
Anthracyclines (e.g doxorubicin)	Stabilizes DNA-topoisomerase II complex inhibits DNA & RNA synthesis	Cardiomyopathy

Antimetabolites

Cytotoxic	**Mechanism of action**	**Adverse effects**
Methotrexate	Inhibits dihydrofolate reductase and thymidylate synthesis	Myelosuppression, mucositis, liver fibrosis, lung fibrosis
Fluorouracil (5-FU)	Pyrimidine analogue inducing cell cycle arrest and apoptosis by blocking thymidylate synthase (works during S phase)	Myelosuppression, mucositis, dermatitis
6-mercaptopurine	Purine analogue that is activated by HGPRTase, decreasing purine synthesis	Myelosuppression
Cytarabine	Pyrimidine antagonist. Interferes with DNA synthesis specifically at the S-phase of the cell cycle and inhibits DNA polymerase	Myelosuppression, ataxia

Acts on microtubules

Cytotoxic	**Mechanism of action**	**Adverse effects**
Vincristine, vinblastine	Inhibits formation of microtubules	Vincristine: Peripheral neuropathy (reversible) , paralytic ileus Vinblastine: myelosuppression
Docetaxel	Prevents microtubule depolymerisation & disassembly, decreasing free tubulin	Neutropaenia

Topoisomerase Inhibitors

Cytotoxic	**Mechanism of action**	**Adverse effects**
Irinotecan	Inhibits topoisomerase I which prevents relaxation of supercoiled DNA	Myelosuppression

Other cytotoxic drugs

Cytotoxic	**Mechanism of action**	**Adverse effects**
Cisplatin	Causes cross-linking in DNA	Nephrotoxicity (the primary dose-limiting side effect), Ototoxicity, peripheral neuropathy, hypomagnesaemia
Hydroxyurea (hydroxycarbamide)	Inhibits ribonucleotide reductase, decreasing DNA synthesis	Myelosuppression

A 63-year-old man is diagnosed with colorectal cancer. Following successful resection he starts adjuvant capecitabine but after six doses develops severe diarrhoea, weakness and desquamation of the hands, feet and face. On admission, he is pancytopenic and has electrolyte abnormalities requiring IV replacement. His initial blood tests are shown bellow.

Na^+	140 mmol/l
K^+	3.6 mmol/l
Urea	9.2 mmol/l
Creatinine	125 µmol/l
Hb	75 g/l
Platelets	$35 * 10^9/l$
WBC	$0.4 * 10^9/l$
Neutrophils	$0.03 * 10^9/l$
Adjusted Ca^{2+}	1.5 mmol/l
Mg^{2+}	0.32 mmol/l
Glucose	4.0 mmol/l

What is the most likely cause?

○ DPD (dihydropyrimidine dehydrogenase) deficiency

○ Infective gastroenteritis

○ Cancer recurrence

○ Pityriasis alba

○ Neutropenic sepsis

What is the most likely cause?

DPD (dihydropyrimidine dehydrogenase) deficiency	63%
Infective gastroenteritis	3%
Cancer recurrence	1%
Pityriasis alba	2%
Neutropenic sepsis	31%

Capecitabine is the oral analog of 5-fluorouracil, a chemotherapeutic agent which is broken down, predominantly, by dihydropyrimidine dehydrogenase (DPD). Deficiency is autosomal recessive and will lead to a toxin buildup which in homozygous patients is usually fatal. The severe toxicity experienced by this patient are likely due to a heterozygous DPD deficiency.

Back to top

A 53 year old patient has undergone six cycles of R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisolone) chemotherapy and is now attending the lymphoma follow up clinic. He complains of an ongoing and unrelenting tingling in his feet and legs as well as his right hand. This is associated with pain in the extremities that is worsened by the cold weather.

Examination reveals normal motor strength throughout all 4 limbs but marked reduction in proprioception in both legs below the knee and also the right hand. The is a 'glove and stocking' distribution of loss when tested for pin-prick sensation and a reduced joint position sense to the ankle in both lower limbs. Plantar reflexes are normal. During the examination you it is noted that the patient has sustained an injury to the sole of foot which he was unaware of.

What is the most likely causative agent for these symptoms?

○ Rituximab

○ Cyclophosphamide

○ Doxorubicin

○ Vincristine

○ Prednisolone

A 53 year old patient has undergone six cycles of R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisolone) chemotherapy and is now attending the lymphoma follow up clinic. He complains of an ongoing and unrelenting tingling in his feet and legs as well as his right hand. This is associated with pain in the extremities that is worsened by the cold weather.

Examination reveals normal motor strength throughout all 4 limbs but marked reduction in proprioception in both legs below the knee and also the right hand. The is a 'glove and stocking' distribution of loss when tested for pin-prick sensation and a reduced joint position sense to the ankle in both lower limbs. Plantar reflexes are normal. During the examination you it is noted that the patient has sustained an injury to the sole of foot which he was unaware of.

What is the most likely causative agent for these symptoms?

Rituximab	1%
Cyclophosphamide	3%
Doxorubicin	3%
Vincristine	92%
Prednisolone	1%

The symptoms being experienced above are classical for chemotherapy induced peripheral neuropathy. This is a condition that can occur in up to 40% of patients being given chemotherapy with agents such as platinum based drugs (cisplatin and oxaliplatin), vinca alakloids (vincristine and vinblastine), thalidomide and taxanes (paclitaxel and docetaxel). The treatment of chemotherapy induced peripheral neuropathy is difficult with patients having severe problems long after the causative agent has been given. In most cases it is irreversible. The best medication for treatment is gabapentin or pregabalin which should be titrated up to therapeutic levels and used in conjunction with another analgesic agents.

There are ongoing trials aiming to find a prophylactic agent to help prevent this painful sequealae of treatment, but as yet there has been no convincing evidence to suggest any one treatment.

DERMATOLOGY
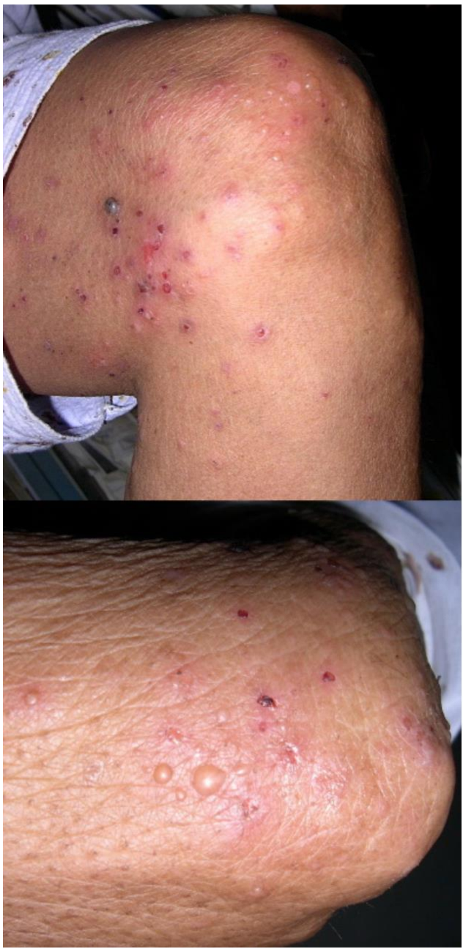
PASSMEDICINE
PART 2 2024

Question 1 of 182

A 32-year-old woman presents to her GP with a rash of several weeks, across the elbows and knees. She also mentions generalised tiredness. Upon examination, the following rash is noticed:



Blood tests reveal iron-deficiency anaemia.

Given the most likely diagnosis, which of the following is an appropriate first-line option?

A. Oral cetirizine
B. Oral dapsone
C. Oral prednisolone
D. Topical clobetasol
E. Topical tacrolimus

B. Oral dapsone

The diagnosis here is that of dermatitis herpetiformis. The photo above depicts a vesicular rash on an erythematous background, overlying an extensor surface (in this case, a knee). As in this photo, the lesions often appear somewhat excoriated due to the intense pruritus associated with the condition. The question also gives some additional clues by way of the tiredness and irondeficiency anaemia - commonly present in coeliac disease, which is very strongly associated with dermatitis herpetiformis. First-line treatment involves the use of oral dapsone.

Oral cetirizine is inappropriate. Whilst useful for the alleviation of itch, it does not help to resolve the condition. If the diagnosis were instead prickly heat rash or urticaria, cetirizine would be the sole appropriate option.

Oral prednisolone may be used as a second- or third-line option if initial measures fail. However, with regards to initial management, oral dapsone is considered most effective for dermatitis herpetiformis.

Topical clobetasol is a second-line option for dermatitis herpetiformis, not first-line. It is first-line for bullous pemphigoid, which would appear quite differently - tense blisters would be visible, rather than the bullae seen here.

Topical tacrolimus is a steroid-sparing agent sometimes used in the management of steroid-resistant eczema, especially for children and on sensitive areas such as the face. It also plays a role in the management of bullous pemphigoid. It is not routinely used in dermatitis herpetiformis.

Question 2 of 182

A 45-year-old man has been referred to the dermatology clinic for a long-standing facial rash that has not been evaluated before. You note that multiple erythematous papules and pustules are present over his nose and cheeks in a centrofacial distribution. The consultant diagnoses him with moderate to severe papulopustular rosacea.

What is the most appropriate management of this patient?

A. Oral isotretinoin
B. Topical azelaic acid and oral isotretinoin
C. Topical ivermectin
D. Topical ivermectin and oral doxycycline
E. Topical metronidazole and oral isotretinoin

D. Topical ivermectin and oral doxycycline

Rosacea: a combination of topical ivermectin + oral doxycycline is first-line for patients with severe papules and/or pustules

Topical ivermectin and oral doxycycline is the correct answer. Rosacea is a chronic skin disorder which primarily affects the central portion of the face. It is characterised by centrofacial erythema, papules, pustules flushing and telangiectasias. Ocular involvement may also be seen in the form of conjunctiva injection and lid telangiectasias. The management of rosacea is detailed in the notes linked to this question. This patient has been diagnosed with moderate-to-severe papulopustular disease, which is treated with a combination of topical ivermectin and oral doxycycline.

Oral isotretinoin is incorrect. Oral isotretinoin is not used as first-line therapy in rosacea. It is used only when patients fail to respond to topical therapies and oral antibiotics. Since this patient is treatment-naive, he should initially be prescribed the standard topical treatment along with an oral antibiotic.

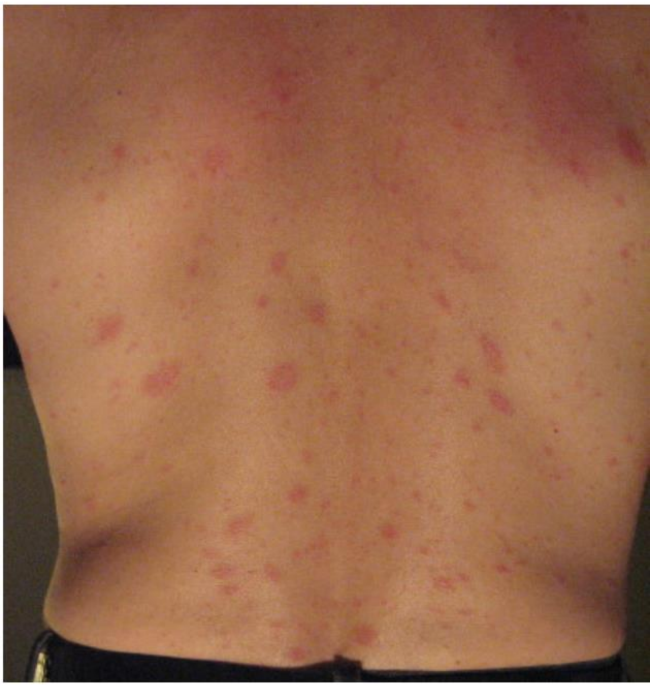
Topical azelaic acid and oral isotretinoin is incorrect. Topical azelaic acid is used to treat mild-tomoderate rosacea with papules and pustules. Hence, it will not apply to this patient with a greater disease severity. As mentioned previously, isotretinoin is not to be used as a first-line treatment, making this an unlikely prescription for this patient.

Topical ivermectin is incorrect. It is a first-line therapy for mild-to-moderate papulopustular rosacea. This patient, however, has a more severe rosacea phenotype and will require a combination of topical therapy and an oral antibiotic like doxycycline.

Topical metronidazole and oral isotretinoin is incorrect. Topical metronidazole is another topical treatment used as first-line therapy for mild-to-moderate papulopustular rosacea. Isotretinoin is not used as first-line therapy, as explained previously. Hence, a combination of topical metronidazole and oral isotretinoin will not be suitable for this patient who has severe disease and is treatment naïve.

Question 3 of 182

A 21-year-old man presents with an itchy rash around 2 weeks after a brief illness with mild fever and malaise. He first noticed a scaly patch on his chest around 2cm in diameter, and 2 days later developed the lesions as shown in the image. He is otherwise well.



What virus has been hypothesized to be a trigger for this condition?

A. Adenovirus
B. Cytomegalovirus
C. Enterovirus
D. Epstein Barr virus
E. Human herpes virus 7

E. Human herpes virus 7

This patient has pityriasis rosea. This is a self-limiting skin condition that presents numerous itchy, scaly oval lesions, mainly on the trunk and proximal aspects of the limbs. In over half the cases, the rash is preceded by the appearance of a 'herald patch' which is a larger lesion around 2-5cm in diameter and which appears around 2 days before the onset of the wider rash. Pityriasis rosea occurs mainly in older children and young adults.

The trigger for the rash is not definitively known but a viral cause is thought likely given that many cases are preceded by a viral-type illness with fever, malaise, headache, and sore throat and because cases can occur in clusters or outbreaks. The strongest evidence is for an association with **human herpes virus 7** (HHV7). This is a similar virus to human herpes virus 6 (HHV6), both of which cause exanthem subitum (also called roseola) in infants, as well as a non-specific febrile illness in older children.

Adenovirus is incorrect. This virus can cause a range of presentations, including conjunctivitis, pharyngitis, and gastroenteritis, but there is no known association with pityriasis rosea.

Cytomegalovirus is incorrect. This virus is also in the herpes virus family. It can cause an acute febrile illness similar to infectious mononucleosis and is associated with complications in immunesuppressed patients or pregnant women, but no association has been shown with pityriasis rosea.

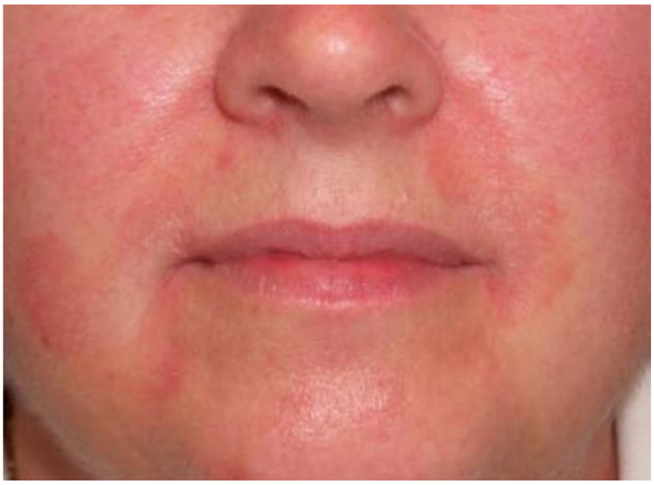
Enterovirus is incorrect. This is a group of viruses that can a range of conditions including gastroenteritis, meningitis/encephalitis, hand foot, and mouth disease, and non-specific rashes. They are not thought to be a trigger for pityriasis rosea.

Epstein Barr virus is incorrect. This is again a herpes virus, but it is not known to trigger pityriasis rosea.

Question 4 of 182

A 34-year-old male sex worker presents with a sudden onset of a flaky, erythematous rash affecting his nasolabial folds and upper chest. He has also noticed dandruff, which has not previously been an issue.

On examination, there is fissuring behind his ears and yellow scaling between his eyelashes.



What investigation is most likely to diagnose the underlying condition predisposing to this patient's skin changes?

A. Anti-dsDNA antibodies
B. HIV serology
C. Hepatitis B serology
D. Oral glucose tolerance test
E. Treponemal EIA

B. HIV serology

The patient in this scenario presents with seborrhoeic dermatitis. While seborrhoeic dermatitis is commonly seen in individuals without underlying medical conditions, it occurs more frequently in immunocompromised patients, particularly those with HIV. Therefore, **HIV serology** testing is recommended to exclude HIV as a predisposing factor, especially given the patient's increased risk as a male sex worker.

Anti-dsDNA antibodies are highly specific to systemic lupus erythematosus (SLE). Although SLE can present with various skin manifestations, such as a malar or discoid rash, it does not cause seborrhoeic dermatitis. Therefore, testing for anti-dsDNA antibodies would be inappropriate in this case.

While it would be prudent to test for hepatitis B given the patient's risk of blood-borne viruses, hepatitis B does not cause seborrhoeic dermatitis. Thus, **hepatitis B serology** is less appropriate than HIV serology. Hepatitis B can present with skin manifestations like erythema nodosum, erythema multiforme, and urticaria, but not seborrhoeic dermatitis.

Diabetes mellitus can present with skin conditions such as diabetic dermopathy, acanthosis nigricans, and necrobiosis lipoidica; however, seborrhoeic dermatitis is not associated with diabetes. An **oral glucose tolerance test** would therefore be unnecessary, as it would not help diagnose the skin condition and there are no indications of diabetes in the patient's history.

While testing for syphilis may be advisable for a sex worker, syphilis does not cause seborrhoeic dermatitis. **Treponema EIA** testing is therefore also incorrect, as seborrhoeic dermatitis is more likely to be related to HIV. Syphilis has characteristic skin manifestations, including the primary chancre and the rash found on the soles of the feet and palms of the hands in secondary syphilis.

Question 5 of 182

A 82-year-old man is reviewed in dermatology clinic as part of ongoing treatment for metastatic melanoma. He had been diagnosed with melanoma three years previously after resection of a lesion on his left shoulder. Surgical margins had been satisfactory, however a metastatic lesion had been identified in the patient's liver four months prior to the present day. Following oncology MDT discussion, patient had been treated with vemurafenib. Initial follow-up with repeat abdominal CT scan had demonstrated an excellent response with dramatic reduction in size of metastatic deposit.

The patient reported continuing to feel well in himself. However, he was concerned about a new skin lesion he had noticed on his right thigh. While he could not recall exactly when this lesion had first appeared, he was confident that it had been present for less than two months. It had not been present during a full dermatological examination at the previous clinic appointment three months previously. The patient reported that the lesion was a bit uncomfortable when he caught it on his trousers but denied any other symptoms.

Examination of the lesion on the patient's thigh revealed a 11 mm diameter erythematous papule with minimally everted edges. A slight scale was noted on the surface of the lesion. There was no evidence of telangiectasia associated with the lesion. Examination of the inguinal lymph nodes was unremarkable.

Following assessment in clinic, a biopsy of the lesion was taken.

What is the most likely diagnosis following histological examination of the biopsy specimen?

A. Melanoma
B. Merkel cell carcinoma
C. Squamous cell carcinoma
D. Atypical fibroxanthoma
E. Keratocanthoma

C. Squamous cell carcinoma

Vemurafenib and dabrafenib are selective BRAF inhibitors that increase overall survival in metastatic melanoma. These drugs paradoxically activates the MAPK pathway in keratinocytes and so can cause squamous cell carcinomas, often within the first three months of therapy. The risk of squamous cell carcinoma with vemurafenib and dabrafenib is higher in older patients and they can occur in sun-protected sites.

Given the typical appearance of the above lesion and the recent treatment with vemurafenib, the most likely histology of the lesion in this case is squamous cell carcinoma. Melanoma is less likely due to the atypical appearance and apparent good treatment response to vemurafenib.

The description of the lesion is not consistent with the typical appearance of the other possible answers.

Question 6 of 182

A 35-year-old man is reviewed in the medical clinic. He has severe eczema and over the last two weeks has had a flare of eczema which the GP has been unable to manage. He normally manages his condition with emollients and hydrocortisone 1%, but has noted worsening flexural irritation and pruritus. He denies any systemic symptoms. He also has a past medical history of asthma for which he rarely needs his salbutamol inhaler, and hay-fever. He takes no oral medications. He has a previous dermatology appointment letter which advises that if his eczema remains poorly controlled he should have a short course of a moderate topical steroid.

Which prescription is most appropriate?

On examination, he has macular erythema of his flexural surfaces, especially elbow and knee creases.

A. Clobetasone butyrate 0.05% (Eumovate)
B. Betamethasone valerate 0.1% (Betnovate)
C. Fluticasone propionate 0.05% (Cutivate)
D. Clobetasol propionate 0.05% (Dermovate)
E. Hydrocortisone 2.5%

A. Clobetasone butyrate 0.05% (Eumovate)

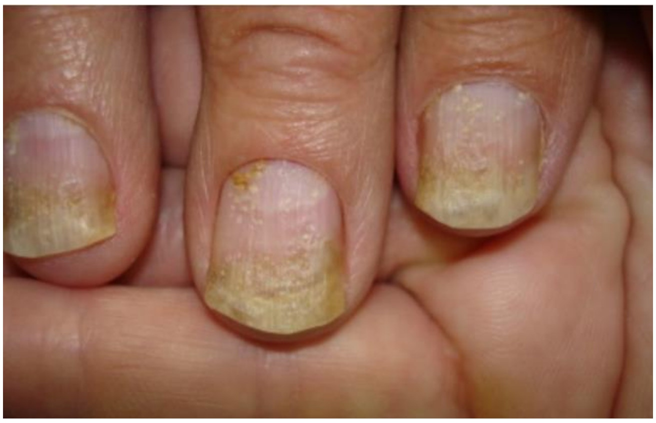
Clobetasol is the most potent topical steroid compared to clobetasone, betamethasone valarate and hydrocortisone

This patient has poorly controlled eczema and needs a moderate strength topical steroid. This question tests knowledge of the strength of different topical steroids. This can be important as the level of systemic absorption can become significant with higher dose topical steroid creams and also stronger topical treatments should not be applied to sensitive skin due to the potential of skin thinning.

Question 7 of 182

A 45-year-old man presents to his GP with a 4-week history of worsening nail changes. He works as a banker and is finding that the appearance of his nails is affecting his confidence. He also describes occasional pain in his wrists and fingers but says this is managed well with over-thecounter analgesia. His past medical history includes coeliac disease and hypothyroidism for which he takes levothyroxine.

On examination, his observations are within normal limits. There are no visible skin or mucosal changes. His nails are examined, as shown below.



What is the most likely diagnosis?

A. Onychomycosis
B. Parakeratosis pustulosa
C. Paronychia
D. Psoriasis
E. Yellow nail syndrome

D. Psoriasis

This patient's nails show signs of onycholysis (lifting of the nail bed) and pitting (indentations to the surface of the nails) which are suggestive of nail psoriasis. Nail psoriasis is commonly associated with chronic plaque psoriasis and is a risk factor for the development of psoriatic arthritis. The clinical history of wrist and finger pain further supports the diagnosis of developing psoriatic arthropathy. Other nail features of psoriasis (although not seen here) include splinter haemorrhages, leukonychia, and nail crumbling.

Onychomycosis is otherwise known as a fungal nail infection. Common organisms include dermatophytes such as *Trichophyton rubrum* and *Candida albicans*. Signs of onychomycosis include distal and lateral onycholysis, subungual hyperkeratosis (scaling under the nail), and nail destruction. Not all nails are necessarily affected by onychomycosis and involvement of all nails should raise suspicion of an alternative diagnosis. This patient also complains of wrist and finger pain and has evidence of nail pitting, making psoriasis the more likely diagnosis.

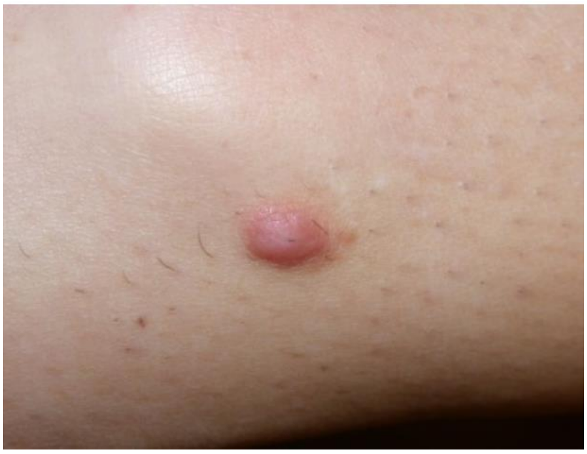
Parakeratosis pustulosa is most commonly seen in younger children and involves the destruction or crumbling of a finger or toenail along with erythema and scaling of the surrounding skin. Similarly to this patient, onycholysis and nail pitting are possible nail features. However, the involvement of all nails with no surrounding skin changes and the older age of the patient makes parakeratosis pustulosa unlikely.

Paronychia is the inflammation of the skin surrounding a finger or toenail secondary to infection with *Staphylococcus aureus* or *Streptococcus pyogenes*. In acute paronychia, usually, only one finger or toe is affected and the nail is less commonly involved compared to chronic disease (i.e. > 6 weeks).

Yellow nail syndrome refers to the thickening and yellow discolouration of nails secondary to halted nail growth. It is associated with multiple conditions including chronic sinus infections, bronchiectasis, and pleural effusions.

Question 8 of 182

A 35-year-old man asks you to review a lesion on his right arm. This has been present for the past six months but has not changed significantly over that period.



What is the most likely diagnosis?

A. Spitz naevus
B. Dermatofibroma
C. Nodular basal cell carcinoma
D. Viral wart
E. Dermoid cyst

B. Dermatofibroma

The correct answer is **Dermatofibroma**. Dermatofibromas are common benign cutaneous nodules of unknown aetiology. This lesion, as seen in the image, is a firm papule or nodule that appears dermal yet is firmly adherent to the epidermis. The colour can vary from skin-coloured to redbrown. It is often asymptomatic but can be tender or itchy, particularly if traumatised. The characteristic 'dimple sign' (a central depression when the lesion is laterally compressed) is usually present.

The first incorrect option is a **Spitz naevus**. Although Spitz naevi may appear similar to dermatofibromas on visual inspection, they are typically seen in children and teenagers rather than adults. They often have a more rapid onset (weeks to months) compared with the six-month history provided in this case. Furthermore, Spitz naevi tend to change significantly over time, unlike the stable nature of the lesion described here.

The second incorrect option is a **Nodular basal cell carcinoma**. While these lesions may also appear similar to dermatofibromas visually, they are typically characterised by more aggressive growth patterns and features such as telangiectasia (tiny blood vessels), ulceration or bleeding which were not described in this case.

The third incorrect option is a **Viral wart**. Viral warts caused by human papillomavirus (*HPV*) are typically keratotic and rough-surfaced lesions that grow rapidly over weeks to months. They may also have black dots representing thrombosed capillaries ('wart seeds'). None of these features were mentioned in this case.

Lastly, a **Dermoid cyst** was an incorrect choice because dermoid cysts are congenital lesions that present early in life and grow slowly over years rather than months. They can be fluctuant or doughy to touch unlike the firm lesion described here.

Question 9 of 182

A 58-year-old man is referred to the clinic with chronic diarrhoea and episodes of facial flushing. A computed tomography scan of his chest and abdomen reveals that he has a neuroendocrine carcinoma of the appendix, causing carcinoid syndrome.

He refuses treatment and presents six months later having been referred by a neurologist as having early onset dementia and a rapidly evolving photosensitive rash on his trunk and upper arms.

Which of the following is the most likely diagnosis?

A. Systemic lupus erythematosus
B. Herpes zoster infection
C. Pellagra
D. Wernicke-Korsakoff syndrome
E. Porphyria

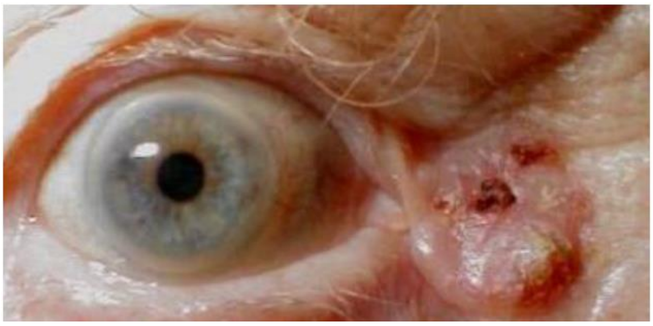
C. Pellagra

Niacin (B3) deficiency is characterised by dermatitis, diarrhoea and dementia, a condition known as pellagra

The most likely diagnosis, in this case, is pellagra, a vitamin deficiency disease most frequently caused by a chronic lack of niacin (vitamin B3). In carcinoid syndrome, neuroendocrine tumours along the GI tract use tryptophan as the source for serotonin production, which limits the available tryptophan for niacin synthesis.

Question 10 of 182

An 80-year-old woman presents due a 'sore' on the medial aspect of her right eye:



What is the most likely diagnosis?

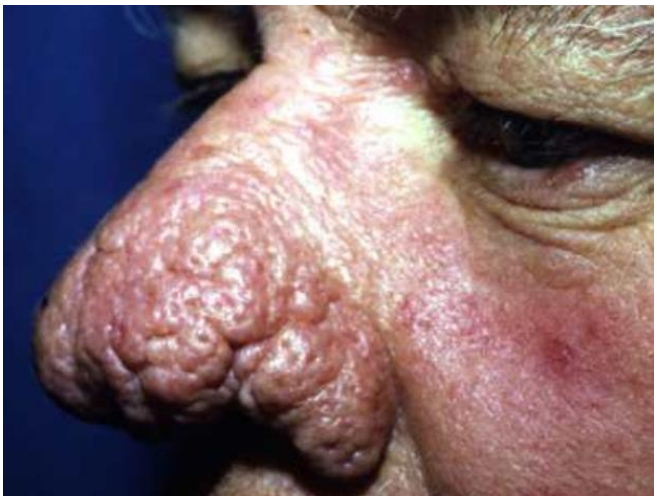
A. Basal cell carcinoma
B. Squamous cell carcinoma
C. Chalazion
D. Stye
E. Indurated dacryocystitis

A. Basal cell carcinoma

The rolled, pearly edges with telangiectasia on the inferior border of the lesion make basal cell carcinoma the most likely diagnosis.

Question 11 of 182

An elderly man complains about the appearance of his nose:



What is the most likely diagnosis?

A. Sarcoidosis
B. Basal cell carcinoma
C. Systemic lupus erythematosus
D. Alcohol excess
E. Acne rosacea

E. Acne rosacea

Rosacea features:

- nose, cheeks and forehead
- flushing, erythema, telangiectasia → papules and pustules

This man has a rhinophyma, a complication of acne rosacea.

Question 12 of 182

A 72-year-old woman is diagnosed with a number of erythematous, rough lesions on the back of her hands. A diagnosis of actinic keratoses is made.

What is the most appropriate management?

A. Reassurance
B. Urgent referral to a dermatologist
C. Topical fluorouracil cream
D. Review in 3 months
E. Topical betnovate

C. Topical fluorouracil cream

The correct answer is **Topical fluorouracil cream**. Actinic keratoses (AKs) are rough, scaly patches on the skin that are caused by excessive exposure to the sun. They can potentially develop into squamous cell carcinoma, a type of skin cancer. Therefore, treatment is recommended to prevent this progression. In the UK, according to NICE guidelines, topical fluorouracil cream is considered first-line therapy for multiple AKs. This medication works by interfering with the DNA in skin cells, preventing their growth and causing them to die.

The first option, **Reassurance**, is incorrect because although actinic keratoses are not malignant themselves, they have the potential to progress into squamous cell carcinoma. Hence it's important to treat them rather than simply reassuring the patient.

The second option, **Urgent referral to a dermatologist**, isn't necessary unless there's suspicion of malignant transformation or if initial treatments fail - neither of which we're told is applicable in this case scenario.

Review in 3 months without any treatment intervention may allow for unnecessary progression of the lesions and hence is not an appropriate management strategy.

Finally, **Topical betnovate**, a corticosteroid cream, is also not a suitable treatment for actinic keratoses as it doesn't target the abnormal proliferation of keratinocytes seen in these lesions. Instead, it's primarily used for conditions involving inflammation and itching such as eczema and dermatitis.

Question 13 of 182

A 68-year-old man presents with blistering lesions on his skin. He reports he has suffered from mouth ulcers recently for which his GP prescribed chlorhexidine mouthwash. However, this has not been of any benefit and the ulcers are now affecting his ability to eat and drink. He reports over the last few days, large blisters have appeared across his torso and back.

His past medical history includes hypertension and angina. He currently takes ramipril, simvastatin and GTN spray when needed.

On examination, you find his mouth is erythematous with multiple superficial blisters; some have ulcerated and the patient reports they have been slow to heal. He has flaccid bullae across his torso and upper back, which appear to be filled with clear fluid. The bullae are fragile, with a thin outer layer. There are some areas where the blisters have ruptured, leaving exposed eroded skin, with some crusting around the edges. Dermatology comes to review and they perform a punch biopsy, but advise you to start treatment whilst the results are awaited.

Given the likely diagnosis, what is the most appropriate first-line treatment?

A. Azathioprine
B. Mycophenolate mofetil
C. Topical emollients
D. Topical potent corticosteroids
E. Oral corticosteroids

E. Oral corticosteroids

Systemic glucocorticoids are the first-line treatment in pemphigus vulgaris

This patient has presented with bullous skin lesions with mucosal involvement therefore the diagnosis is pemphigus vulgaris. The first-line treatment for this is oral corticosteroids.

Azathioprine and mycophenolate mofetil are steroid-sparing agents that can be used longer-term to control the disease, but would not be initiated in the acute phase.

Topical emollients are useful for dry skin, eczema, psoriasis and lots of other skin conditions. However, they will not be useful in the management of bullous skin disease.

Topical potent corticosteroids are not appropriate treatment in pemphigus vulgaris due to the widespread nature of the disease, including mucosal involvement. Oral steroids are of greater benefit.

Question 14 of 182

A 38-year-old patient is referred to the dermatology clinic due to persistent pruritus. She has a long-standing history of eczema and is using topical corticosteroids and emollients as prescribed. On examination, you note erythematous, excoriated patches of eczema on the flexural surfaces of the legs. The patient complains of intense itching and seeks additional relief.

What non-pharmacological method is most appropriate for controlling pruritus in this patient?

A. Bandaging lesions
B. Low humidity environment
C. Multiple baths a day
D. Oral antihistamines
E. Use of hard water

A. Bandaging lesions

Bandaging can help control itching in eczema to prevent further scratching

Bandaging lesions is the correct answer. Bandaging eczematous lesions can provide significant relief from itching as it protects the skin from further scratching, thereby interrupting the itchscratch cycle. It also helps to maintain moisture and enhance the penetration of topical medications. Dressings can also be worn overnight to prevent involuntary scratching during sleep.

Low humidity environment is incorrect. Low-humidity environments have been recognised to aggravate eczema as they dry the skin, which can lead to itching. Maintaining skin hydration is an essential cornerstone of managing eczema, and this is done with the help of emollients and moisturisers applied multiple times during the day.

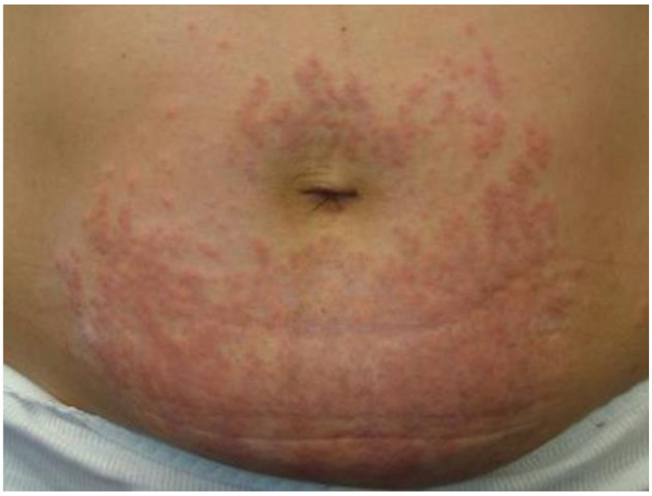
Multiple baths a day is incorrect. Excessive bathing or washing can cause flares of eczema and increase pruritus, as it can dry the skin and expose it to chemicals in the water that can irritate it. Daily bathing/showering should be accompanied by using a mild cleanser during the bath, followed immediately by applying an emollient to prevent the skin from drying.

Oral antihistamines is incorrect. Oral antihistamines, especially the first-generation antihistamines, which have an additional sedative effect, are commonly used to relieve pruritis in patients with eczema. However, they are a pharmacological method to control pruritus, which makes them the wrong answer in the given context.

Use of hard water is incorrect. It has been reported that areas with hard water have a higher prevalence of eczema in the population. It is postulated that the minerals in the hard water cause the deposition of soap compounds like sodium lauryl sulfate on the skin, which can cause skin irritation and itching.

Question 15 of 182

A woman who is 30 weeks pregnant asks you about an itchy rash on her abdomen:



What is the most likely diagnosis?

A. Pre-eclampsia
B. Polymorphic eruption of pregnancy
C. Primary herpes simplex infection
D. Pemphigoid gestationis
E. Pompholyx

B. Polymorphic eruption of pregnancy

The correct answer is **Polymorphic eruption of pregnancy**. This condition, also known as PEP or pruritic urticarial papules and plaques of pregnancy (PUPPP), typically presents in the third trimester. It is characterised by an itchy rash that usually starts on the abdomen, particularly around stretch marks, and can spread to the rest of the body except for the face. The rash consists of small red bumps and hives, and sometimes larger patches of raised skin. The exact cause is unknown, but it may be related to stretching of the skin.

Pre-eclampsia is incorrect because this condition does not typically present with a rash. Preeclampsia is a serious disorder of pregnancy characterised by high blood pressure and signs of damage to another organ system, most often the liver and kidneys. Symptoms often include severe headaches, visual disturbances, upper abdominal pain, swelling in your face or hands, and shortness of breath.

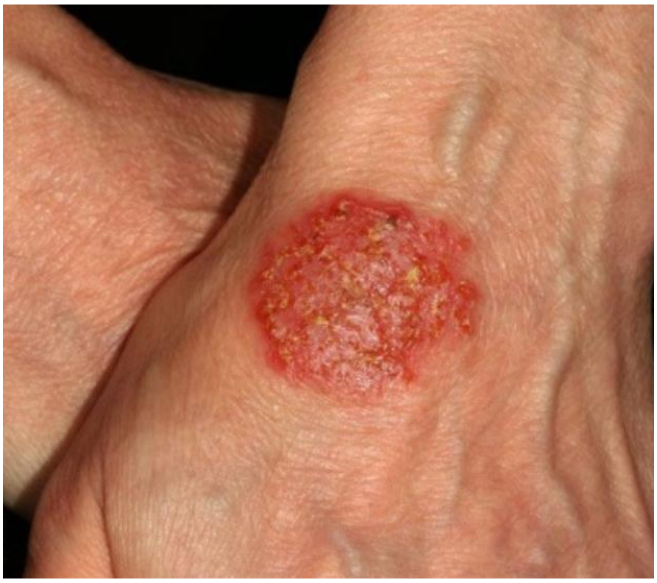
Primary herpes simplex infection during pregnancy could potentially occur but would be unusual to only affect the abdomen and would likely present with painful vesicles rather than an itchy rash. Herpes simplex virus (HSV) infections during pregnancy can lead to neonatal herpes, which can be deadly.

Pemphigoid gestationis, also known as gestational pemphigoid, is an autoimmune blistering disorder that occurs during pregnancy. This option is incorrect because this condition typically presents with blisters rather than a rash. It usually begins with itchy bumps or hives that quickly develop into large blisters over large areas of your body.

Pompholyx, also known as dyshidrotic eczema, causes tiny blisters to erupt across the fingers, palms of the hands and sometimes the soles of your feet. It's extremely itchy but doesn't tend to affect other parts of the body so wouldn't explain a rash on a pregnant woman's abdomen.

Question 16 of 182

A 65-year-old man presents after developing an intensely itchy 'rash' or the dorsum of his left hand. This has now been present for around 6 weeks. He also points out a similar lesion on the dorsum of the right wrist which has appeared in the past week. His past medical history includes type 2 diabetes mellitus and depression. From reviewing his medication history it seems that citalopram has recently been changed to sertraline around 8 weeks ago due to a poor response. The lesion is shown below:



What is the most likely diagnosis?

A. Discoid eczema
B. Contact dermatitis
C. Psoriasis
D. Allergic reaction to sertaline
E. Lichen planus

A. Discoid eczema

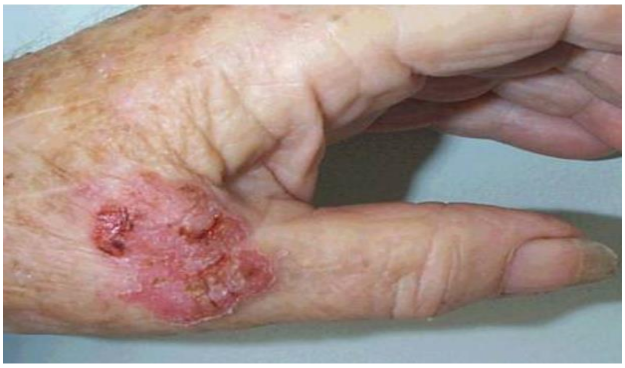
This lesion is typical of discoid eczema. Lesions are typically well defined, intensely pruritic and located on the peripheries. Discoid, or nummular, eczema shows a bimodal distribution, being more common in the 20's (predominately females) and the 60's (predominately males).

These lesions are not consistent with an allergic reaction. If the option of a fixed drug eruption had been given the differential would have been much harder as the appearance is much more similar. Fixed drug eruptions however tend to occur within 24 hours of starting the drug and disappear after 10 days.

The location of the lesions is not consistent with contact dermatitis.

Question 17 of 182

Please look at the image below:



The lesion has been getting bigger for the past few weeks. There is no history of trauma.

What is the most likely diagnosis?

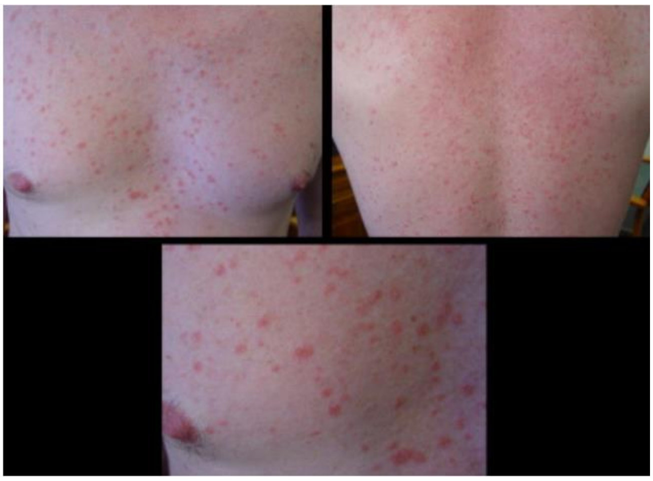
A. Basal cell carcinoma
B. Seborrhoeic keratosis
C. Bowen's disease
D. Tinea corporis
E. Nummular eczema

C. Bowen's disease

Question 18 of 182

A 23-year-old man presents to his General Practitioner with a 3-day history of a widespread rash across his body. He denies fever, pain or itch but is very concerned as the rash is unsightly and is affecting his confidence. Other than recovering from a sore throat and coryzal symptoms over the past week, there is no other past medical history of note and he has no known allergies. He is a teaching assistant in a nursery school.

His rash is examined, as shown below:



What is the most likely diagnosis?

A. Disseminated varicella zoster
B. Guttate psoriasis
C. Pityriasis rosea
D. Pityriasis versicolor
E. Tinea corporis

B. Guttate psoriasis

Guttate psoriasis is correct. This patient has multiple pinky-red scaly lesions predominantly over his trunk. They are numerous in number and relatively small in size (<1cm) in keeping with guttate psoriasis. These lesions can typically have a tear-drop shape to them. Guttate psoriasis is most common in children and young adults and often follows an upper respiratory tract infection with *Streptococcus* species (which may be more likely in an occupational setting with young children).

Disseminated varicella zoster is incorrect. Chickenpox causes a macular, papular and vesicular rash with crusting of lesions over time. In cases of disseminated chickenpox, there is often cerebral involvement and thrombocytopenia, causing purpura. This is not seen in this scenario.

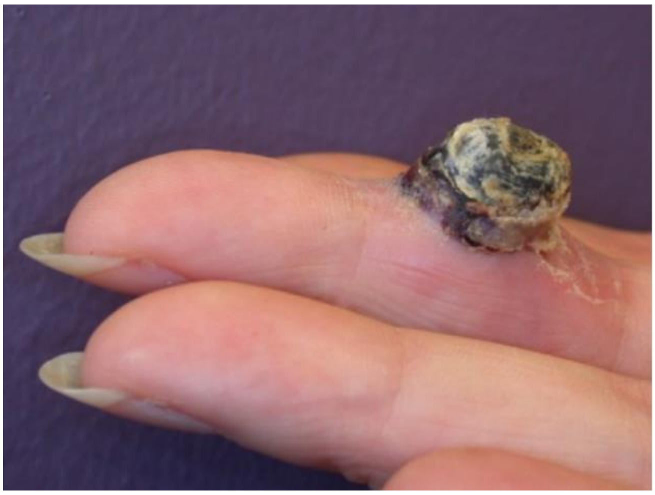
Pityriasis rosea is incorrect. This is a self-limiting rash with no clear cause. The onset of the rash typically begins with a 'herald patch' found on the torso, followed by a widespread salmon-pink or red rash consisting of small (2-5cm) plaques with a peripheral scale. There is no history of a herald patch in this scenario making the diagnosis less likely.

Pityriasis versicolor is incorrect. This is a skin infection caused by the *Malassezia* species of yeast. Features of pityriasis versicolor include asymptomatic hyper- or hypopigmentation or pinkcoloured skin lesions. It is more common in hot climates where perspiration is frequent.

Tinea corporis is incorrect. This is a superficial fungal infection that causes a solitary erythematous and scaly circular lesion on the skin surface. In contrast, this patient has multiple lesions, making tinea corporis incorrect.

Question 19 of 182

A 23-year-old woman who is 10 weeks pregnant presents with a rapidly growing lesion on her finger. This has grown from the size of a 'pin-prick' when it first appeared 4 weeks ago.



What is the most likely diagnosis?

- A. Viral wart
- B. Orf
- C. Pyogenic granuloma
- D. Capillary haemangioma
- E. Squamous cell carcinoma

C. Pyogenic granuloma

The most likely diagnosis in this case is a **Pyogenic granuloma**. Pyogenic granulomas are benign, vascular skin lesions that grow rapidly over weeks or months. They can occur at any age but are more common in children and young adults, particularly pregnant women due to hormonal changes. The lesion often appears as a small, red, raised bump that may bleed easily. In this case, the rapid growth of the lesion and the patient's pregnancy status make pyogenic granuloma the most likely diagnosis.

A **Viral wart** is less likely because these typically grow slowly over time rather than rapidly.

Moreover, they usually have a rough surface whereas the lesion in question appears smooth.

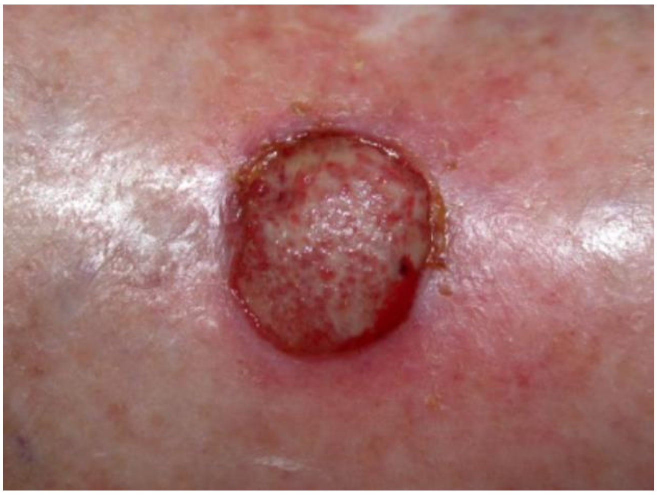
Orf is an infectious disease caused by a parapoxvirus affecting sheep and goats. Humans can contract it through direct contact with infected animals or contaminated objects. However, it usually presents as one or few lesions on hands or fingers with surrounding erythema and regional lymphadenopathy which does not seem to be the case here.

A **Capillary haemangioma**, also known as strawberry naevus, commonly occurs in infants and usually regresses spontaneously by childhood. It would be rare for it to first appear in an adult woman.

Finally, **Squamous cell carcinoma** (SCC) is unlikely given the patient's age - SCC typically occurs in older individuals who have had significant sun exposure over their lifetime. Furthermore, SCCs generally grow slowly over time rather than rapidly.

Question 20 of 182

A 54-year-old man presents with a lesion on his forearm. This has been slowly developing over the past 2-3 months and has bled on one occasion. His past medical history includes Alport syndrome for which he had a renal transplant ten years ago. He currently takes ciclosporin as immunosuppression. He also takes ramipril and amlodipine for hypertension. The lesion is shown below:



What is the most likely diagnosis?

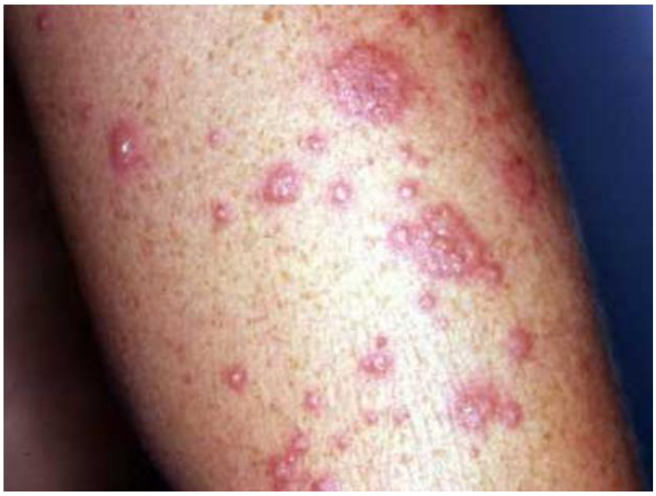
- A. Squamous cell carcinoma
- B. Basal cell carcinoma
- C. Pyogenic granuloma
- D. Haemangioma
- E. Pyoderma gangrenosum

A. Squamous cell carcinoma

The clue here is immunosuppression. Patients on ciclosporin and other immunosuppressants have a much higher risk of squamous cell carcinoma.

Question 21 of 182

A 50-year-old man who has had a cough for the past week develops a rash. It initially appeared on his arms but has now spread to the torso:



What is the most likely underlying diagnosis?

A. Goodpasture's syndrome
B. Adenovirus
C. Mycoplasma pneumoniae
D. Legionella pneumophilia
E. Rhinovirus

C. Mycoplasma pneumoniae

This patient has developed erythema multiforme (EM), a known complication of Mycoplasma infection. *Mycoplasma pneumoniae* is the second most common trigger of EM after the herpes simplex virus.

Question 22 of 182

A 67-year-old gentleman is reviewed in the medical clinic. He was diagnosed by his GP with scabies two weeks ago, but despite treatment he has ongoing itching. He was diagnosed following a GP visit to his house which was found to be unkempt. He was treated with permethrin 5% with the aid of his daughter, who has confirmed that his whole body was treated in two sessions, one week apart, and that his clothes were washed at high temperature at both occasions, as well as his bed sheets.

He has a past medical history of heart failure, ischaemic heart disease and dementia. He lives on his own with the assistance of his daughters. He normally takes bisoprolol, aspirin, ramipril and simvastatin. On examination, there are burrows with track marks on his fingers.

What is the most appropriate plan?

A. Investigate for immunosuppression
B. Repeat treatment with permethrin 5%
C. Treat with malathion 0.5%
D. No further treatment needed
E. Skin biopsy

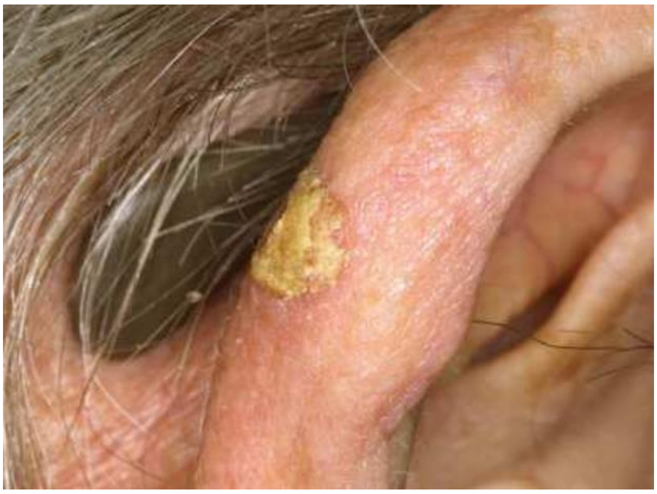
C. Treat with malathion 0.5%

In scabies treatment failure, if application was applied appropriately, then treat with difference insecticide, e.g. malathion 0.5% or permethrin 5%

This is a patient with scabies who has failed treatment despite correct treatment. Whilst patients with may have pruritus until six weeks following treatment completion, there should not be any burrows. For such patients they should be treated with malathion 0.5% if they have been treated correctly with permethrin 5%. If they were treated with malathion 0.9% then they should be treated with permethrin 5%. Skin biopsy is not needed, and immunosuppression is unlikely; only if evidence crusted scabies should this be done, or if extremely wide-spread.

Question 23 of 182

A 60-year-old man asks you to have a look at a 'sore' on his right ear.



It has been present for around 6 months and is not painful.

What is the most likely diagnosis?

A. Fungal otitis externa
B. Actinic keratosis
C. Pyogenic granuloma
D. Basal cell carcinoma
E. Chondrodermatitis nodularis helicis

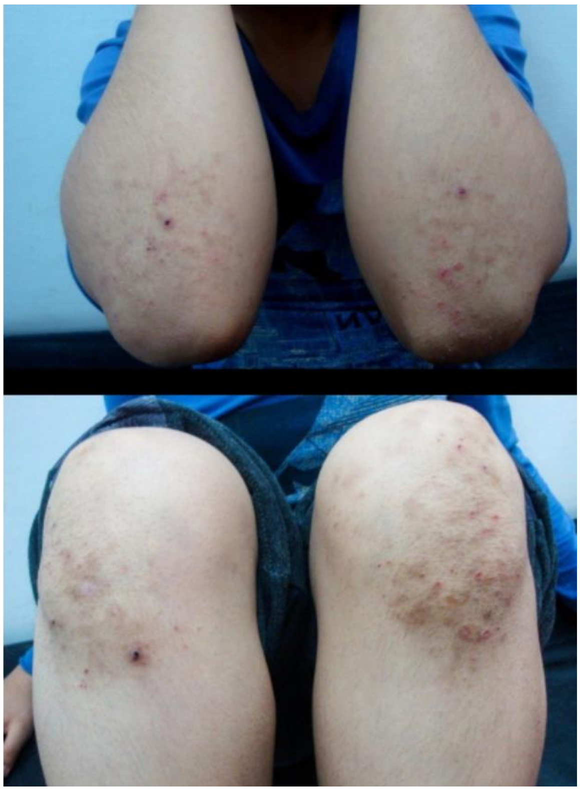
B. Actinic keratosis

Chondrodermatitis nodularis helicis is usually painful.

Question 24 of 182

A 31-year-old man presents with an itchy rash that has been present for several weeks, across both the elbows and knees. He mentions general fatigue but is otherwise well in himself.

On examination, the rash appears as shown below:



Blood tests are also performed:

Hb	118 g/L	Male: (135-180)Female: (115 - 160)
Platelets	267 * 10 /L 9	(150 - 400)
WBC	5.6 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	5.8 mmol/L	(2.0 - 7.0)
Creatinine	62 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)

Given the likely diagnosis, which of the following is the most appropriate first-line treatment?

A. Oral dapsone
B. Oral prednisolone
C. Topical calcipotriol
D. Topical clobetasol
E. Topical tacrolimus

A. Oral dapsone

The diagnosis is that of dermatitis herpetiformis. The photo shows a bilateral, symmetrical, papulovesicular rash across the elbows and knees. This is consistent with dermatitis herpetiformis, which usually overlies extensor surfaces. The lesions appear excoriated due to pruritus. Dermatitis herpetiformis is strongly associated with coeliac disease, which is likely in this case, particularly given the concomitant anaemia and fatigue. Initial management involves the use of oral dapsone.

If initial measures were to fail, oral prednisolone may be used. However, for first-line management, oral dapsone is usually used for dermatitis herpetiformis.

Topical calcipotriol is a vitamin D analogue commonly used in the management of psoriasis. The images here do not clearly demonstrate psoriatic plaques, which would have a scaly appearance - rather, the papulovesicular rash is more suggestive of dermatitis herpetiformis.

Topical clobetasol is a second-line option for dermatitis herpetiformis. First-line, oral dapsone remains the most appropriate option.

Topical tacrolimus is a steroid-sparing agent sometimes used for steroid-resistant eczema, especially for children and on sensitive areas such as the face. It also plays a role in the management of other conditions such as bullous pemphigoid. It is not routinely used in dermatitis herpetiformis.

Question 25 of 182

A 60-year-old man with a history of renal transplant presents to the dermatology clinic.

He has a 7mm scaly nodular lesion on his left left forearm with an inflamed red base. This appears similar to two squamous cell skin carcinomas he has had excised in the past. The lesion is not painful and he has no lymphadenopathy.

He continues to take tacrolimus, though his dose was lowered following his last squamous cell carcinoma excision. He also suffers from hypertension which is well controlled on ramipril.

His blood tests are as follows:

Hb	120 g/l	Na +	136 mmol/l
Platelets	308 * 10 /l 9	K +	4.9 mmol/l
WBC	6 * 10 /l 9	Urea	5 mmol/l
Neuts	4 * 10 /l 9	Creatinine	98 µmol/l

What is the most appropriate management?

A. Curettage and acitretin
B. Radiotherapy and acitretin
C. Surgery alone
D. Surgery and acitretin
E. Systemic chemotherapy

D. Surgery and acitretin

This man has a high risk squamous cell carcinoma (SCC) of the skin given that he is on immunosuppression. He also has a history of previous SCC. Given these factors, surgery is indicated and systemic retinoids, such as acitretin, should be considered to prevent further SCCs.

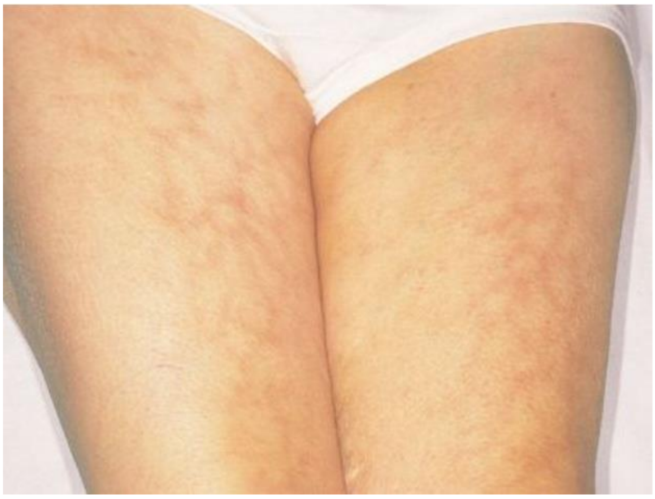
Curettage is acceptable management for a low risk SCCs. Radiotherapy would be considered postoperatively if there were inadequate tumour margins or evidence of invasion at surgery but is not an appropriate a primary curative therapy in this case. Studies to date have not shown sufficient evidence for systemic chemotherapy for SCC.

In patients on immunosuppression with recurrent SCC, reduction of immunosuppression should be considered and discussion at a multidisciplinary team meeting is warranted.

Reference: Scottish Intercollegiate Guidelines Network. 2014. SIGN 140. Management of primary cutaneous squamous cell carcinoma.

Question 26 of 182

A 41-year-old woman shows you a rash on her legs:



What is the most likely cause of such a rash?

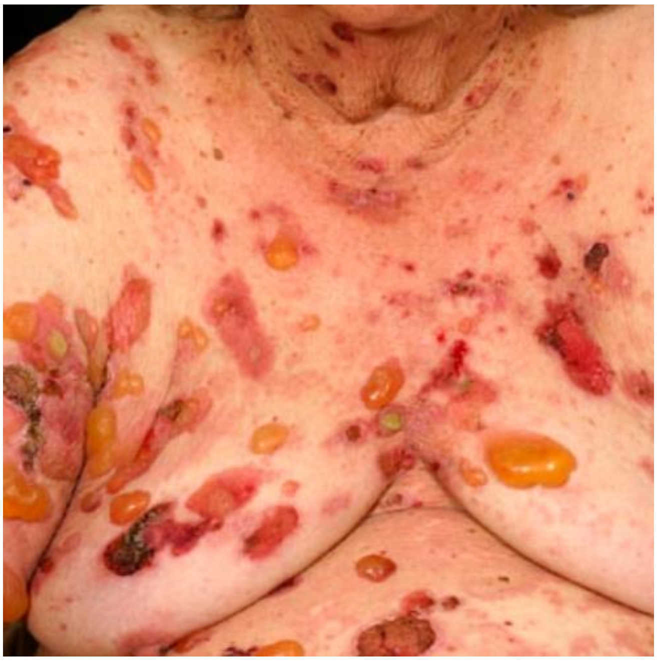
A. Domestic abuse
B. Excessive ultraviolet light
C. Drug reaction
D. Infrared radiation
E. Syphilis

D. Infrared radiation

This patient has erythema ab igne, a skin reaction caused by excessive infrared radiation.

Question 27 of 182

A 79-year-old woman presents with an itchy, blistering rash. Examination of her mouth is unremarkable.



What is the most likely diagnosis?

A. Dermatitis herpetiformis
B. Drug reaction to lisinopril
C. Bullous pemphigoid
D. Pemphigus vulgaris
E. Epidermolysis bullosa

C. Bullous pemphigoid

Blisters/bullae

- no mucosal involvement (in exams at least*): bullous pemphigoid
- mucosal involvement: pemphigus vulgaris

The correct answer to this question is **Bullous pemphigoid**. Bullous pemphigoid is a blistering skin condition that typically occurs in elderly patients, and the presentation of an itchy, blistering rash in a 79-year-old woman is highly suggestive of this diagnosis. The blisters in bullous pemphigoid are usually large and filled with clear fluid, appearing on normal or red skin. They do not typically affect mucosal surfaces, which aligns with the unremarkable examination of the patient's mouth.

The first incorrect option is **dermatitis herpetiformis**. Dermatitis herpetiformis also presents with an itchy, blistering rash, but it is most commonly associated with coeliac disease and tends to present at a younger age than bullous pemphigoid. Additionally, dermatitis herpetiformis often affects extensor surfaces like elbows and knees, whereas the image provided does not suggest this distribution.

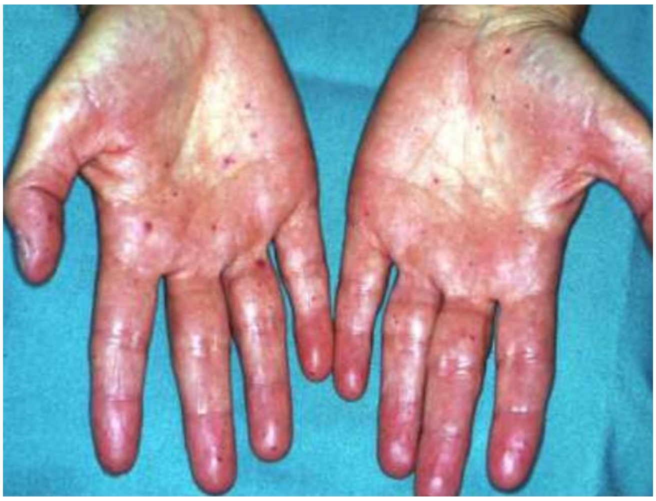
The second incorrect option is a **drug reaction to lisinopril**. While drug reactions can certainly cause rashes and even blisters in some cases, they would typically be more widespread and may be accompanied by other symptoms such as fever or involvement of other organ systems. There is no information given suggesting that this patient has recently started taking lisinopril or any other new medications.

Pemphigus vulgaris, the third incorrect option, is another blistering skin condition which could potentially present similarly to bullous pemphigoid. However, pemphigus vulgaris typically involves mucosal surfaces initially or exclusively - often starting in the mouth - which does not fit with this patient's unremarkable oral examination.

Finally, **epidermolysis bullosa** is incorrect because it's a group of rare inherited conditions causing fragile skin that blisters easily from minor injuries or friction. This condition usually becomes apparent at birth or soon afterwards.

Question 28 of 182

A 30-year-old man is investigated for recurrent nose bleeds and iron deficiency anaemia. You notice a number of erythematous lesions on his skin:



What is the most likely underlying diagnosis?

A. Peutz-Jeghers syndrome
B. Alcohol excess
C. Hereditary haemorrhagic telangiectasia
D. Haemophilia A
E. Idiopathic thrombocytopenic purpura

C. Hereditary haemorrhagic telangiectasia

The correct answer is **Hereditary haemorrhagic telangiectasia**. This condition, also known as Osler-Weber-Rendu syndrome, is a genetic disorder characterised by abnormal blood vessel formation in the skin, mucous membranes, and often in organs such as the lungs, liver, and brain. The erythematous lesions seen on the skin of this patient are likely telangiectasias - small dilated blood vessels near the surface of the skin. Recurrent nosebleeds (epistaxis) and iron deficiency anaemia due to chronic bleeding are common manifestations of this condition.

Peutz-Jeghers syndrome is an autosomal dominant genetic disorder characterised by the development of non-cancerous growths called hamartomatous polyps in the gastrointestinal tract and a characteristic pigmentation around the mouth, lips, eyes and genitalia. It does not typically present with recurrent nosebleeds or erythematous skin lesions.

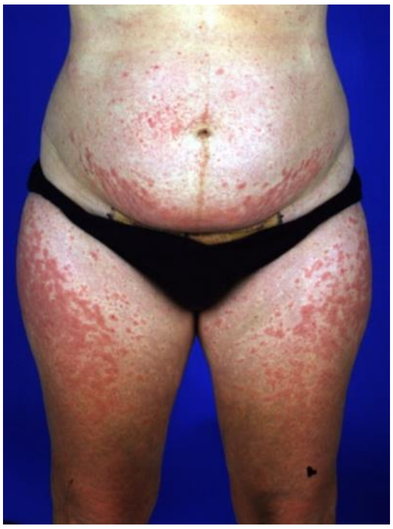
Alcohol excess can cause numerous health issues including liver disease and coagulopathy which might lead to easy bruising and bleeding. However, it would not cause erythematous skin lesions as seen in this case. Furthermore, alcohol-related nosebleeds would usually be associated with other signs of alcohol misuse or its complications.

Haemophilia A is an X-linked recessive disorder characterised by a deficiency in factor VIII leading to prolonged bleeding times. Although patients with haemophilia may experience frequent nosebleeds due to impaired coagulation, they do not develop telangiectasias or similar skin lesions.

Lastly, **Idiopathic thrombocytopenic purpura (ITP)** is an autoimmune disorder causing platelet destruction which leads to a low platelet count (thrombocytopenia). Patients with ITP typically present with petechiae and purpura but not telangiectasia as seen in this case. Nosebleeds could occur due to thrombocytopenia but ITP wouldn't explain the specific type of skin lesion observed here.

Question 29 of 182

A woman who is 31 weeks pregnant presents with a rash on her abdomen and thighs:



The rash is very itchy and she is having difficulty sleeping at night.

What is the most likely diagnosis?

A. Primary herpes simplex infection
B. Pityriasis rosea
C. Polymorphic eruption of pregnancy
D. Pemphigoid gestationis
E. Pompholyx

C. Polymorphic eruption of pregnancy

The correct answer is **Polymorphic eruption of pregnancy**. Polymorphic eruption of pregnancy (PEP), also known as pruritic urticarial papules and plaques of pregnancy (PUPPP), is a benign dermatological condition that occurs in late pregnancy. It typically presents with intensely itchy, polymorphic lesions including erythematous papules, vesicles or plaques. The rash often starts on the abdomen, particularly within stretch marks (striae), and can spread to the thighs and buttocks but rarely involves the face or mucous membranes. This presentation matches the patient's symptoms and her stage of pregnancy.

Primary herpes simplex infection would typically present with painful grouped vesicles on an erythematous base, which may then ulcerate. Primary infections can be associated with systemic symptoms such as fever and malaise. Herpes simplex is not confined to late stages of pregnancy and does not specifically target areas with striae.

Pityriasis rosea usually starts with a single 'herald patch', followed by a 'Christmas-tree' distribution of smaller patches along skin cleavage lines, predominantly on the trunk. It is not related to pregnancy nor does it preferentially affect areas with striae.

Pemphigoid gestationis, previously known as herpes gestationis, is a rare autoimmune blistering disorder associated with pregnancy. It usually begins in the second or third trimester or immediately postpartum. Lesions often start around the umbilicus before spreading to other parts of the body but unlike PEP, pemphigoid gestationis frequently involves the palms, soles and mucous membranes.

Lastly, **pompholyx**, also known as dyshidrotic eczema, primarily affects hands and feet causing itchy vesicles; therefore it wouldn't explain this patient's rash location.

Question 30 of 182

A 52-year-old male was referred to the outpatients dermatology clinic with a four-month history of a persistent rash. He described the rash as a very itchy blistering rash occurring on the popliteal fossa as well as his buttocks. He had been prescribed levocetirizine 5mg OD as well as a four-week course of Eumovate BD (moderately-potent corticosteroid) and Diprobase (emollient) QDS but despite the treatment his symptoms had worsened. He had a past medical history comprising refractory eczema, gout, angina, hypertension and diabetes mellitus type 2 for which he was prescribed allopurinol 100mg OD, aspirin 75mg OD, simvastatin 40mg OD, ramipril 5mg OD and metformin M/R 1g BD. Regarding his eczema, this is presently in a state of remission, having been treated with azathioprine six months ago. Other than the rash he was otherwise well though he mentioned he had a history of abdominal bloating and diarrhoea which was diagnosed as irritable bowel syndrome several years ago.

On examination, he was systemically well with a blood pressure of 142/76 mmHg. Examination of the cardiovascular, respiratory and gastrointestinal systems was unremarkable. Examination of his skin revealed the presence of multiple bullae and papules on the extensor surface of his knees and buttocks, with excoriation.

Which of the following is the most likely diagnosis?

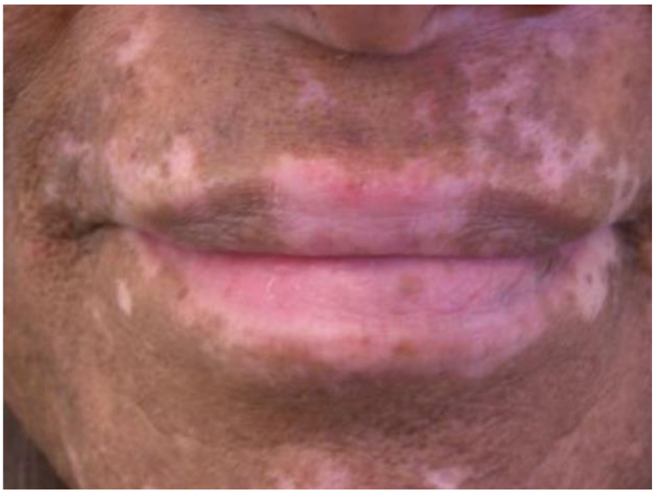
A. Bullous pemphigoid disease
B. Linear IgA bullous dermatosis
C. Dermatitis herpetiformis
D. Transient acantholytic dermatosis
E. Eczema

C. Dermatitis herpetiformis

This rash tends to present as an intensely itchy bullous rash comprising of blisters and papules on extensor surfaces, though can also occur on any other part of the body. This disease is strongly associated with uncontrolled coeliac disease, and the clue in this question is the presence of abdominal bloating and diarrhoea (red herring being diagnosed with irritable bowel syndrome, a common mistake to make in clinical practice!).

Question 31 of 182

You review a 27-year-old man who is under the care of the dermatology department.



Which one of the following conditions is most associated with this skin disorder?

A. Addison's disease
B. Asthma
C. Iron-deficiency anaemia
D. Toxic multinodular goitre
E. Type 2 diabetes mellitus

A. Addison's disease

Vitiligo is associated with other autoimmune conditions such as Addison's disease, type 1 diabetes mellitus and autoimmune thyroid disorders.

Question 32 of 182

A 47-year-old lady presented with shortness of breath and a nosebleed. She had been experiencing heavy nosebleeds over the past fifteen years and had twice required cauterization. On this admission she felt very tired, with shortness of breath and chest pain on minimal exertion.

Aside from nosebleeds she had a past medical history of hypertension and hypothyroidism. She had recently consulted a cosmetic surgeon privately as she had spider veins over her lips which she wished to have removed.

She lived with her husband who had been diagnosed with multiple sclerosis and her 18-year-old son who had learning difficulties and epilepsy. She reported that her mother and sister also experienced frequent nosebleeds.

On examination there was conjunctival pallor. The lung fields were clear on auscultation and both heart sounds were present with a systolic murmur audible over the aortic region. The abdomen was soft and non-tender with no palpable masses or organomegaly. On inspection of the skin there was a bruise in the left antecubital fossa and no rashes.

What is the most likely unifying diagnosis?

A. Von Willebrand disease
B. Wegeners granulomatosis
C. Von Hippel Lindau disease
D. Idiopathic Thrombocytopaenic Purpura
E. Hereditary haemorrhagic telangiectasia

E. Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT), also known as Osler Weber Rendu syndrome, is an autosomal dominant disorder leading to abnormal blood vessel formation in the skin, mucous membranes, liver, lungs and brain. In this case, both the patients mother, sister and son are also affected indicating a likely autosomal dominant inheritance. Telangiectasia, such as the ones on this patients lips, are found on mucosal surfaces and in the gastrointestinal tract. These can cause nosebleeds and this is the most common presentation of HHT. Nosebleeds and bleeding from telangiectasia in the gastrointestinal tract can lead to an iron deficiency anaemia which explains the shortness of breath, pallor, chest pain and flow murmur in this case. Other manifestations of HHT occur secondary to the formation of arteriovenous malformations (AVMs) and include haemoptysis, portal hypertension and oesophageal varices, congestive cardiac failure, headache, intracerebral haemorrhage and seizures. Treatment is largely symptomatic and anaemia is treated with transfusions and iron replacement.

Von Willebrand disease can present with nosebleeds and may be inherited in an autosomal dominant fashion. However, this diagnosis would not account for the severe symptomatic anaemia, telangiectasia or the neurological features in this patients son. Other features of von Willebrands disease include bleeding gums and purpura.

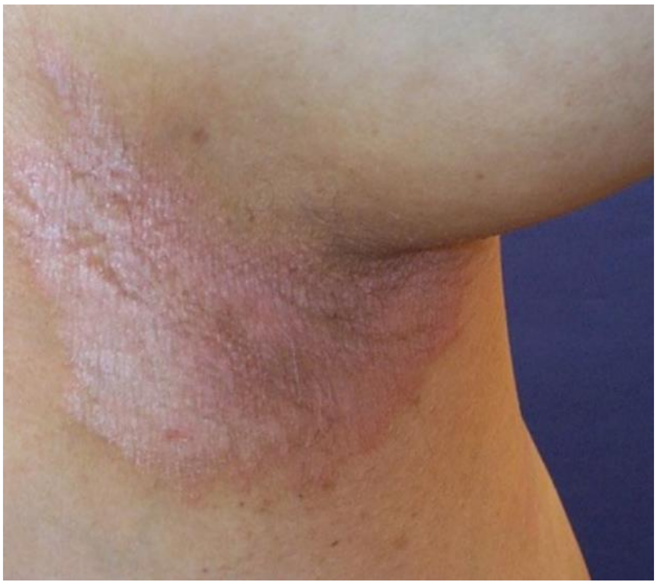
Wegeners granulomatosis is a form of vasculitis that can cause nosebleeds. It is not a genetic condition and other clinical manifestations include haemoptysis, rapidly progressive glomerulonephritis, arthritis and a purpuric rash.

Von Hippel Lindau disease is a rare autosomal dominant condition which is associated with many tumour types including haemangioblastomas, neuroendocrine tumours and renal cell carcinoma. It can present with walking difficulties, headaches and hypertension in addition to other symptoms and signs however nosebleeds are not a commonly recognised feature of this disease.

Idiopathic Thrombocytopaenic Purpura (ITP) is an autoimmune condition which can present with easy bruising, purpura and nosebleeds. In patients with ITP there is usually no family history and the condition does not cause telangiectasia.

Question 33 of 182

A 33-year-old woman with a history of psoriasis presents with a 'rash' in both axillae.



What is the most appropriate first-line treatment?

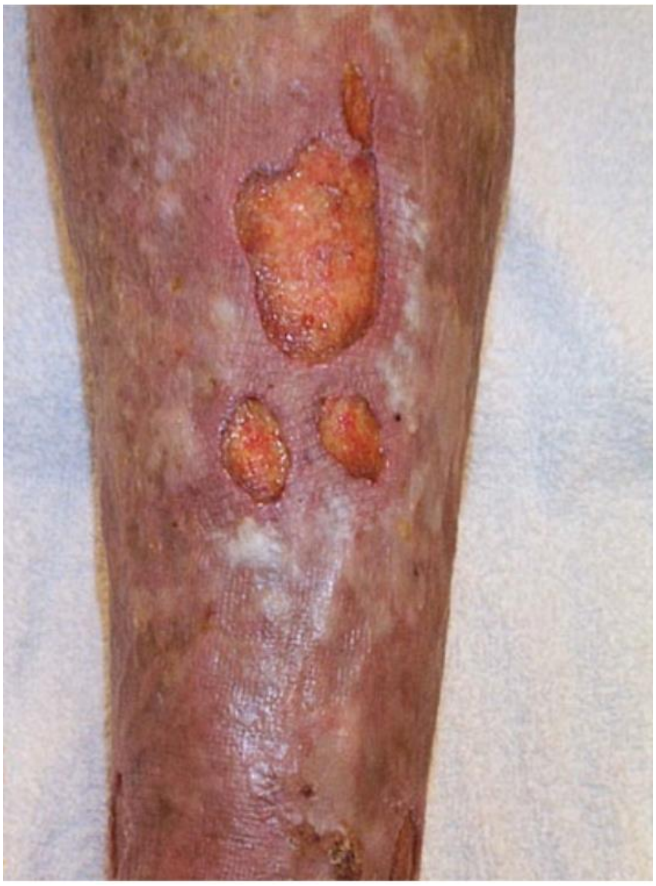
A. Miconazole twice a day
B. Dithranol once a day
C. Calcipotriol twice a day
D. Eumovate (clobetasone butyrate) once a day
E. Calcipotriol + beclomethasone once a day

D. Eumovate (clobetasone butyrate) once a day

This patient has flexural psoriasis - a mild or moderately potent steroid should be used.

Question 34 of 182

You review an 82-year-old woman who has developed 'sores' on her legs. For the past two years she has had dry, itchy skin around her ankles but over the past few weeks the skin has started to break down.



What is the most likely diagnosis?

A. Necrobiosis lipoidica diabeticorum
B. Pyoderma gangrenosum
C. Arterial ulcers
D. Venous ulcers
E. Pretibial myxoedema

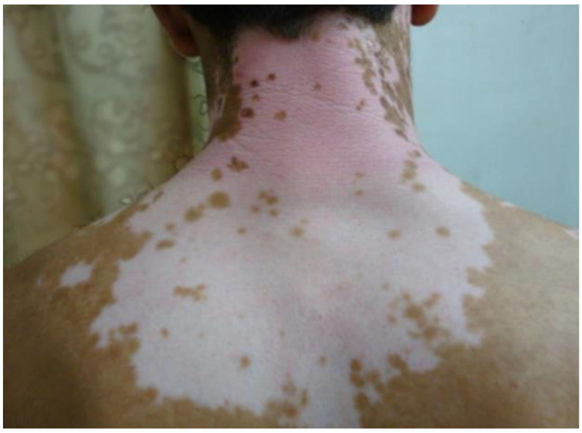
D. Venous ulcers

The dry, skin represents varicose eczema. Arterial ulcers tend to have a more 'punched-out' appearance.

Question 35 of 182

A 45-year-old man has been referred to the dermatology clinic to seek treatment for a long-term skin condition. He is an asylum seeker who has recently arrived in the UK and has never previously been able to access healthcare regarding his skin. He has not yet been started on any treatment. Approximately 20% of his total body surface area is affected by the condition.

His skin is examined, as shown below:



What other condition is this patient most likely to have in addition to his skin disorder?

A. Grave's disease
B. Inflammatory bowel disease
C. Melanoma
D. Microcytic anaemia
E. Systemic lupus erythematosus

A. Grave's disease

The image shows a clear area of skin depigmentation with irregular borders, affecting the patient's back, shoulders and neck. This is a typical presentation of vitiligo, which is an autoimmune condition resulting from the destruction of melanocytes. Vitiligo can be challenging to treat, but treatment options are available that can help to restore pigment in depigmented skin and prevent further depigmentation from occurring in other areas.

The correct answer is **Grave's disease**. As vitiligo is an autoimmune disease, it has a number of associations with other autoimmune conditions. The most common association is with autoimmune thyroid disease, which is found in 15% of adults with vitiligo.

Microcytic anaemia is incorrect. Vitiligo can be associated with pernicious anaemia, but this would cause B12 deficiency which typically causes a macrocytosis rather than microcytosis.

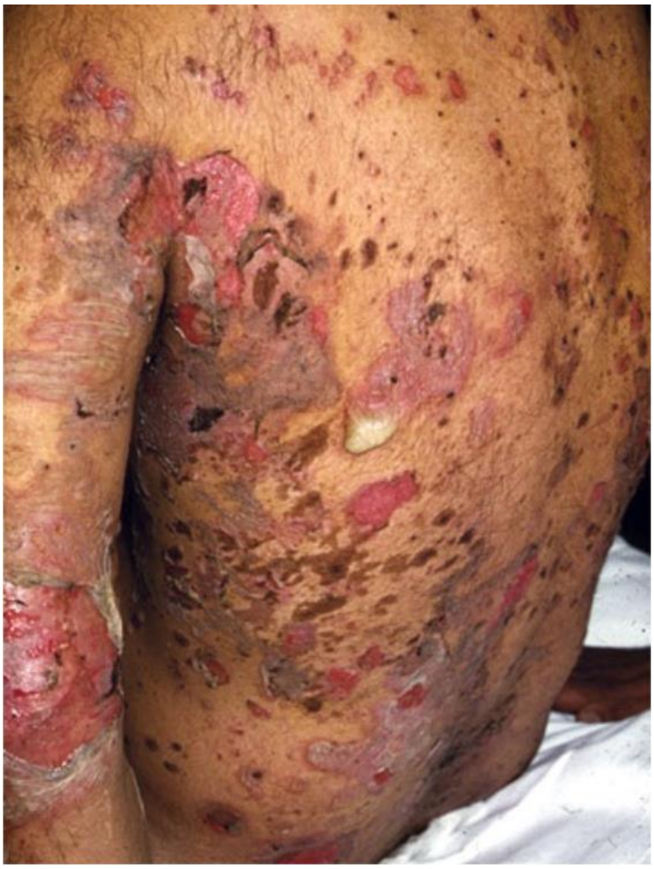
Systemic lupus erythematosus is incorrect. There is an association between systemic lupus erythematosus (SLE) and vitiligo, but this is much less common than thyroid disorders. Other conditions which can be associated with vitiligo include rheumatoid arthritis, Addison's disease, pernicious anaemia, alopecia areata, psoriasis and lichen sclerosis.

Inflammatory bowel disease is incorrect. There is a possible link between vitiligo and inflammatory bowel disease, although this requires further research and is less well established than the association between vitiligo and the conditions above.

Melanoma is incorrect. Surprisingly patients with vitiligo are at lower risk than the general population from skin malignancies, including squamous cell carcinoma, basal cell carcinoma and melanoma, even though the depigmented areas of skin are prone to sun damage. The mechanism for this lower risk is not completely understood and is an ongoing area of research.

Question 36 of 182

A 78-year-old woman presents with a number of blistering lesions on her torso. Around one week prior to the skin lesions developing she noticed widespread mouth ulceration:



What is the most likely diagnosis?

A. Epidermolysis bullosa
B. Pemphigus vulgaris
C. Bullous pemphigoid
D. Stevens-Johnson Syndrome
E. Staphylococcal scalded skin syndrome

B. Pemphigus vulgaris

The correct answer is **Pemphigus vulgaris**. This condition is an autoimmune blistering disorder that often initially presents with oral lesions, which may precede the onset of skin blisters by weeks to months. The image demonstrates flaccid bullae and erosions, which are characteristic of pemphigus vulgaris. In this condition, autoantibodies target desmoglein 3, a protein in the desmosomes that connect keratinocytes in the epidermis. This results in intraepidermal blistering.

Epidermolysis bullosa is incorrect because it typically begins in infancy or early childhood with blistering that occurs following minor trauma to the skin. It's a group of rare inherited skin disorders characterised by blister formation in response to mechanical trauma.

The diagnosis of **Bullous pemphigoid** is also incorrect. Bullous pemphigoid generally affects patients over the age of 60 and usually starts with pruritus, followed by the development of tense bullae. Oral involvement is less common than in pemphigus vulgaris and when present, usually follows rather than precedes cutaneous involvement.

Stevens-Johnson Syndrome (SJS) can be ruled out as well. SJS is usually drug-induced and involves not only the skin but also the mucous membranes such as eyes and genitals along with systemic symptoms like fever and malaise. The rash usually starts as erythematous macules which progress to form blisters and then slough off leading to painful erosions.

Lastly, **Staphylococcal scalded skin syndrome** (SSSS) is unlikely due to the patient's age and presentation. SSSS typically affects neonates and children under 5 years old, presenting with widespread erythema, exfoliation, and purulent conjunctivitis without mucosal involvement. It's caused by exfoliative toxins produced by certain strains of *Staphylococcus aureus*.

Question 37 of 182

A 19-year-old man develops multiple tear-drop papules on his trunk and limbs. He is otherwise well. A diagnosis of guttate psoriasis is suspected.

What is the most appropriate management?

A. Oral penicillin for 14 days
B. Reassurance + topical treatment if lesions are symptomatic
C. Oral penicillin for 14 days + topical treatment if lesions are symptomatic
D. Referral to secondary care
E. Oral corticosteroids

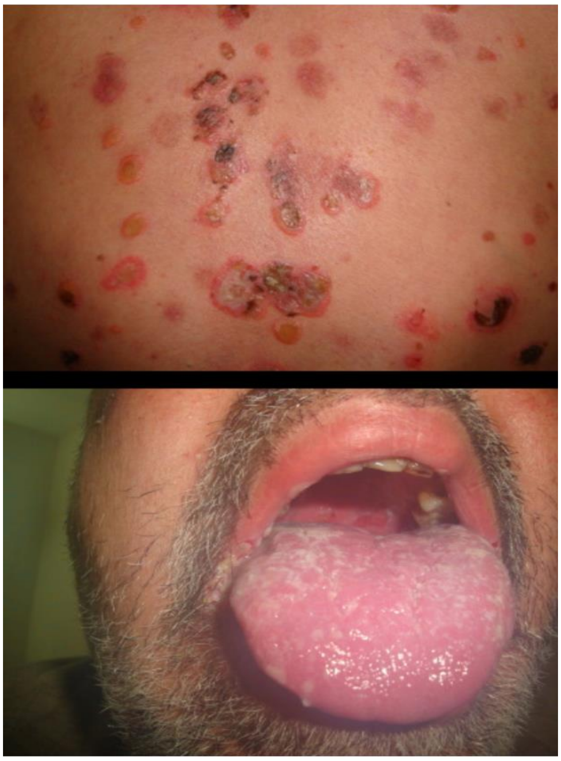
B. Reassurance + topical treatment if lesions are symptomatic

The British Association of Dermatologists state in their psoriasis guidelines that 'evidence does not support a therapeutic benefit from antibiotic therapy'.

Question 38 of 182

A 40-year-old man presents to the dermatology clinic with a 2-week history of an evolving, painful rash. He reported that the lesions initially began inside his mouth before spreading to the rest of his body. Other than a brief coryzal illness before the onset of the rash, he has no past medical history of note and takes no regular medications.

On examination, he has a temperature of 37.8ºC with a heart rate of 96bpm and blood pressure of 117/61mmHg. His rash is examined, as shown below:



What is the most likely diagnosis?

A. Bullous pemphigoid
B. Pemphigus vulgaris
C. Steven Johnson syndrome
D. Toxic epidermal necrolysis
E. Toxic shock syndrome

B. Pemphigus vulgaris

Pemphigus vulgaris is correct. This patient has multiple flaccid blistering lesions, a portion of which have burst. These blisters are filled with a clear fluid that, once ruptured, causes itchy, erythematous and painful erosions. Pemphigus vulgaris is an autoimmune disease that causes skin blistering that often ruptures. Unlike bullous pemphigoid, mucosal ulceration is a common presenting feature in pemphigus vulgaris and can precede the spread of other lesions on the body. Approximately 50-70% of patients have oro-mucosal involvement in pemphigus vulgaris with widespread superficial blistering and erosions and ulceration.

Bullous pemphigoid is incorrect. Unlike pemphigus vulgaris, bullous pemphigoid causes tense blisters that are less likely to rupture. The condition is also more common in the elderly population, particularly elderly women.

Steven Johnson syndrome (SJS) is classically a drug reaction secondary to anti-epileptics, antibiotics and anti-inflammatory medications. Symptoms include flu-like symptoms, widespread blistering and mucosal involvement. Although there is some overlap with this patient's symptoms, there is no history of recent drug administration.

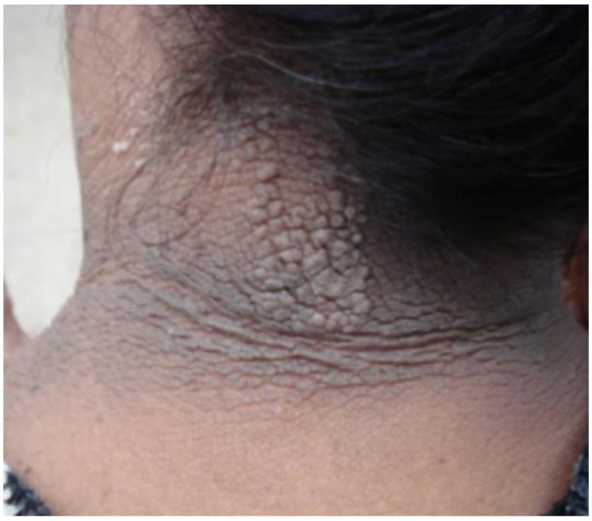
Toxic epidermal necrolysis (TEN) is incorrect. This is a severe form of SJS where > 30% of the total body surface area of the skin is affected. Similarly to SJS, TEN is caused by a drug reaction, which is not described in this scenario.

Toxic shock syndrome is incorrect. This is a severe illness secondary to exotoxin-producing bacteria such as *Staphylococcus aureus*. It causes systemic upset and a diffuse macular erythematous rash with skin-shedding. However, blistering is uncommon.

Question 39 of 182

A 44-year-old woman presents to the dermatology clinic with a 5-week history of skin irritation. She reports that the skin on the back of her neck feels thick and rough to the touch and is occasionally itchy. She used a hand mirror to visualise the skin and was concerned that the colour seems to have changed compared to normal.

On examination, her observations are recorded within normal limits. Her neck is examined, as shown below:



Given the likely diagnosis, what is the most appropriate investigation to consider?

A. ANA panel
B. IgA tissue transglutaminases
C. Random cortisol
D. Random glucose level
E. Skin biopsy

D. Random glucose level

Random glucose level is correct. This patient has a diagnosis of acanthosis nigricans characterised by hyperkeratosis and hyperpigmentation of the skin, predominantly affecting the flexural skin folds such as the axillae, back of the neck and groin. The skin may have a velvety texture secondary to papillomatous overgrowth of the epidermis (which can be visualised in this patient). Common underlying causes include metabolic diseases such as obesity, type 2 diabetes mellitus and polycystic ovarian syndrome. Therefore, an important initial investigation includes checking random or fasting glucose levels to check for the presence of diabetes mellitus.

ANA panel is incorrect. This is used in the diagnosis of autoimmune diseases such as rheumatic disease and vasculitis. However, it has no role in the diagnosis of acanthosis nigricans as it is not associated with underlying rheumatological disease.

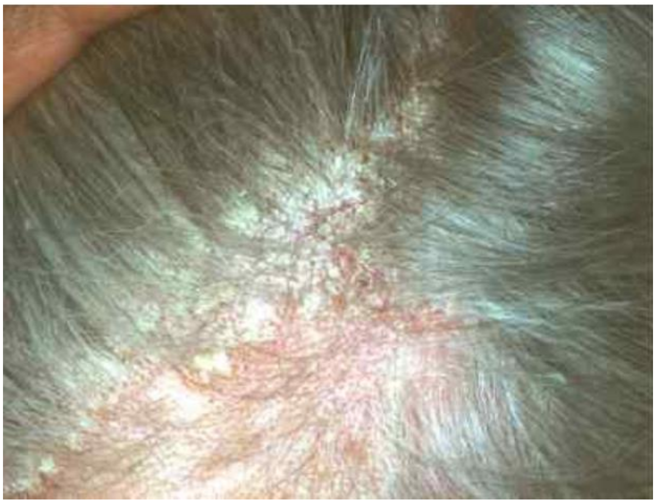
IgA tissue transglutaminase is incorrect. This is used to diagnose coeliac disease that is associated with a vesicular, erythematous and itchy rash seen on the extensor surfaces of the skin.

Random cortisol is incorrect. This is used in the diagnosis of primary hypoadrenalism (e.g. Addison's disease). Addison's disease is associated with the appearance of tanned skin due to excess ACTH production causing stimulation of melanocytes. However, it is not used to diagnose acanthosis nigricans.

Skin biopsy is incorrect. It is not used in the diagnosis of acanthosis nigricans.

Question 40 of 182

A 53-year-old man presents complaining of an itchy scalp and dandruff. On examination he is noted to have the following lesions on his scalp, along with similar lesions behind his ears and around his nose.



He has tried 'Head and Shoulders' and 'Neutrogen T-gel' but with poor results.

Which one of the following is the most appropriate treatment for his scalp?

A. Topical hydrocortisone
B. Topical dermovate
C. Topical selenium sulphide
D. Oral terbinafine
E. Topical ketoconazole

E. Topical ketoconazole

Seborrhoeic dermatitis - first-line treatment is topical ketoconazole

The most appropriate treatment for this patient's scalp is **topical ketoconazole**. The clinical presentation of an itchy scalp, dandruff, and eczema on the scalp, behind the ears, and around the nose suggests a diagnosis of seborrhoeic dermatitis. Seborrhoeic dermatitis is a common inflammatory skin condition that mainly affects areas rich in sebaceous glands such as the scalp, face, and upper trunk. It is thought to be related to an overgrowth of yeast-like fungi from the genus *Malassezia*, which are part of the normal skin flora.

Topical ketoconazole is an antifungal medication that targets *Malassezia* species and helps reduce inflammation in seborrhoeic dermatitis. It can be applied as a shampoo or cream depending on the affected area. In this case, since the patient has already tried other shampoos without success and his symptoms involve both his scalp and face, topical ketoconazole would be suitable to manage his condition.

Topical hydrocortisone may provide some relief from itching and inflammation associated with seborrhoeic dermatitis; however, it does not target the underlying fungal overgrowth contributing to the condition. Additionally, long-term use of topical corticosteroids on facial skin can cause thinning of the skin and other side effects.

Topical dermovate, which contains clobetasol propionate (a potent corticosteroid), may also help reduce inflammation but carries similar risks as hydrocortisone regarding long-term use on facial skin. Moreover, it does not address the fungal component of seborrhoeic dermatitis.

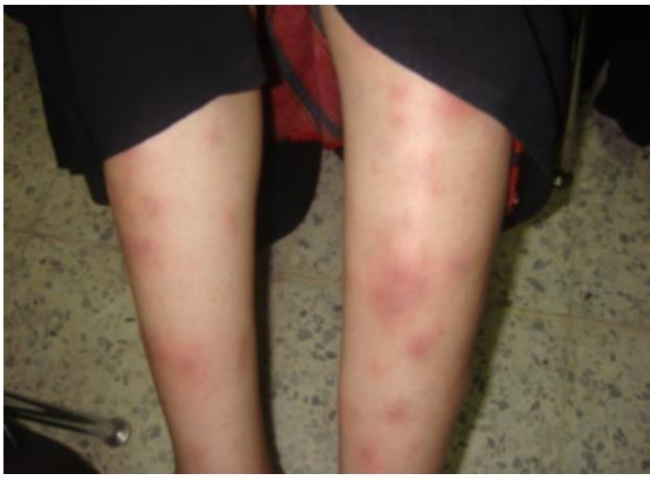
Topical selenium sulphide is another antifungal agent that may be used in treating seborrhoeic dermatitis. However, it is not as effective as ketoconazole and can cause skin irritation, making it a less suitable option for this patient who has already tried other shampoos without success.

Oral terbinafine is an antifungal medication that is primarily used to treat dermatophyte infections such as tinea pedis (athlete's foot), tinea corporis (ringworm), and tinea capitis (scalp ringworm). It is not typically prescribed for seborrhoeic dermatitis, as its efficacy against *Malassezia* species is limited compared to topical ketoconazole. Additionally, oral antifungal therapy carries a risk of systemic side effects and potential drug interactions, making it a less desirable option in this case.

Question 41 of 182

A 29-year-old woman presents with a rash over the shins for the past week, as shown below:

A 29-year-old woman presents with a rash over the shins for the past week, as shown below:



She describes the lesions as tender. She is otherwise well. She has a past medical history of asthma, recurrent acne vulgaris, chronic knee pain following a sports injury and epilepsy. Her medications include salbutamol and beclometasone inhalers, montelukast, oxytetracycline, a combined oral contraceptive pill, naproxen and lamotrigine.

Given the likely diagnosis, which of the following is the most likely cause?

A. Combined oral contraceptive pill
B. Lamotrigine
C. Montelukast
D. Naproxen
E. Oxytetracycline

A. Combined oral contraceptive pill

The diagnosis here is that of erythema nodosum - tender, nodular inflammation of subcutaneous fat, typically over the shins. The image above depicts this well - multiple red lesions are visible, appearing slightly raised and obviously inflamed, across both shins. They are generally oval or round in shape and no ulcers can be seen in the photo, in keeping with erythema nodosum, which does not ulcerate. It normally resolves within 6 weeks and heals without scarring. There are a number of associations, including infections, sarcoidosis, inflammatory bowel disease, Behcet's, and various medications. Of the drugs listed above, the most likely cause is the combined oral contraceptive pill, which is well documented as causing erythema nodosum.

Very rarely, lamotrigine is associated with erythema multiforme and Stevens-Johnson syndrome, which are much more severe, widespread cutaneous disorders than erythema nodosum and can be life-threatening if they progress. It is not associated with erythema nodosum.

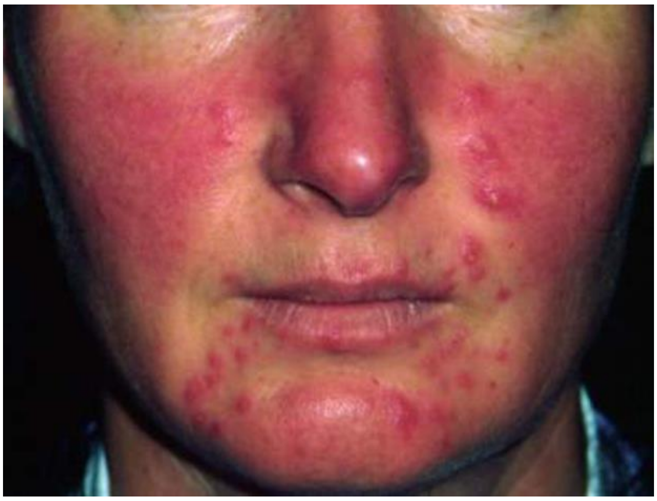
Montelukast is used for control of this patient's asthma, as the next step-up after a low-dose steroid inhaler; it is not linked to erythema nodosum.

Naproxen is presumably being used for her knee pain. It is not linked to the development of erythema nodosum and is, in fact, mentioned in various case reports as being effective in the management of pain arising from the condition.

Oxytetracycline is an antibiotic, being used here for acne vulgaris. Whilst penicillins and sulphonamides are linked to erythema nodosum, tetracyclines are not.

Question 42 of 182

A 43-year-old woman comes for review. A few months ago she developed redness around her nose and cheeks. This is worse after drinking alcohol. She is concerned as one of her work colleagues asked her if she had a drink problem despite her drinking 10 units per week.



What is the most likely diagnosis?

A. Mitral stenosis
B. Seborrhoeic dermatitis
C. Alcohol-related skin changes
D. Acne rosacea
E. Systemic lupus erythematosus

D. Acne rosacea

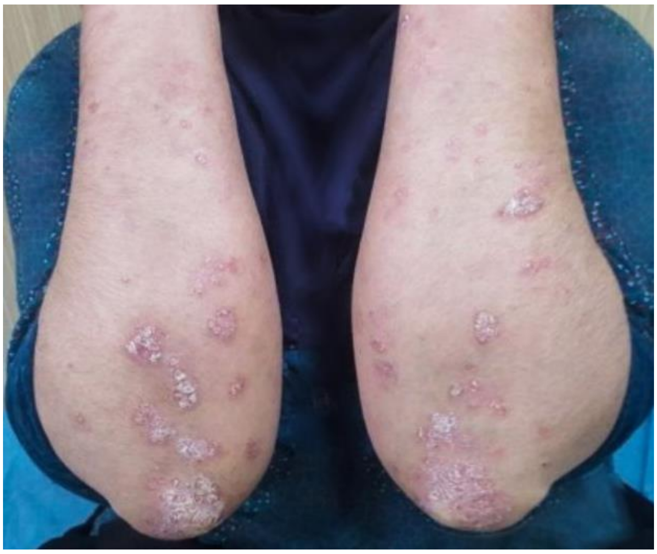
Rosacea features:

- nose, cheeks and forehead
- flushing, erythema, telangiectasia → papules and pustules

This is a typical history of acne rosacea.

Question 43 of 182

A 34-year-old man attends a dermatology clinic with a rash that isn't improving, the rash is pictured below:



He has recently moved to the area but, for the past 3 months, has been using a clobetasol propionate cream in the morning and calcipotriol in the evening, as recommended by his previous dermatologist.

What would be the most appropriate next treatment step?

A. Coal tar applications
B. Increase calcipotriol to twice a day
C. Increase clobetasol propionate cream to twice daily
D. Oral prednisolone
E. Switch to potent topical steroids

B. Increase calcipotriol to twice a day

The picture shows the classic extensor surface plaques of psoriasis.

This patient has been using once-a-day calcipotriol for over 8 weeks without resolution of his psoriasis. It is therefore appropriate to escalate his treatment further.

Increase calcipotriol to twice a day is the correct answer. It would be appropriate to increase the frequency of applications and re-review in 8 weeks.

Increase clobetasol propionate cream to twice daily is incorrect. This is the third-line option and should be considered if the psoriasis rash is not improving after increasing calcipotriol to twice a day.

Coal tar applications is incorrect. This could be considered if twice daily calcipotriol has failed, however, many patients prefer topical steroids as coal tar applications can be messy.

Oral prednisolone is incorrect. This is not the next step in treatment escalation according to NICE guidelines.

Switch to potent topical steroids is incorrect. Clobetasol propionate is already a potent steroid. There is no evidence to suggest that switching to an alternative potent topical steroid is an appropriate option as a second-line treatment for psoriasis.

Question 44 of 182

A 27-year-old man is referred to clinic with an intensely pruritic rash on both his forearms and buttocks.

The rash started around one month ago as papules and vesicles that were very itchy. Once scratched they would quickly crust over. Older lesions would leave pale and dark patches after the crusting had healed over. He had tried multiple emollients and creams including over the counter hydrocortisone cream which had not helped.

He has a history of intermittent abdominal bloating, nausea and diarrhoea which he diagnosed as irritable bowel syndrome (IBS) after reading about it on the internet. Despite trying to adjust his diet, his symptoms are ongoing. He is otherwise fit and well.

Of note in his family history, his mother has a history of hypothyroidism and diabetes. He currently manages his IBS with diet and takes no regular medication.

On examination he is thin but well. Physical observations are all within normal ranges. There are multiple crops of vesicles and papules over the extensor aspects of both his forearms and over his buttocks with evidence of excoriation, erythema and crusting.

Cardiorespiratory, abdominal and neurological examinations are all unremarkable.

Bloods come back as:

Na+	140 mmol/L
K+	3.7 mmol/L
Urea	4.0 mmol/L
Creatinine	68 µmol/L
Hb	98.0 g/dL
MCV	94 fL
WBC	6.5x10^9/L
Platelets	200x10^9/L
Serum folate	1.1 mcg/L
Serum B12	160 ng/L
Ferritin	10 g/L

In view of the likely diagnosis, what is the most appropriate initial treatment?

A. Reassurance
B. Oral steroids
C. Potent topical steroids
D. Oral acyclovir
E. Dapsone

E. Dapsone

Dermatitis herpetiformis is typically treated with a gluten-free diet and topical dapsone

This patient has a rash suggestive of dermatitis herpetiformis characterised by highly pruritic vesicles and papules on extensor surfaces and buttocks. The self-diagnosis of IBS is likely to be incorrect. In view of the low folate and low ferritin (suggestive of malabsorption) an underlying diagnosis of coeliac disease is most likely here.

Dermatitis herpetiformis responds very well to dapsone with relief of itch within a few days. Oral and potent steroids are used second line in patient intolerant or with contraindications to dapsone.

Aciclovir can be used in severe forms of herpes zoster which doesn't fit with this clinical picture. Reassurance is wrong as this condition is unlikely to get better without treatment.

In the long term this patient would need further investigation to confirm the diagnosis of coeliac disease and start a gluten-free diet.

Question 45 of 182

A 25-year-old Caucasian male presents with his first ever episode of witnessed generalised seizure, with witnessed jerking of his right arm and leg, lasting for 4 minutes terminated by benzodiazepines administered by paramedics. There is no other past medical history and documentation of head injuries. His past medical history includes recurrent epistaxes since childhood and current treatment for a left calf deep vein thrombosis provoked following two recent long-haul flights from Australia. A thrombophilia screen has subsequently been negative. Family history is unavailable.

On examination, the patient is confused postictally and is uncooperative with the examination. You note that his pupils are equal and reactive, he is moving all 4 limbs with no obvious focal neurology. There appears to be no visual or sensory neglect. A urinary toxicology screen is negative.

His blood tests and arterial blood gas are as follows:

Hb	175 g/l
MCV	87 fl
Platelets	223 * 10 /l9
WBC	9.2 * 10 /l9
Urea	6.6 mmol/l
Creatinine	64 µmol/l
CRP	24 mg/l
pH	7.32
PaO2	9.1 kPa
PaCO2	4.2 kPa
Lactate	4.2 mmol/l
Bicarbonate	16 mmol/l

With sedation, the patient undergoes a CT head, which demonstrates an arterio-venous fistula in his right parietal lobe.

The patient remains an inpatient while discussed for management with neurosurgeons and returns to baseline with no focal neurological deficits. At 48 hours after admission, he develops sudden onset left face, arm and leg weakness and loss of sensation, with flaccid tone, downgoing plantars.

A repeat CT head confirms a right middle cerebral artery ischaemic stroke.

What is the unifying diagnosis?

A. Malignancy of unclear primary
B. Haemorrhagic hereditary telangiectasia
C. Saddle pulmonary embolus
D. Polycythaemia rubra vera
E. Paroxysmal nocturnal haemoglobinuria

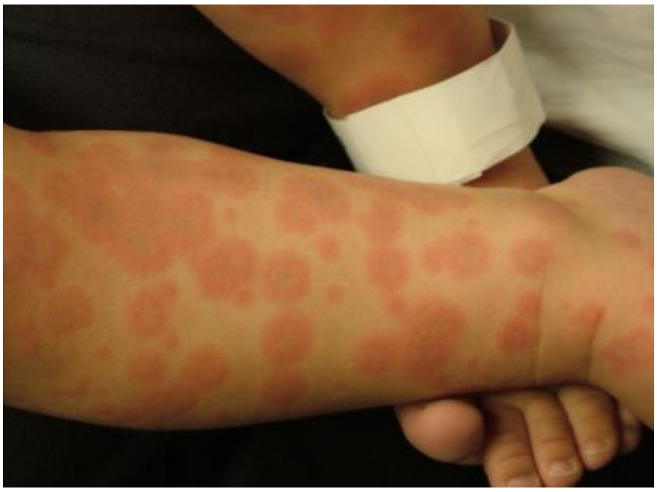
B. Haemorrhagic hereditary telangiectasia

This is a difficult question: the patient has an intracerebral arterio-venous fistula and likely at least another in his pulmonary vasculature, resulting in a chronic hypoxaemia (note normal bicarbonate and secondary polycythaemia), ruling out an acute pulmonary embolus and likely resulting in a paradoxical stroke. Primary polycythaemia rubra vera should not result in hypoxaemia. There does not appear to be an underlying prothrombotic element: his current DVT is uncommon but appears provoked with a negative thrombophilia. There is little to suggest malignancy.

A previous history of epistaxis is also suggestive of haemorrhagic hereditary telangiectasia (HHT), which appears to be the most common and earliest clinical feature. Diagnosis is clinched by the consensus Curacao criteria, requiring the following 4 features to be investigated in this case: spontaneous or recurrent epistaxis, multiple cutaneous telangiectasia (a full dermatological examination is essential), visceral involvement (in this case, pulmonary and cerebral AVMs) and a first-degree relative with HHT (family history is required). Meeting at least 3 features produces a definite diagnosis while 2 of 4 features suggests 'suspected' diagnosis.

Question 46 of 182

A 2-year-old girl develops a rash on her legs. The following day she is brought to the Emergency Department by which time the rash has spread to the rest of her body.



What is the most likely diagnosis?

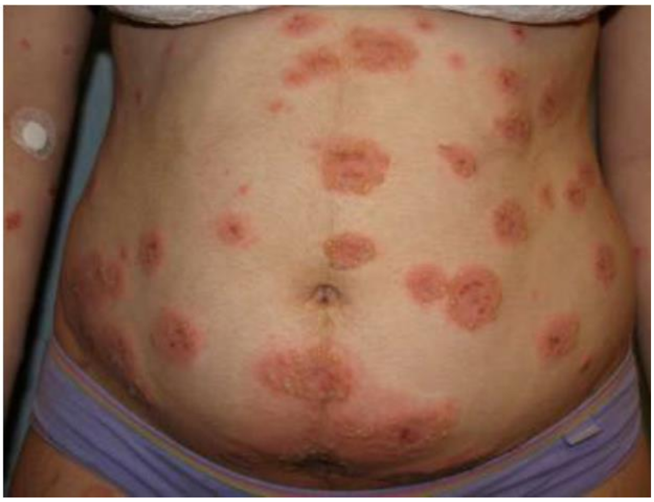
A. Erythema multiforme
B. Erythema chronica migrans
C. Erythema nodosum
D. Urticaria
E. Dermatitis artefacta

A. Erythema multiforme

The classic 'target' lesions of erythema multiforme can be seen clearly on this image.

Question 47 of 182

A woman who is 24 weeks pregnant presents with a rash:



What is the most likely diagnosis?

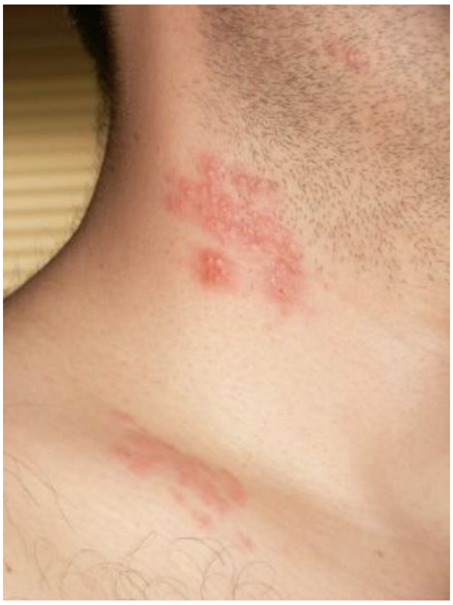
A. Pityriasis rosea
B. Pompholyx
C. Primary herpes simplex infection
D. Polymorphic eruption of pregnancy
E. Pemphigoid gestationis

E. Pemphigoid gestationis

The blistering lesions are clearly visible on this image.

Question 48 of 182

A 34-year-old who has recently returned from a business trip to New York presents with a one-day history of a painful rash on his neck:



What is the most appropriate management?

A. Topical fusidic acid
B. Topical clotrimazole + hydrocortisone
C. Oral aciclovir + prednisolone
D. Oral aciclovir
E. Send blood for antibodies to Borrelia burgdorferi

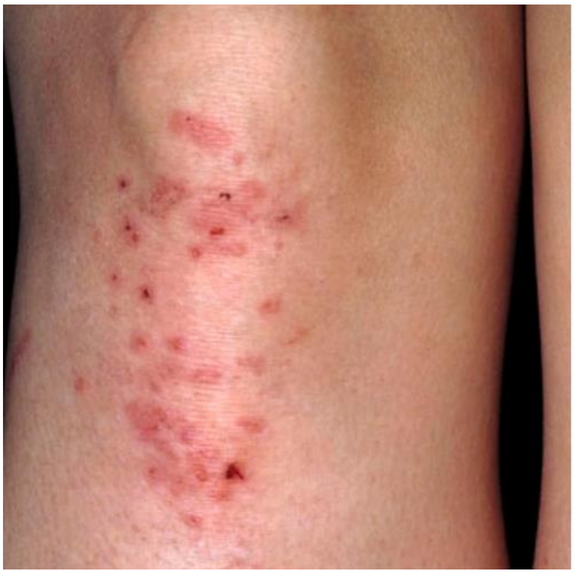
D. Oral aciclovir

One of the main clues in the question is the combination of a rash with pain. Other than shingles, there are not many conditions which cause both.

Whilst there is some evidence that systemic steroids speed up the healing of shingles, consensus guidelines do not advocate their use as adverse effects probably outweigh potential benefits.

Question 49 of 182

A 34-year-old man presents with a three week history of an intensely itchy rash just below his knees. On examination he has a symmetrical vesicular rash as shown below and also some early lesions on the back of his arms.



Which one of the following antibodies is most likely to be positive?

A. Anti-mitochondrial antibody
B. Anti-tissue transglutaminase antibody
C. Anti-nuclear antibody
D. Anti-neutrophil cytoplasmic antibody
E. Anti-Jo-1 antibody

B. Anti-tissue transglutaminase antibody

The correct answer in this case is **Anti-tissue transglutaminase antibody**. This patient's presentation of an intensely itchy, symmetrical vesicular rash on the knees and back of arms is highly suggestive of dermatitis herpetiformis. Dermatitis herpetiformis is an autoimmune skin condition associated with coeliac disease, and it often presents as a pruritic, blistering rash on extensor surfaces such as the elbows, knees, and buttocks. The presence of anti-tissue transglutaminase antibodies confirms the diagnosis as these antibodies are commonly found in patients with coeliac disease.

Anti-mitochondrial antibody is incorrect because these antibodies are typically associated with primary biliary cholangitis (PBC), a chronic liver disease characterised by destruction of intrahepatic bile ducts. PBC usually presents with fatigue, pruritus, and jaundice rather than a vesicular rash.

Anti-nuclear antibody (ANA) is also incorrect because ANAs are generally associated with systemic autoimmune diseases such as systemic lupus erythematosus (SLE) or Sjogren's syndrome. Although these conditions can present with skin manifestations like rashes, they do not typically present with the characteristic vesicular rash seen in dermatitis herpetiformis.

Anti-neutrophil cytoplasmic antibody (ANCA) is not correct either because ANCAs are primarily associated with vasculitides like granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA). These conditions can have cutaneous manifestations like purpura or nodules but not the specific vesicular rash seen in this patient.

Lastly, **Anti-Jo-1 antibody** is incorrect because Anti-Jo-1 antibodies are associated with idiopathic inflammatory myopathies, particularly polymyositis and dermatomyositis. While dermatomyositis does present with skin manifestations like a heliotrope rash or Gottron's papules, these are distinct from the vesicular rash seen in dermatitis herpetiformis.

In summary, the presence of **Anti-tissue transglutaminase antibody** is most likely in this patient due to the characteristic presentation of dermatitis herpetiformis, which is associated with coeliac disease.

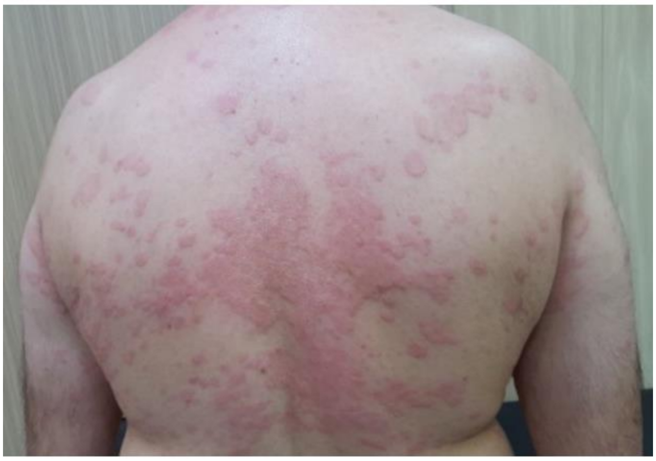
Question 50 of 182

A 25-year-old man presents with a rash predominantly affecting his back. The rest of his skin is unaffected.

The rash is not painful, although is very itchy. He had a similar occurrence last week but the rash resolved spontaneously within the same day. He denies any shortness of breath, and there is no swelling surrounding his mouth. He has not tried any new foods or started any new medicines. There is no past medical history of note, no regular medicines, and no recent illness.

His observations are as follows:

- Respiratory rate: 12 /min
- Saturations: 98% on room air
- Heart rate: 64bpm
- Blood pressure: 122/74mmHg
- Temperature: 37.2 deg C



Given the likely diagnosis, which is the most appropriate next step in management?

A. Diphenhydramine
B. Epinephrine
C. Fexofenadine
D. Omalizumab
E. Prednisolone

C. Fexofenadine

The picture here shows the superficial irregular raised swellings/plaques surrounded by erythema that are characteristic of urticaria.

Urticaria can be classed based on its duration as acute (≤6 weeks) or chronic (>6 weeks). It can also be further subdivided as either spontaneous (with no definite trigger involved) or inducible (specific definite trigger involved). This man is presenting with acute spontaneous urticaria without signs of anaphylaxis or angioedema.

Acute urticaria is generally self-limiting. As such, it usually does not require a diagnostic workup apart from enquiring about possible trigger factors. Acute urticarias that may require further diagnostic workup would include those likely due to a type I food allergy or drug hypersensitivity. In these instances, allergy tests and patient education would play a role, enabling patients to avoid re-exposure to causative factors.

Here, there is no suggestion this is the case and so initial management is symptom-based. The predominant symptom is pruritus, so the focus is on short-term management of this.

Fexofenadine is the most appropriate of the given options as it is a second-generation antihistamine and so is non-sedating.

Diphenhydramine is a first-generation anti-histamine, and so is sedative and to be avoided in the first instance. It could be considered in addition to the above if there is an inadequate response to the first-line antihistamine treatment, and itch is interfering with sleep.

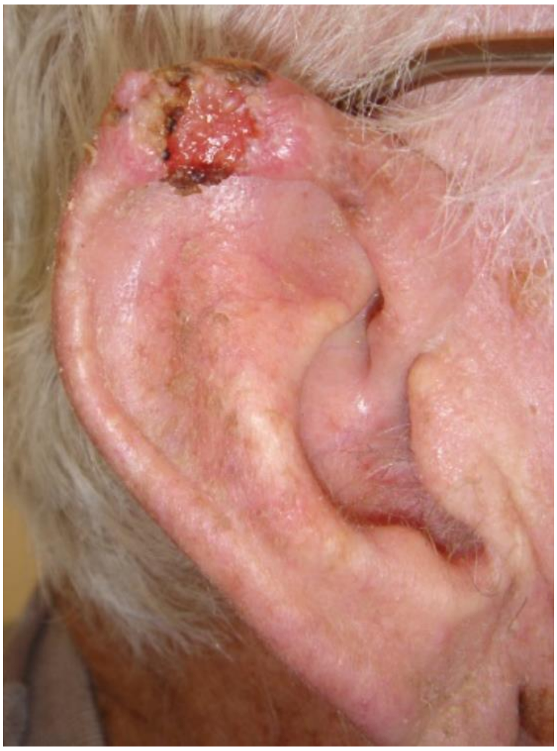
Omalizumab is a monoclonal anti-immunoglobulin E antibody that is used in the treatment of chronic idiopathic urticaria, however would not be the first line in this instance.

Prednisolone as a short course could be given if symptoms were considered particularly severe, in addition to the non-sedating oral antihistamine. This patient has only a relatively small area of skin involved.

Finally, whilst anaphylaxis is something that should always be ruled out with urticaria, the above patient does not have any other features to suggest this and so **epinephrine** is not indicated here.

Question 51 of 182

An 85-year-old man complains of a persistent 'scab' on his right ear. This has been present for the past year and causes some discomfort if he lays on his right side at night. It is mildly pruritic. His past medical history includes having an actinic keratosis removed from his left temple two years ago. A number of seborrhoeic keratoses are also noted across his body.

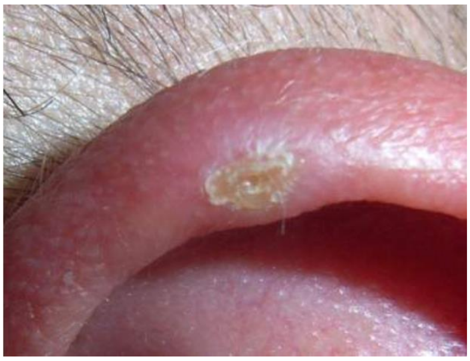


What is the most likely diagnosis?

A. Marjorin's ulcer
B. Squamous cell carcinoma
C. Basal cell carcinoma
D. Chondrodermatitis nodularis helicis

B. Squamous cell carcinoma

The main differential diagnosis here is chondrodermatitis nodularis helicis, however, this has a very different typical appearance - much more well defined with regular features. A typical lesion is shown below:

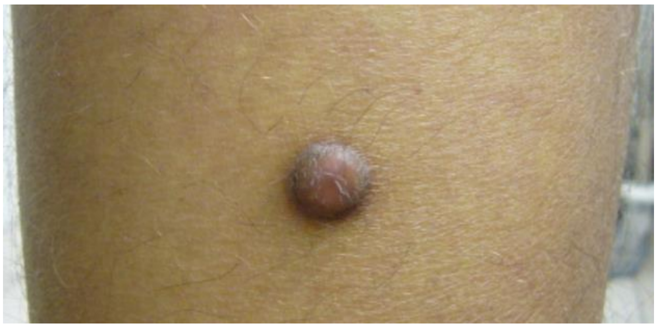


Typical appearance of chondrodermatitis nodularis helicis

Question 52 of 182

A 48-year-old male presents with a solitary skin nodule on his forearm which he first noticed a few weeks ago. He reports he was bitten by some form of insect prior to noticing the skin nodule.

On questioning, he describes the site as original very itchy with some tenderness after the bite but by the time he noticed the skin lesion, the area was and has remained, non-painful with only a mild itch.



He is otherwise well with no systemic symptoms.

What is the most likely diagnosis?

A. Basal-cell carcinoma
B. Dermatofibroma
C. Prurigo nodularis
D. Leiomyoma
E. Keratoacanthoma

B. Dermatofibroma

This patient has presented with a dermatofibroma, also called a histiocytoma. These are fibrous solitary, slow-growing papules caused by abnormal growth of dermal dendritic histiocyte cells. As seen in the picture they are raised and normal brown in colour. Although they can be itchy they are rarely painful and are associated with 'dimple sign', where applying lateral pressure produces a central depression. They can occur anywhere but are commonly seen on the arms and leg as they are often precipitated by an injury such as an insect bite (as with this patient) or a thorn prick.

Basal-cell carcinomas (BCC) are the most common form of skin cancer and often appear over several months, in sun-exposed areas. They are normally painless, slightly raised/macular areas of skin with a shiny, vascular appearance. BCC are rarely symmetrical and are unrelated to previous skin trauma.

Prurigo nodularis, also known as nodular prurigo, is a dermatological condition characterised by multiple, pruritic nodules commonly affecting the legs and arms. Unlike in dermatofibroma, itching only develops after the nodules have formed and increases in intensity as the condition progresses. Due to their pruritic nature patients commonly present with multiple excoriated lesions due to scratching and symptoms may only be alleviated by steroid use.

A leiomyoma, also known as a fibroid, is a smooth muscle tumour that is most commonly benign, only progressing to cancer in extremely rare cases (0.1%). As they arise in the smooth muscle they are seen within organs, commonly the uterus, small bowel, or oesophagus. Cutaneous leiomyomas are rare but when they do occur they are seen as multiple, freely movable nodules seen with overlying reddish skin.

A keratoacanthoma is a common, normally benign skin lesion that is thought to originate from the hair follicle. They are often dome-shaped and symmetrical, similar to a dermatofibroma however keratoacanthomas are surrounded by a smooth wall of inflamed skin and have a characteristic cap made of keratin scales and debris. The exact cause of keratoacanthomas is unclear but they are believed to be linked to ultraviolet light, chemical carcinogens and immunosuppression.

Question 53 of 182

A 19-year-old man presents to the dermatology clinic with his parents. He has a background of learning difficulties and eczema. His parents have noticed that he has had difficulty in controlling his eczema with topical emollients. He has previously had several episodes of infections of his eczema, but it is free of infection currently. On examination, his flexural folds are erythematous with clear discharge. There are no pungent odours. He has been using E45 cream three times a day with the assistance of his parents.

His parents wonder what else could be done to help control his eczema?

A. Change E45 to a urea containing emollient
B. Long-term prophylactic antibiotics
C. Oral steroids
D. Bandaging after emollient use
E. Topical immunosuppressant therapy

D. Bandaging after emollient use

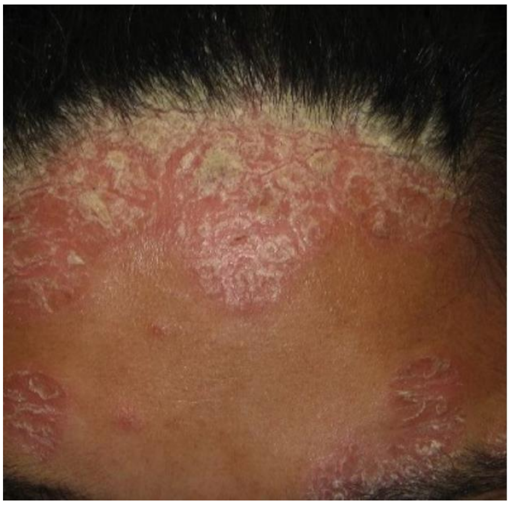
Bandaging can help control itching in eczema to prevent further scratching

The most appropriate action is the use of bandaging. Bandaging in eczema can be used in noninfected patients for weeping or lichenified skin in combination with emollients and, if needed, topical corticosteroids. This patient's weeping skin could be helped by bandaging to help absorb the discharge and enhance the emollient effect.

Oral steroids and topical immunosuppressant therapy are only used in severe cases or when topical treatment has failed. Using a urea-containing topical agent can help with itching and moisturising effect, but can provoke further inflammation and would, therefore, be inappropriate for this patient. Long-term antibiotics are not used for eczema.

Question 54 of 182

A 28-year-old woman with a history of psoriasis presents with dandruff and an itchy scalp. She has tried using 'Head & Shoulders' with limited effect. A photograph of her scalp problems is shown below:



What is the most appropriate first-line treatment?

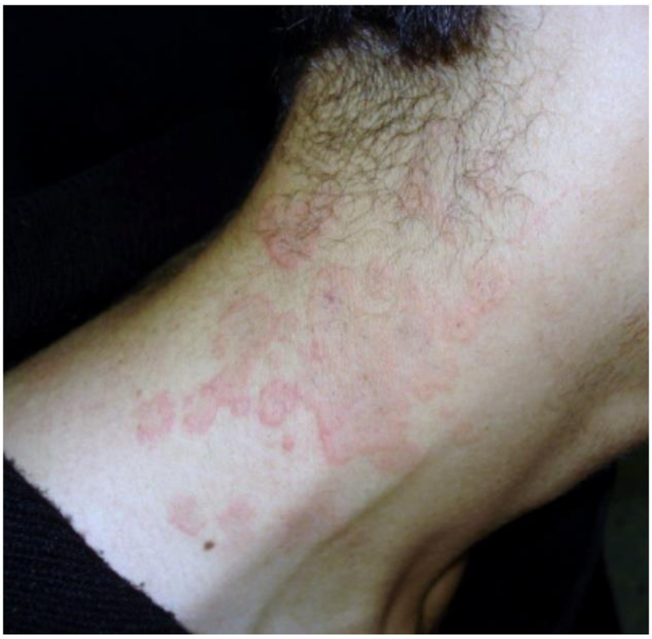
A. A coal tar based shampoo
B. A ketoconazole based shampoo
C. Topical beclomethasone
D. Topical calcipotriol
E. Topical calcipotriol + beclomethasone

C. Topical beclomethasone

Scalp psoriasis - first-line treatment is topical potent corticosteroids

Question 55 of 182

A 44-year-old woman visits her general practitioner with a 48-hour history of a new, erythematous rash on her neck. She described initially noticing lesions on the backs of her hands the day before. The rash is mildly itchy but not painful. There is no past medical history of note other than taking a course of antibiotics for a lower respiratory tract infection, diagnosed 4 days earlier. Her rash is examined, as pictured below:



What is the most likely diagnosis?

A. Dermatitis herpetiformis
B. Erythema multiforme
C. Guttate psoriasis
D. Pityriasis rosea
E. Tinea corporis

B. Erythema multiforme

This patient has multiple, round erythematous lesions on her neck. On closer inspection, the lesions appear as the classical target lesions with an outermost erythematous ring and paler centre. This is in keeping with a diagnosis of erythema multiforme. Erythema multiforme is an acute, self-limiting skin eruption most commonly secondary to an infective trigger (e.g. herpes simplex virus or *Mycoplasma pneumoniae*). The rash appears abruptly and affects the upper limbs most often before spreading down towards the trunk. The ongoing lower respiratory tract infection points toward an infection with *Mycoplasma pneumoniae*, the second most common infective cause of erythema multiforme.

Dermatitis herpetiformis is an itchy vesicular rash commonly associated with coeliac disease. It typically has a symmetrical distribution appearing on the elbows, knees, shoulders and buttocks. The rash seen in the above image is not symmetrical, nor does it appear vesicular. Furthermore, the absence of a history of autoimmune disease or coeliac disease makes dermatitis herpetiformis unlikely.

Guttate psoriasis is a subtype of psoriasis that commonly occurs after a streptococcal infection and is characterised by multiple small scaly plaques on the trunk and limbs. The onset of guttate psoriasis can be rapid and occur within days of initial infection. Although this patient has had a recent bacterial infection, the appearance of this rash is not scaly, but instead, shows target lesions in keeping with erythema multiforme.

Pityriasis rosea is a viral rash that is characterised by an initial herald patch followed by multiple red plaques developing over the trunk. The rash is usually asymptomatic with the only symptoms present being of an underlying viral infection (e.g. cough and coryza). There is no history of a herald patch in this question and the location and appearance of the lesions are not in keeping with pityriasis rosea.

Tinea corporis or ringworm is a fungal skin infection capable of affecting most parts of the body. The rash initially presents as a single well-demarcated, erythematous circular patch with a raised edge and central hypopigmentation. Itching is a prominent clinical feature. it does not classically cause multiple defined lesions as shown in this picture and tends to have a slower onset of development.

Question 56 of 182

A 45-year-old woman presents to her GP with an ulcer on her left shin. It has been present for the past 4 months and gradually got bigger. It is tender and yellow-brown in colour and there appears to be another smaller lesion that is growing next to the bigger one. She has a past medical history of multiple sclerosis, of which she is currently in remission phase and type 1 diabetes mellitus. Her only regular medication includes insulin.

What is the most appropriate treatment?

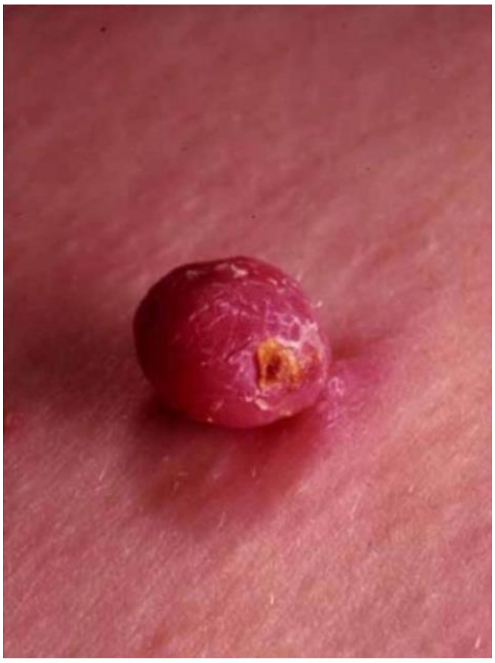
A. Flucloxacillin
B. Topical corticosteroids
C. TED stockings
D. Oral corticosteroids
E. Topical tacrolimus

B. Topical corticosteroids

The most likely diagnosis is necrobiosis lipoidica, a rare granulomatous skin disorder which can affect the shin of insulin dependent diabetics. Skin biopsy can confirm the diagnosis, although it is often done clinically and topical steroids are a useful treatment, along with injectable corticosteroids and camouflage creams.

Question 57 of 182

A 19-year-old woman asks you to have a look at a 'tag' on her neck. It developed around two months ago and has bled on a number of occasions after catching it.



What is the most likely diagnosis?

A. Pyogenic granuloma
B. Capillary haemangioma
C. Vital wart
D. Malignant melanoma
E. Molluscum contagiosum

A. Pyogenic granuloma

The most likely diagnosis for this patient is a **Pyogenic granuloma**. Pyogenic granulomas are benign skin lesions that often appear as small, reddish bumps on the skin. They can develop rapidly over a few weeks and tend to bleed easily because they contain many blood vessels. The history of this lesion developing over two months and bleeding after minor trauma is consistent with a pyogenic granuloma.

A **Capillary haemangioma**, also known as a strawberry naevus, is an incorrect choice. These usually present at birth or shortly thereafter and grow rapidly before starting to regress by 1-2 years of age. They are rarely seen in adults and do not typically bleed unless traumatised.

The option of **Viral wart** is also incorrect. Viral warts caused by human papillomavirus (HPV) are usually rough, hard, and non-bleeding unless injured.

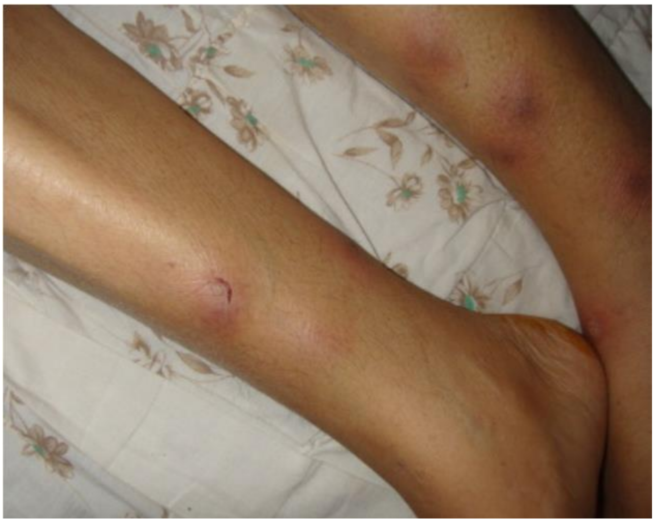
Malignant melanoma is unlikely given the patient's history and clinical presentation. Melanomas usually have irregular borders, vary in colour from one area to another, have a diameter larger than 6mm and evolve over time (ABCDE criteria). Furthermore, malignant melanomas don't typically bleed unless they ulcerate or are traumatised.

Finally, **Molluscum contagiosum** is also an incorrect choice. Molluscum contagiosum presents as multiple small, dome-shaped papules with a central umbilication caused by a poxvirus. It does not generally cause bleeding but may become inflamed or itchy. The solitary nature of this lesion makes molluscum contagiosum less likely.

Question 58 of 182

A 35-year-old woman who was born in Eastern Europe presents with a 5-day history of skin changes on her legs, as shown in the image below. She has a past medical history of asthma and type I diabetes. She has had a recent illness with persisting sore throat, myalgia and fatigue for 10 days.

There are no skin changes elsewhere in the body. She has some mild arthralgia affecting the knees and ankles on both sides, but no effusion or erythema affecting the joints.



What is the most likely precipitating cause?

A. Haemophilus influenzae infection
B. Epstein Barr virus
C. Sarcoidosis
D. Streptococcal throat infection
E. Tuberculosis

D. Streptococcal throat infection

This patient has erythema nodosum (EN) - as shown by the several raised erythematous tender lesions on her shins. This is a classical appearance of erythema nodosum, which is a delayed-typehypersensitivity reaction, causing inflammation of the subcutaneous fat. Lesions are most common on the shins, but may also be found on the thighs, buttocks, or forearms. Erythema nodosum is more common in women than in men. There are numerous potential triggers for erythema nodosum, which can be broadly grouped into infectious, inflammatory, drug, or malignancy. In many cases, a specific trigger is never found.

The correct answer is **Streptococcal throat infection**. The most common trigger for erythema nodosum is a preceding infection with a beta-haemolytic Streptococcus, which is usually pharyngitis caused by *Streptococcus pyogenes* (Group A Strep). It is thought that 25-45% of all cases of erythema nodosum are due to Streptococcal throat infections.

Epstein Barr virus is incorrect. This virus is the causative agent of infectious mononucleosis. It can trigger EN but it is a less common cause than Streptococcal infections and accounts for <1% of cases.

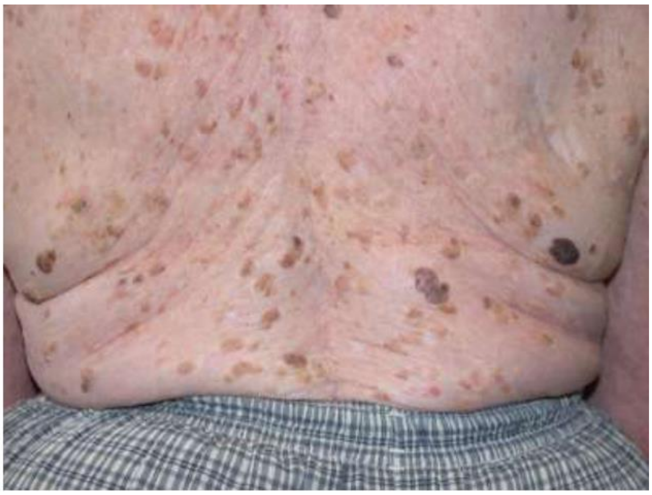
Haemophilus influenzae is incorrect. This is a common cause of upper respiratory tract infections but has no significant association with erythema nodosum.

Sarcoidosis is incorrect. Sarcoidosis is associated with around 10-25% of cases of EN, which is less than Streptococcal throat infections.

Tuberculosis is incorrect. TB and other mycobacteria can be associated with EN but the association is much less frequent than with Streptococcal infection.

Question 59 of 182

A 74-year-old man is admitted with an infective exacerbation of chronic obstructive pulmonary disease. Whilst auscultating his chest you notice a number of lesions on his back:



What is the most likely diagnosis?

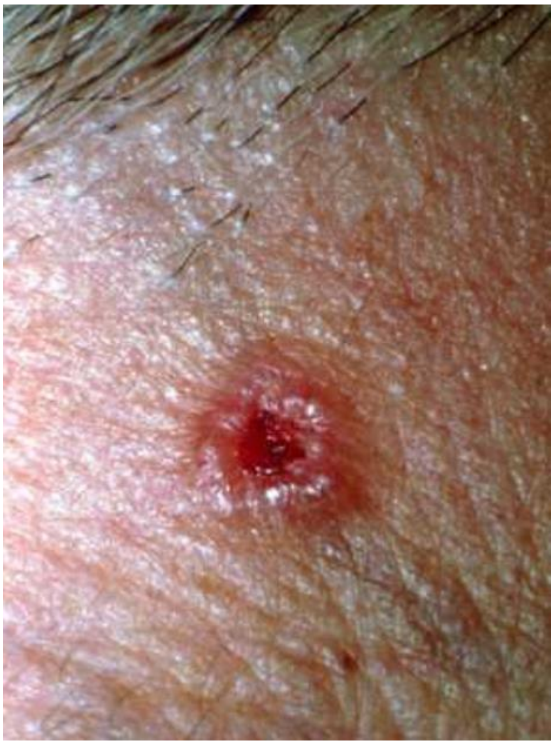
A. Bowen's disease
B. Multiple benign moles
C. Metastatic malignant melanoma
D. Seborrhoeic keratoses
E. Dysplastic naevus syndrome

D. Seborrhoeic keratoses

This man has multiple seborrhoeic keratoses, also known as basal cell papillomas.

Question 60 of 182

Please look at the skin lesion shown below:



Which one of the following statements regarding this type of skin lesion is true?

A. Curettage is an acceptable treatment option
B. They exhibit the Koebner phenomenon
C. They typically grow rapidly
D. Bleeding is unusual
E. Metastases are present in 10% of patients at the time of diagnosis

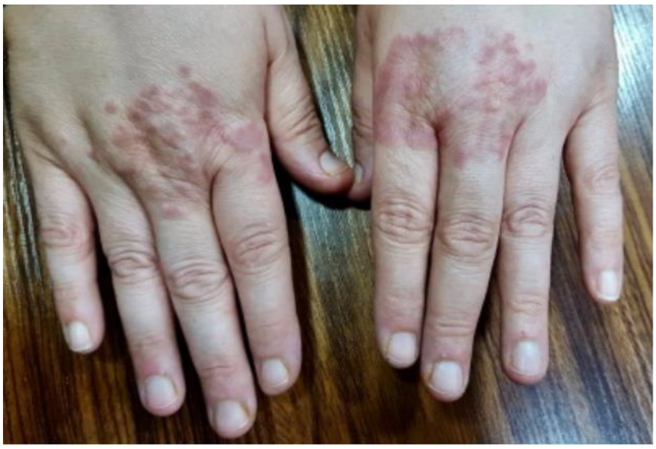
A. Curettage is an acceptable treatment option

Question 61 of 182

A 60-year-old homeless female is brought to the emergency department intoxicated. You note from her medical records she had diabetes mellitus only. You also note that her blood glucose levels are frequently high on attendances.

Her examination, other than the intoxication, is normal and observations are all within normal range except a slightly raised blood glucose.

After a few hours she beginnings to sober up and is preparing to leave the department. Prior to leaving, she asks you to have a look at the rash on the back of her hands (see below). She reports she has similar, mildly itchy rashes on her elbows and the dorsal of her feet.



What is the most likely diagnosis?

A. Dermatitis herpetiformis
B. Erythema migrans
C. Granuloma annulare
D. Necrobiosis lipoidica
E. Scabies

C. Granuloma annulare

Granuloma annulare is a papular rash often with slightly hyperpigmented lesions which have depressed centres. They are commonly found on the dorsal surfaces of the hands and feet as well as the elbows and knees. The lesions are sometimes mildly itchy and are through to be due to clustering of T cells below the skin. Granuloma annulare is 4x more prevalent in females and is thought to be linked to diabetes but there is limited evidence to confirm this.

Dermatitis herpetiformis is a cutaneous manifestation of coeliac disease, characterised by an intensely itchy, papulovesicular like rash, with blisters filled with watery fluid. The rash is similar in appears to a herpes rash (hence the name) and is normal found on the trunk.

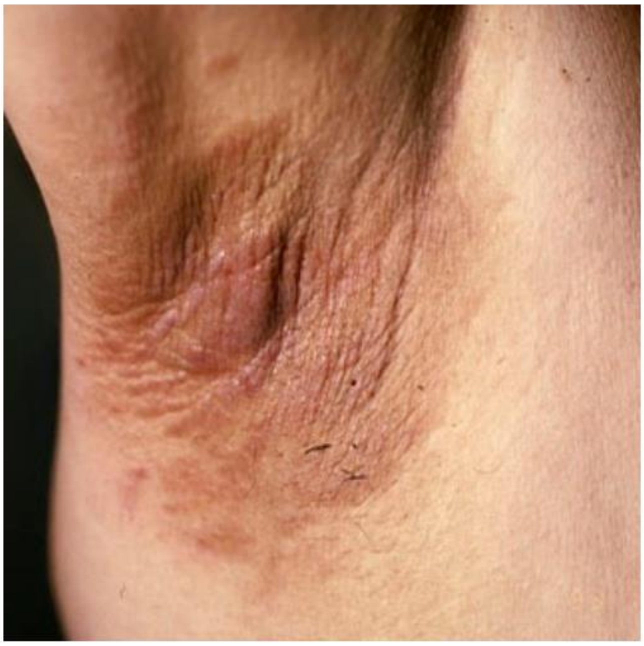
Erythema migrans is an expanding erythematous plaque with central clearing, creating a 'bull's eye/target' like rash, often associated with the early stages of Lyme disease. The skin lesions occur at the site of a tick bite, normal around skin folds or on the trunk, and as such patient's common present following outdoor activities in a woodland area.

Necrobiosis lipoidica is a dermatological feature of a few conditions but is most commonly associated with diabetes. It presents as an initially asymptomatic, necrotising rash normally found on the shins which can become tender and ulcerate when injured.

Scabies is an intensely itchy, rash with associated small burrow lesions, caused by the mite *Sarcoptes scabiei*. The rash is normally found in the finger webs but also around the feet, ventral wrists, elbows, trunk, and external genitals.

Question 62 of 182

A 56-year-old woman develops a rash in both axilla:



What is the most likely diagnosis?

A. Pellagra
B. Erythema gyratum repens
C. Hidradenitis suppurativa
D. Tinea corporis
E. Acanthosis nigricans

E. Acanthosis nigricans

The correct answer is **Acanthosis nigricans**. Acanthosis nigricans is a skin condition characterised by dark, thickened patches of skin that can appear in various parts of the body including the axilla. The image shows a velvety, hyperpigmented rash which is typical of acanthosis nigricans. It's often associated with insulin resistance and can be an early sign of type 2 diabetes.

Pellagra is incorrect because it typically presents with the 'three Ds': dermatitis, dementia, and diarrhoea. The dermatitis caused by pellagra usually occurs on areas exposed to sunlight and takes on a symmetrical, butterfly-shaped appearance on the face. It does not typically present as darkened patches in the axilla.

Erythema gyratum repens is also incorrect. This condition produces concentric circles or waves of erythema that migrate across the skin surface, giving it a wood-grain appearance. These patterns are not visible in the provided image.

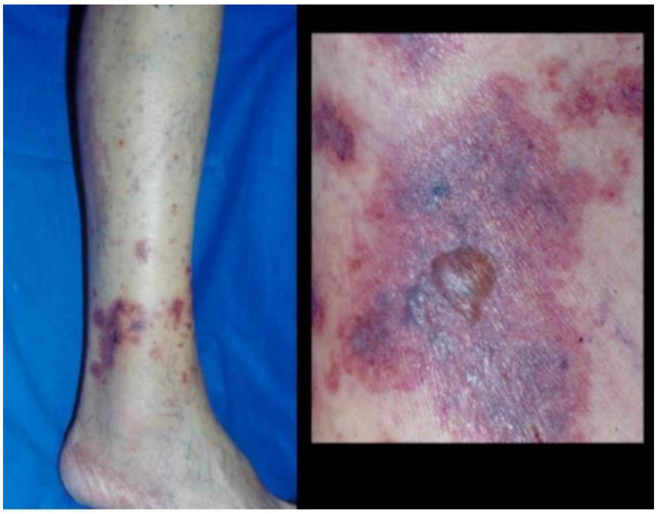
Hidradenitis suppurativa would be an incorrect choice as well because this chronic inflammatory skin condition causes painful lumps under the skin. These lumps or abscesses occur near hair follicles where many oil and sweat glands are found such as in the armpits or groin area. However, they do not resemble the darkened patches seen in this patient's axillae.

Lastly, **Tinea corporis** (ringworm) is also an incorrect option. Tinea corporis presents with circular rashes with raised borders that expand over time - often leaving clear or normal-looking skin in the centre which gives it a ring-like appearance hence its common name 'ringworm'. This pattern cannot be seen in this image either.

Question 63 of 182

A 60-year-old man has been an inpatient in a general medical ward for 2 weeks. He presented with a 10-day history of fever and malaise. He developed lesions on his lower legs the day before his admission. Despite the administration of broad-spectrum antibiotics since admission, he is continuing to have temperatures greater than 38ºC on a daily basis. The rest of his observations remain stable.

On examination, his skin appears as shown below:



Blood tests are taken with the following results:

Hb	108 g/L	Male: (135-180)Female: (115 - 160)
Platelets	114 * 10 /L 9	(150 - 400)
WBC	14.5 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	9.5 mmol/L	(2.0 - 7.0)
Creatinine	145 µmol/L	(55 - 120)
CRP	120 mg/L	(< 5)

What is the most likely cause for this patient's skin changes?

A. Drug reaction
B. Haemolytic uraemic syndrome
C. Kaposi's sarcoma
D. Small vessel vasculitis
E. Thrombocytopenia

D. Small vessel vasculitis

The image shows a number of petechial and purpuric lesions of different sizes on the lower legs. This is a classic cutaneous presentation of the small vessel vasculitides, which can cause inflammation of the blood vessels in the skin, as well as elsewhere in the body.

The correct answer is **small vessel vasculitis** . This is a group of conditions, including ANCAassociated vasculitides, cryoglobulinaemia and Henoch-Schonlein purpura. They may often present with non-specific symptoms, including as pyrexia of unknown origin as in this scenario. The raised creatinine also points to a systemic condition.

Drug reaction is incorrect. Skin manifestations of drug reactions are varied, and drug-induced small vessel vasculitis can occasionally occur but this is rare. The patient also developed the lesions before his admission to the hospital, making a drug reaction less likely. This would also not explain the rest of his symptoms.

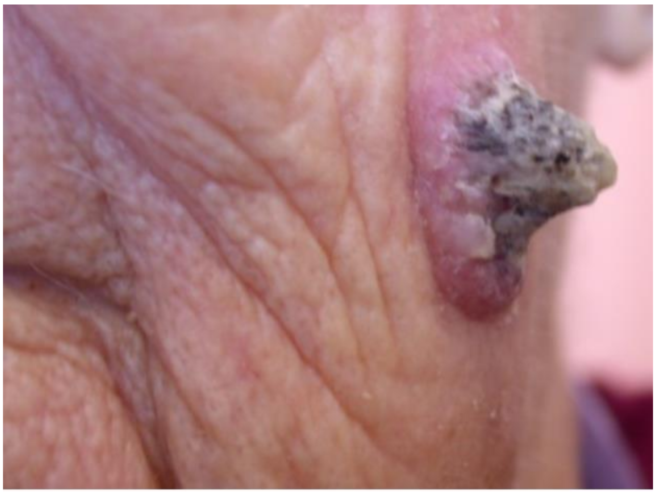
Kaposi's sarcoma is incorrect. This condition causes red to purplish lesions on the skin, but they tend to be solitary or few in number in the early stages, and would not be on a background of numerous small lesions as in this image. The progression of lesions also tends to be much slower than in this patient.

Haemolytic uraemic syndrome (HUS) is incorrect. This condition can cause a purpuric rash due to thrombocytopenia. It is unlikely in this patient as the renal function is only mildly abnormal, thrombocytopenia is mild and there is no clear evidence of haemolytic anaemia. HUS is also much more common in children than in adults. There is also no history of diarrhoea given in this patient, and HUS is usually triggered by infection with a verotoxin-producing strain of *E.coli* causing diarrhoea before the onset of HUS.

Thrombocytopenia is incorrect. Low platelets can cause petechiae and purpura due to bleeding into the skin, but this is unlikely with relatively mild thrombocytopenia as in this patient.

Question 64 of 182

An elderly man presents with a lesion on his cheek that has got progressively worse over the past year. He asks for it to be removed as it is catching:



What is the most likely diagnosis?

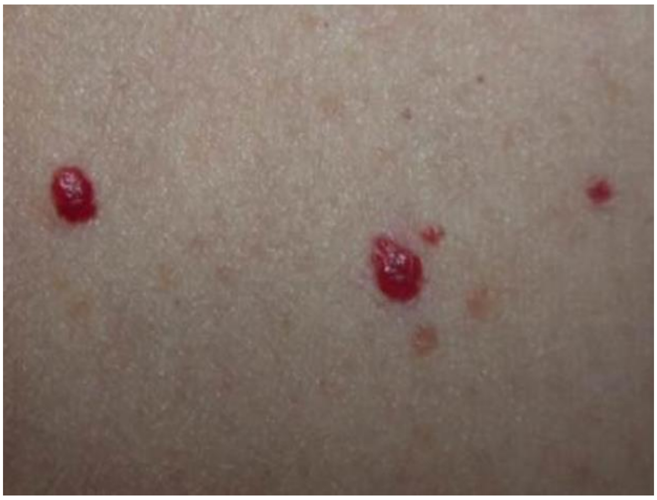
A. Nodular malignant melanoma
B. Viral wart
C. Solar keratosis
D. Seborrhoeic keratosis
E. Squamous cell carcinoma

E. Squamous cell carcinoma

The main differential diagnosis here is keratoacanthoma which are often described as 'minivolcanos' with a central core filled with keratin.

Question 65 of 182

A 55-year-old man asks you to have a look at some 'red spots' on his torso. They have been present for about the past six months.



What is the most likely diagnosis?

A. Kaposi sarcoma
B. Blue rubber bleb naevus syndrome
C. Thrombocytopaenia
D. Malignant melanoma
E. Cherry haemangioma

E. Cherry haemangioma

The most likely diagnosis for the 'red spots' on the 55-year-old man's torso is **Cherry haemangioma**. This condition is characterized by small, bright red raised bumps that are usually found on the skin of adults aged over 30 years. The 'red spots' in the image provided are consistent with this description. Cherry haemangiomas are benign vascular proliferations and do not require treatment unless they become symptomatic or for cosmetic reasons.

Kaposi sarcoma is incorrect because it typically presents as purple, red, or brown blotches or tumours on the skin. It is a rare type of cancer that can occur in people with weakened immune systems such as those with AIDS or who have had organ transplants, which does not seem to be applicable to this patient based on the information given.

Blue rubber bleb naevus syndrome is also unlikely as it involves venous malformations that appear as compressible blue nodules and can occur anywhere on the body including internal organs. These lesions are typically blue rather than red and often present at birth or during early childhood.

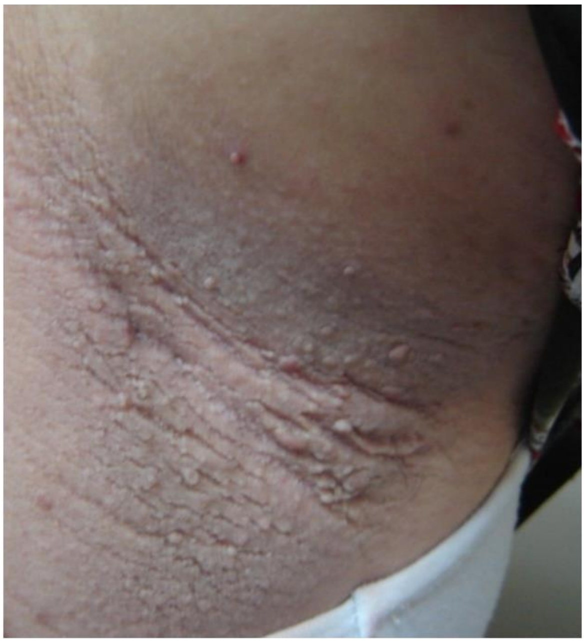
The option of **Thrombocytopaenia**, which translates to low platelet count, would usually present with petechiae (small red or purple spots), purpura (larger areas of bleeding into skin), easy bruising or mucosal bleeding rather than these isolated 'red spots'.

Finally, **Malignant melanoma** is an aggressive form of skin cancer that often appears as a new mole or changes in an existing mole rather than presenting as multiple 'red spots'. Melanomas typically have irregular borders, variations in colour within one lesion, larger diameter and evolving changes over time. This presentation does not match the image provided.

Question 66 of 182

A 50-year-old man presents to the dermatology clinic with a 1-month history of axillary skin discolouration. He finds it unpleasant to look at and is now complaining of increasing pruritus. He has no past medical history of note and smokes 15-20 cigarettes/day.

On examination, he is afebrile with a heart rate of 76 beats/min and a blood pressure of 130/65mmHg. His skin is examined, as shown below:



Given the diagnosis, what is most likely to be associated with this presentation?

A. Acromegaly
B. Acute lymphoblastic leukaemia
C. Addison's disease
D. Coeliac disease
E. Diabetes insipidus

A. Acromegaly

Acromegaly is correct. This patient has a diagnosis of acanthosis nigricans characterised by hyperkeratosis and hyperpigmentation of the skin, predominantly affecting the flexural skin folds such as the axillae and groin. The skin may have a velvety texture secondary to papillomatous overgrowth of the epidermis. Common underlying causes include metabolic diseases such as obesity, type 2 diabetes mellitus, polycystic ovarian syndrome and acromegaly.

Acute lymphoblastic leukaemia is incorrect. Haematological malignancies are associated with Sweet syndrome, characterised by fever and inflamed and blistered skin with mucosal involvement.

Addison's disease is incorrect. Due to excess ACTH, patients with Addison's disease may have the appearance of tanned skin due to the stimulation of melanocytes. However, it does not cause acanthosis nigricans.

Coeliac disease is incorrect. Coeliac disease is associated with dermatitis herpetiformis, a vesicular rash commonly seen on the extensor surfaces of the skin. This is not the rash that is demonstrated here.

Diabetes insipidus is incorrect. Diabetes mellitus is associated with acanthosis nigricans. However, diabetes insipidus is not associated with any dermatological manifestations.

Question 67 of 182

A 68-year-old lady is reviewed in the cardiology outpatient clinic following a recent admission for a non-ST-elevation myocardial infarction (NSTEMI). An echocardiogram performed during her inpatient stay showed mild-moderate LV systolic dysfunction with an ejection fraction of 40%.

Since discharge, she has been feeling well and has experienced no further episodes of chest pain. She reports only mild breathlessness on climbing two flights of stairs but draws your attention to an itchy rash on her lower legs. On examination, there are tense blisters covering her lower limbs bilaterally with minimal underlying oedema.

Which of her medications is most likely to be implicated?

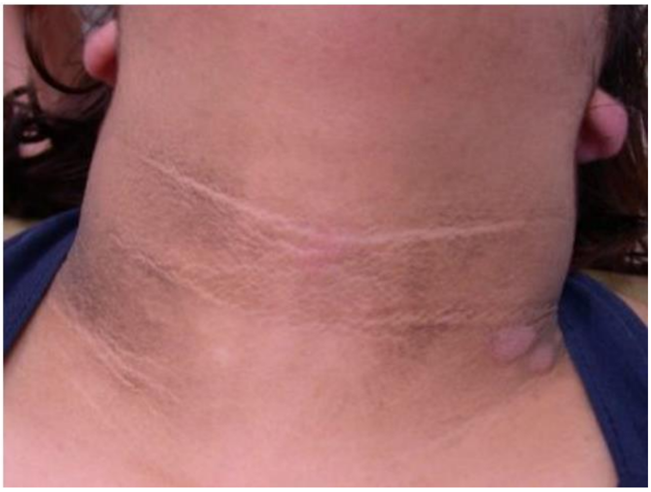
A. Spironolactone
B. Clopidogrel
C. Bisoprolol
D. Furosemide
E. Ramipril

D. Furosemide

The patient has developed bullous pemphigoid, of which furosemide is a classic cause. Penicillamine, captopril, and penicillin derivatives are other common causes. The condition may remit or even disappear on cessation of the offending agent.

Question 68 of 182

You notice an abnormality on the neck of a 40-year-old woman:



Which one of the following is most associated with this appearance?

- A. Lung cancer
- B. Acute pancreatitis
- C. Haemochromatosis
- D. Polycystic ovarian syndrome
- E. Digoxin use

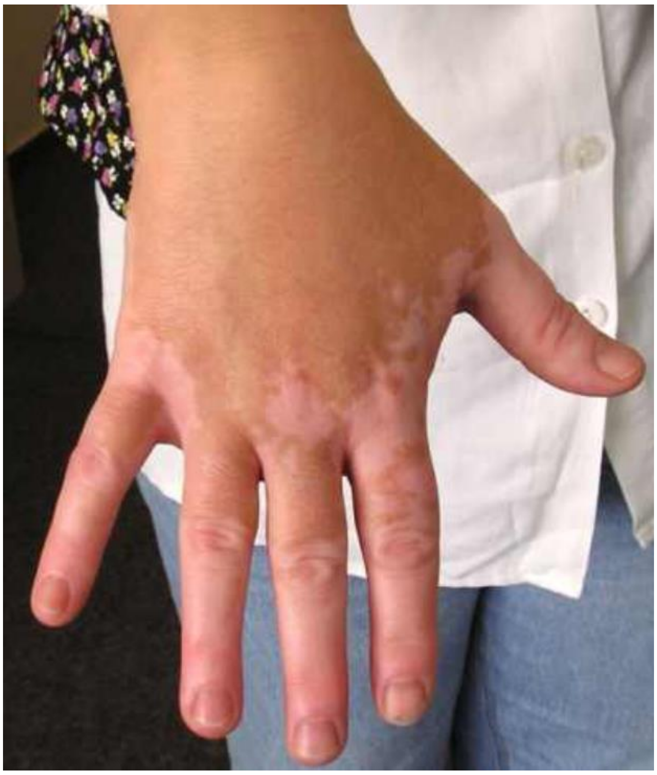
D. Polycystic ovarian syndrome

This patient has acanthosis nigricans which is associated with a number of hyperinsulinaemia states such as polycystic ovarian syndrome.

Whilst acanthosis nigricans can be associated with any type of cancer by far the most common malignant cause is gastrointestinal adenocarcinoma.

Question 69 of 182

A 21-year-old woman with a history of eczema presents with a change in the colour of her skin affecting the hands and feet symmetrically:



What is the most likely diagnosis?

- A. Excessive topical corticosteroid use
- B. Leprosy
- C. Tuberous sclerosis
- D. Vitiligo
- E. Pityriasis versicolor

D. Vitiligo

The correct answer is **Vitiligo**. Vitiligo is a condition that causes loss of skin colour in patches. It can affect the skin on any part of your body and may also affect hair, the inside of the mouth and even the eyes. The main symptom is a loss of pigment which produces white patches on the skin, often symmetrical, as seen in this patient.

The first incorrect option, **Excessive topical corticosteroid use**, can lead to changes in skin colour, but these are typically characterised by thinning of the skin and formation of stretch marks rather than depigmentation. Additionally, excessive use would likely not produce such symmetrical patterns.

Leprosy, another incorrect option, is an infectious disease caused by *Mycobacterium leprae*. It usually presents with hypopigmented or reddish patches with a definite loss of sensation. However, it's rare in the UK and does not usually present symmetrically.

Tuberous sclerosis is a genetic disorder that causes non-cancerous (benign) tumours to grow in many parts of your body. Skin manifestations include hypomelanotic macules (white patches), facial angiofibromas or shagreen patches but these do not have a symmetrical distribution.

Lastly, **Pityriasis versicolor** is an infection caused by yeast from the Malassezia family. This condition causes small, scaly patches of discoloured skin that might be lighter or darker than the surrounding skin. However, unlike vitiligo, pityriasis versicolor does not cause complete depigmentation and it tends to affect the trunk more commonly than the hands and feet.

Question 70 of 182

A 72-year-old woman presents with a new skin marking. She has noticed it recently and is fairly sure it was not present six months ago. It has not caused her any symptoms and has not been itching. On examination, it is a raised, slightly ulcerated, 7mm diameter lesion on her chest.

What clinical finding would make squamous cell carcinoma more likely than basal cell carcinoma?

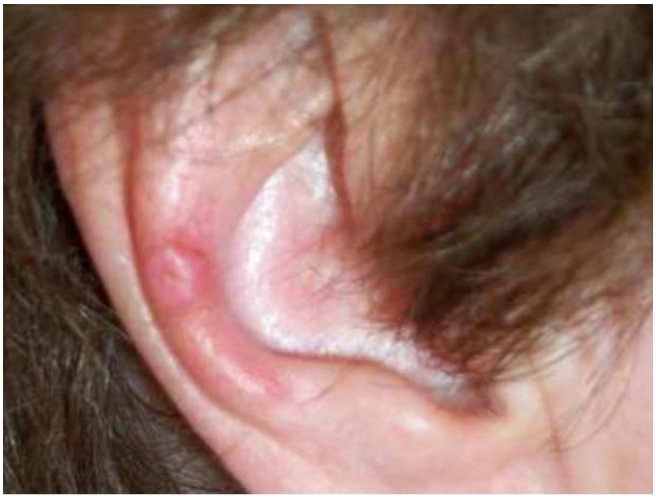
A. Telangiectasia
B. Not associated with ulceration
C. Pearly appearance
D. Erythematous base
E. Nodular edge

D. Erythematous base

The correct answer is erythematous base. Squamous cell cancers present as crusty enlarging lumps on a background of acinic keratosis on sun-exposed skin. They may ulcerate and are often tender or painful. Basal cell cancers usually have telangiectasia, pearly appearance and have a nodular edge.

Question 71 of 182

A 60-year-old man presents with a painful lesion on his right ear:



What is the most likely diagnosis?

A. Actinic keratosis
B. Pseudocyst of the auricle
C. Chondrodermatitis nodularis helicis
D. Basal cell carcinoma
E. Keratoacanthoma

C. Chondrodermatitis nodularis helicis

The correct answer is **Chondrodermatitis nodularis helicis**. This condition typically presents as a painful, inflamed nodule on the helix or antihelix of the ear. It most commonly affects middle-aged or elderly individuals and is thought to be related to pressure and sun exposure. The image provided shows a characteristic lesion of Chondrodermatitis nodularis helicis.

Moving on to the incorrect options:

Actinic keratosis is a precancerous skin condition characterised by scaly, crusty spots on the skin caused by damage from the sun's ultraviolet (UV) rays. While it may present in similar areas such as face, lips, ears, back of your hands, forearms, scalp or neck due to sun exposure, it does not typically cause painful lesions.

Pseudocyst of the auricle, also known as auricular pseudocyst, presents as a non-inflammatory, fluid-filled swelling on the anterior aspect of the pinna. It's usually painless unless infected and does not appear erythematous like in this case.

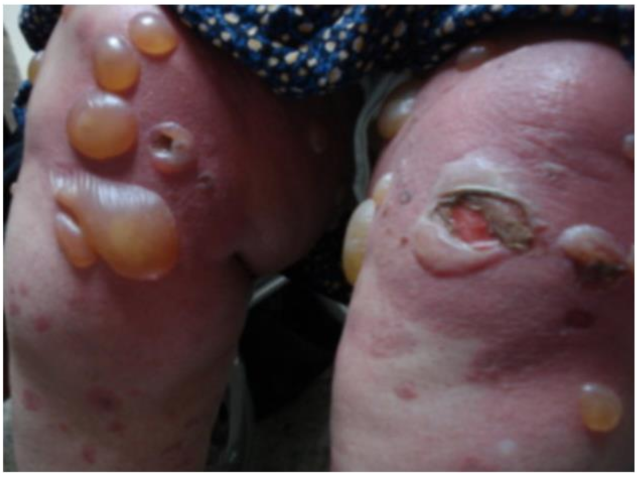
Basal cell carcinoma is a type of skin cancer that begins in the basal cells which produce new skin cells when old ones die off. It often appears as a slightly transparent bump on the skin, though it can also form as red patches or sores. While it could potentially present with similar characteristics to our patient's lesion (especially if ulcerated), BCCs are typically less painful than Chondrodermatitis nodularis helicis.

Lastly, **Keratoacanthoma** manifests as a round, flesh-coloured growth that might resemble a small volcano with a central plug of keratin. They are rapidly growing tumours that often develop over weeks to months which then may resolve spontaneously over many months. However, they are usually solitary and painless, unlike our patient's presentation.

Question 72 of 182

A 79-year-old woman presents to the dermatology clinic with a 2-week history of a blistering rash over her body. She describes the rash to be predominantly over the lower limbs and forearms. Her past medical history includes hypothyroidism and mild hypertension for which she takes levothyroxine and amlodipine daily.

On examination, her observations are within normal limits. Her rash is examined, as shown below:



Given the likely diagnosis, what findings are most likely to be seen on biopsy?

A. Acantholysis
B. IgA deposition
C. IgG and C3 deposition
D. Keratinocyte necrosis
E. Positive gram stain

C. IgG and C3 deposition

This patient has a diagnosis of bullous pemphigoid, given the presence of a blistering rash over the body, predominantly affecting the limbs. The image shows tense blisters that are full of fluid with surrounding erythema. There are discrete, raised erythematous lesions that have a similar appearance to urticaria-like weals. Unlike, pemphigus vulgaris, the oral mucosa is usually spared.

The risk of bullous pemphigoid increases with age and those with a history of autoimmune disease. In order to confirm the diagnosis of bullous pemphigoid, a skin biopsy may be taken which shows **IgG and C3 deposition at the dermo-epidermal junction** on immunofluorescence.

Acantholysis is incorrect. Acantholysis is the loss of cohesion between adjacent keratinocytes due to a loss of intercellular connections. It is seen in pemphigus vulgaris and is absent in bullous pemphigoid, making a skin biopsy a useful diagnostic test to distinguish between the two blistering diseases.

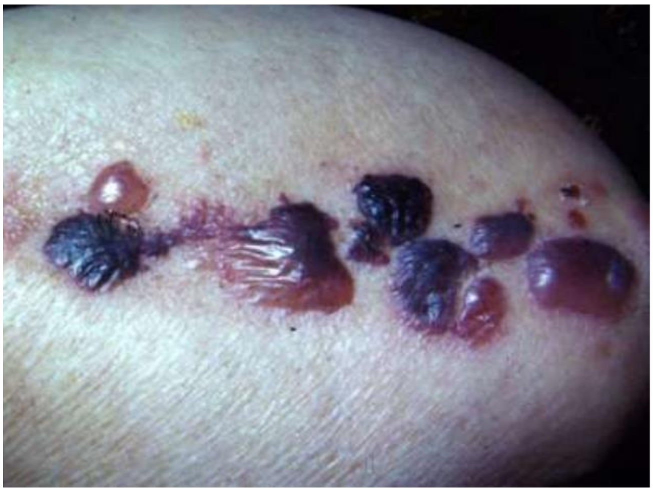
IgA deposition is incorrect. IgA deposition is seen in dermatitis herpetiformis, a condition associated with coeliac disease. It causes a vesicular eruption, most commonly on the shins but would not be responsible for the rash seen in this patient.

Keratinocyte necrosis is incorrect. Keratinocyte necrosis is classically seen in Steven-Johnson syndrome (SJS). SJS is a rare, life-threatening condition that is almost always caused by a drug reaction. It is associated with fever, flaccid blistering causing large amounts of skin detachment, erythema and shock. Although this patient has evidence of a blistering disease, they are otherwise stable, making SJS unlikely.

Positive gram stain is incorrect. Although these blisters can become infected with a bacterial organism, bullous pemphigoid is not an infective process and a positive gram stain is not a diagnostic feature of the disease.

Question 73 ofttt 182

An elderly man develops a blistering skin rash:



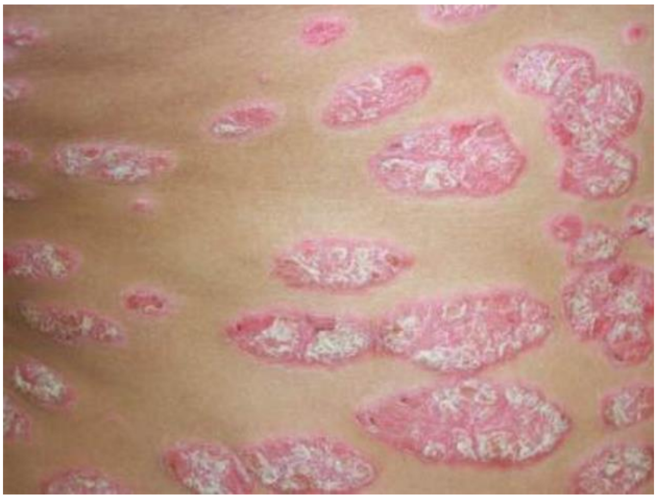
Which one of the following statements regarding the likely diagnosis is correct?

A. It is associated with coeliac disease
B. Eye involvement is the most common complication
C. Topical corticosteroids are the mainstay of treatment
D. It is less common than pemphigus vulgaris
E. The blisters usually heal without scarring

E. The blisters usually heal without scarring

Question 74 of 182

Please look at the image below:



Which one of the following is this patient most likely to go on and develop?

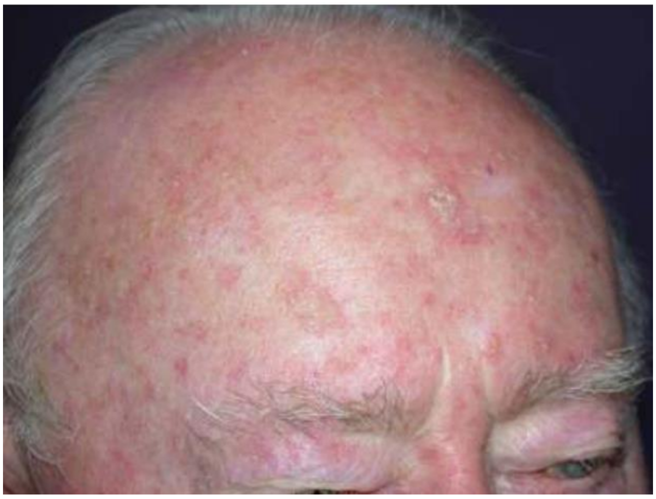
A. Parkinson's disease
B. Hypothyroidism
C. Rheumatoid arthritis
D. Sarcoidosis
E. Metabolic syndrome

E. Metabolic syndrome

Along with psoriatic arthritis, metabolic syndrome is one of the most common and significant complications of psoriasis.

Question 75 of 182

A 67-year-old man who is a retired builder presents following the development of a number of red, scaly lesions on his forehead. These were initially small and flat but are now erythematous and rough to touch.



What is the most likely diagnosis?

A. Pityriasis versicolor
B. Seborrhoeic keratosis
C. Polymorphous light eruption
D. Actinic keratoses
E. Malignant melanoma

D. Actinic keratoses

The most likely diagnosis for this 67-year-old retired builder presenting with red, scaly lesions on his forehead is **actinic keratoses**. Actinic keratoses are premalignant skin lesions caused by chronic exposure to ultraviolet (UV) radiation, typically seen in fair-skinned individuals and those with a history of outdoor work such as builders. The appearance of these lesions as erythematous, rough patches is consistent with actinic keratoses. In some cases, they can progress to squamous cell carcinoma if left untreated.

Pityriasis versicolor is an incorrect answer because it is a superficial fungal infection caused by the yeast *Malassezia*. It typically presents as hypopigmented or hyperpigmented scaly macules and patches on the trunk and upper extremities. The distribution and lack of pigmentary changes make pityriasis versicolor less likely in this case.

Seborrhoeic keratosis is also an incorrect answer. Seborrhoeic keratoses are benign epidermal growths that appear as waxy, brownish-black 'stuck-on' plaques. They commonly occur on the trunk and face but have a different appearance than the erythematous, rough lesions described in this case.

Polymorphous light eruption is not the correct answer either. Polymorphous light eruption is a delayed hypersensitivity reaction to UV radiation that presents as pruritic papules, vesicles, or plaques on sun-exposed skin areas shortly after sun exposure. While the patient's age and occupation might suggest sun exposure as a factor, the chronic nature of these lesions makes polymorphous light eruption less likely.

Finally, **malignant melanoma** would be an incorrect answer because malignant melanoma typically presents as an asymmetrical, irregularly bordered, variably coloured lesion with a diameter greater than 6mm. The red, scaly lesions described in this case do not fit the typical presentation of malignant melanoma.

Question 76 of 182

A 69-year-old man presents to the dermatology clinic for review due to a suspicious skin lesion. He noticed that a particular mole was of concern as it had been irritated and rubbed against his shirt. On his back, he has a 11x13mm brown lesion with an irregular border with a variation in colour. On view under a dermatoscope, there is no telangiectasia, the lesion looks like there are dark pigmented pin-prick spots within the brown lesion.

What feature of this description provides reassurance that the diagnosis is more likely to be benign?

A. The absence of telangiectasia
B. Irregular border of lesion
C. Presence of dark pigmented pin-prick spots
D. The size of the lesion
E. Variation in colour

C. Presence of dark pigmented pin-prick spots

Pseudo-comedones and pale spots help distinguish seborrhoeic lesions from malignant melanomas

The presence of dark pigmented pin-prick spots, sometimes described as pseudo-commodones, are consistent with seborrhoeic keratosis rather than malignant melanoma. Seborrhoeic keratosis can normally be distinguished clinically by a 'stuck-on' appearance, rather than an invasive one. The other features described are not reassuring and could be consistent with a melanoma, but it is also important to establish if there is change in the lesion.

Irregular shape, a size greater than 6mm, and variation in colour are all features which can be considered with skin malignancy. Telangiectasia is a feature of basal cell carcinoma rather than melanoma or seborrhoeic keratosis.

Question 77 of 182

A 32-year-old woman is reviewed in the emergency department. She has developed a very painful rash on her left arm. It is a burning pain which preceded the formation of a rash. She has felt low in energy with this and has noticed that the rash is intensely tender to light touch. Apart from this she feels well in herself. She has a past medical history of appendicitis at the age of 18 which was treated surgically, and depression for which she has been attending cognitive behavioural therapy. On examination, she has an erythematous rash within on the underarm on the left side, roughly 8cm in length. There are small vesicles within this. She is diagnosed with shingles, and told that she can infect people with chicken-pox. She wonders how long she will be infectious for.

What is the most appropriate advise?

A. She will be infectious until she starts aciclovir
B. She will be infectious up to two weeks from onset of rash
C. She will be infectious up to two months from onset of rash
D. She will be infectious until her vesicles have crusted over
E. She will no longer be infectious as vesicles have appeared

D. She will be infectious until her vesicles have crusted over

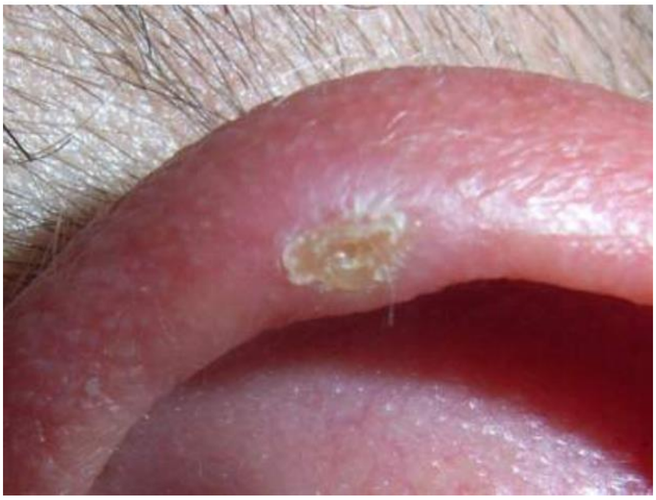
People with shingles should be advised that they are infectious until the vesicles have crusted over, usually 5-7 days following onset

This patient has shingles, acute reactivation of herpes zoster virus (HZV). HZV in the form of shingles is contagious, but exposure could cause chickenpox, rather than shingles. People who have had chickenpox previously would be considered immune, but adults and especially pregnant women who have not had chickenpox are at risk of serious infection.

The patient is infectious until the vesicles have crusted over.

Question 78 of 182

A 75-year-old asks you to have a look at a lesion on his right ear. It has developed slowly over the past few months and is tender to palpation.



What is the most likely diagnosis?

A. Cystic chondromalacia
B. Actinic keratosis
C. Chondrodermatitis nodularis helicis
D. Perichondritis
E. Keratin horn

C. Chondrodermatitis nodularis helicis

The correct answer is **Chondrodermatitis nodularis helicis**. This condition is a benign inflammatory process affecting the ear's cartilage and overlying skin. It typically presents as a tender nodule on the helix or antihelix of the ear, often in elderly patients. The slow development and tenderness to palpation of this patient's lesion are classic signs of chondrodermatitis nodularis helicis.

Cystic chondromalacia, also known as Relapsing Polychondritis, is an incorrect choice because it is a rare multi-system disorder characterized by recurrent episodes of painful inflammation and deterioration of cartilage throughout the body. It would not present as a solitary lesion on the ear; instead, it often affects multiple sites including ears, nose, joints, respiratory tract and eyes.

Actinic keratosis is another incorrect option. While actinic keratosis can indeed present as a rough, scaly patch on sun-exposed skin (such as the ear), it is usually not tender unless it has progressed into squamous cell carcinoma. Furthermore, actinic keratosis lesions generally develop more rapidly than what was described in this case.

The option **Perichondritis** does involve inflammation of the ear cartilage but it's incorrect because perichondritis is typically caused by trauma to the ear or following ear surgery. It presents acutely with severe pain, redness and swelling around the entire ear structure rather than a slowly developing single nodule.

Finally, **Keratin horn** refers to a projection from the skin resulting from overgrowth of keratin. These lesions are typically hard and non-tender which contrasts with this patient's presentation of a tender lesion.

Question 79 of 182

A 37-year-old gentleman is referred to the cardiology clinic with a 7-month history of bilateral foot pain. Initially, the pain only occurred towards the end of his daily commute; improving when he sat at his desk, but over the past 3 weeks his symptoms have progressed. The pain is now provoked by walking short distances and has occasionally occurred at rest. He describes being woken by the pain at night, although he is able to obtain relief by standing on the cool tiles in his bathroom. He eventually decided to see his GP when he developed similar pain in his right wrist 10 days ago.

His past medical history is unremarkable. There is no history of hypertension, dyslipidaemia or diabetes. He is a current smoker with a 20 pack year history. He drinks alcohol in moderation.

On examination, both feet are noted to be smooth and hairless. The right dorsalis pedis is difficult to feel and the medial 3 toes are cold and dusky. Urgent angiography is performed and shows a number of distal stenoses in the right limb affecting the anterior and posterior tibial arteries as well as the distal fibular artery. A number of similar stenoses are seen in the contralateral limb with 'corkscrew' collateral formation.

Blood tests are as follows:

Hb	130 g/l	Na +	139 mmol/l
Platelets	322*10 /l 9	K +	4.1 mmol/l
WBC	9.1*10 /l 9	Urea	5.3 mmol/l
Neuts	6.2*10 /l 9	Creatinine	113 µmol/l
Lymphs	2.1*10 /l 9	CRP	19 mg/l
Eosin	0.1*10 /l9		
MPO		negative	
PR3		negative	

anti-cardiolipin	negative

What is the most likely diagnosis?

A. Peripheral vascular disease
B. Microscopic polyangiitis
C. Takayasu arteritis
D. Thromboangiitis obliterans
E. Polyarteritis nodosa

NOT ANSWERED

Question 80 of 182

A 54-year-old man comes to the dermatology clinic for review. He has a hyperpigmented rash affecting the back of his neck, his axillae and his groin that has become more prominent over the past few weeks. There has been increased shortness of breath and decreased exercise tolerance over the past 3 months. He smokes 20 cigarettes per day and is treated for COPD with a high dose salmeterol / fluticasone combination inhaler. Examination reveals a blood pressure of 132/82 mmHg, and a pulse of 65 beats per minute. You confirm the rash. There is quiet wheeze on auscultation of the chest. Abdomen is soft and he complains of mild tenderness in epigastrium. His body mass index is 22 kg/m².

Investigations

Hb	90 g/l	Na +	140 mmol/l
Platelets	191 * 10 /l 9	K +	4.3 mmol/l
WBC	7.0 * 10 /l 9	Urea	7.2 mmol/l
Neuts	3.2 * 10 /l 9	Creatinine	110 µmol/l
Lymphs	1.4 * 10 /l 9	CRP	32 mg/l
ESR	72 mm/hr		

Which of the following is the most useful next investigation?

A. Bronchoscopy
B. Colonoscopy
C. Skin biopsy
D. Ultrasound abdomen
E. Upper gastrointestinal endoscopy

E. Upper gastrointestinal endoscopy

The most common malignancy associated with acanthosis nigricans is gastrointestinal adenocarcinoma

The character of the rash is most suggestive of a diagnosis of acanthosis nigricans. Given the history of smoking and the anaemia, the possibility of underlying gastric cancer is raised, for this reason, an endoscopy +/- biopsy of any lesion is the most useful next step.

Bronchoscopy isn't indicated, nor is a colonoscopy, because lung cancer and colon cancer are not as strongly associated with acanthosis. Ultrasound of the abdomen may reveal an epigastric mass, but it is a relatively insensitive way of detecting gastric cancer.

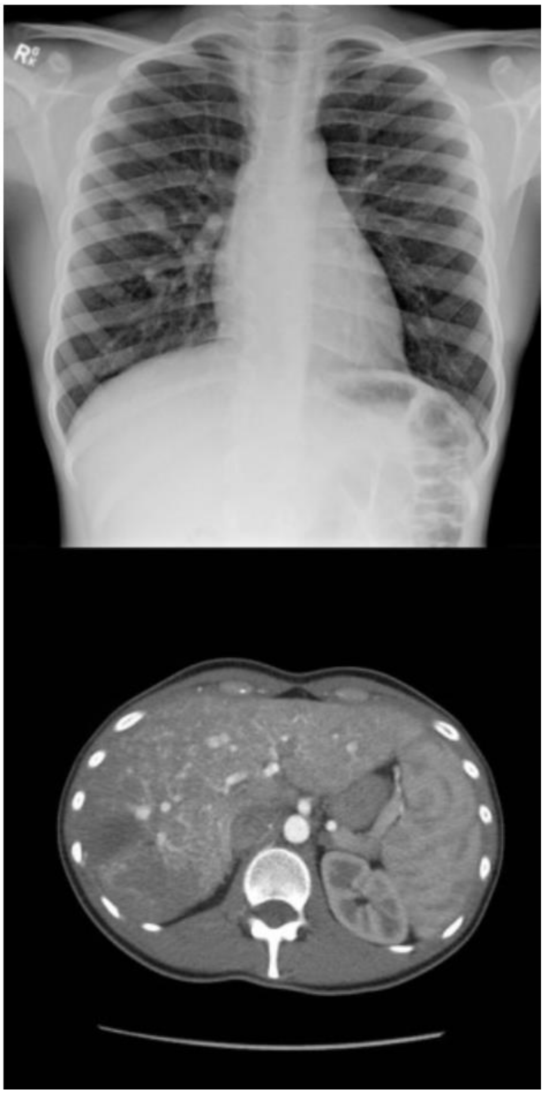
Skin biopsy reveals hyperkeratosis and papillomatosis, relatively minor hyperpigmentation is also seen.

Question 81 of 182

A 16-year-old male is investigated for recurrent epistaxis, haemoptysis and iron-deficiency anaemia. Blood tests show the following:

Hb	11.1 g/dl
Platelets	341 * 10 /l9
WBC	4.3 * 10 /l9
Bilirubin	33 µmol/l
ALP	131 u/l
ALT	54 u/l
γGT	135 u/l
Albumin	40 g/l

A chest x-ray and CT abdomen are requested:



What is the most likely diagnosis?

A. Acute lymphoblastic leukaemia
B. Metastatic cancer secondary to familial adenomatous polyposis
C. Hereditary haemorrhagic telangiectasia
D. Metastatic pleuropulmonary blastoma

E. Peutz-Jeghers syndrome

C. Hereditary haemorrhagic telangiectasia

The correct answer is **Hereditary haemorrhagic telangiectasia**. This is a rare autosomal dominant disorder characterised by the presence of multiple arteriovenous malformations (AVMs)

that lack intervening capillaries and result in direct connections between arteries and veins.

The chest x-ray shows multiple pulmonary nodules representing arteriovenous malformations, the largest in the right mid-zone. The CT scan shows multiple hepatic arteriovenous malformations.

The clinical presentation of recurrent epistaxis, haemoptysis, and iron-deficiency anaemia in this 16-year-old male is suggestive of Hereditary haemorrhagic telangiectasia (HHT), also known as Osler-Weber-Rendu syndrome. HHT can affect various organs, including the lungs, liver, brain, and gastrointestinal tract, causing bleeding.

The other options are less likely based on the given information:

Acute lymphoblastic leukaemia typically presents with symptoms related to bone marrow suppression, such as fatigue, pallor, fever or infection due to neutropenia. This patient's blood test results do not show any significant abnormalities in white blood cell count or platelet count that would be expected in acute leukaemia.

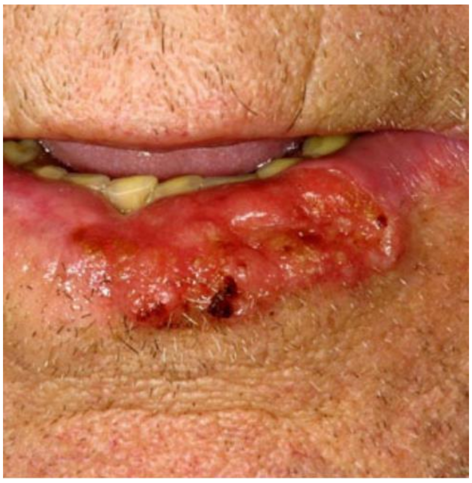
Metastatic cancer secondary to familial adenomatous polyposis is an unlikely diagnosis as this condition is primarily associated with colorectal cancers developing from numerous adenomatous polyps in the colon. The patient's presenting symptoms of recurrent epistaxis and haemoptysis do not fit this diagnosis.

Metastatic pleuropulmonary blastoma, a rare malignant mesenchymal tumour of childhood affecting the lung parenchyma and pleura, usually presents with respiratory distress or pneumonia-like symptoms rather than recurrent epistaxis and haemoptysis.

Finally, **Peutz-Jeghers syndrome** is characterised by hamartomatous gastrointestinal polyps and mucocutaneous pigmentation. While this syndrome can cause anaemia due to gastrointestinal bleeding, it does not typically present with recurrent epistaxis or haemoptysis as seen in this patient.

Question 82 of 182

A 75-year-old man presents with a 'sore' on his lip. This has been present for around four months and has been getting slowly worse. His past medical history includes ischaemic heart disease and chronic obstructive pulmonary disease. He still smokes around 20 cigarettes per day.



What is the most likely diagnosis?

A. Actinic keratosis
B. Leukoplakia
C. Squamous cell carcinoma
D. Mucocoele
E. Bowen's disease

C. Squamous cell carcinoma

The most likely diagnosis in this case is **Squamous cell carcinoma**. The patient's age, history of smoking, and the appearance of the lesion with its chronicity and progressive worsening are all suggestive of squamous cell carcinoma (SCC). SCC is a malignant tumour arising from keratinocytes in the epidermis. It commonly affects sun-exposed areas like the face and lips. Smoking is a significant risk factor for SCC development.

Actinic keratosis is an incorrect option because it typically presents as a rough, scaly patch on sun-exposed skin. It is a precursor to SCC but does not have the same appearance as the lesion described in this case.

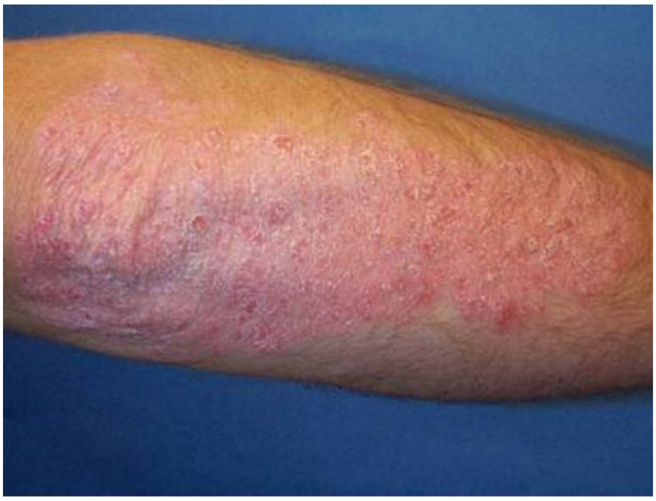
Leukoplakia is also incorrect as it usually presents as white patches or plaques on the oral mucosa, which cannot be scraped off. While leukoplakia can be associated with malignancy, it does not have the same clinical appearance as the lip sore described here.

Mucocoele is another incorrect choice because it presents as a painless, fluid-filled swelling that often occurs on the lower lip due to trauma or obstruction of salivary glands. The chronicity and worsening nature of the lesion in this case do not fit with a mucocoele.

Finally, **Bowen's disease** is an incorrect option because it typically appears as an erythematous, scaly patch with well-defined borders on sun-exposed skin. Although Bowen's disease represents squamous cell carcinoma in situ and shares some risk factors with invasive SCC, its clinical presentation differs from that described in this scenario.

Question 83 of 182

A 34-year-old man presents with a scaly rash on his elbows and knees that has been getting progressively worse for the past 3 months. He has tried using some of his wife's Diprobase cream which has helped the itching somewhat.



Following NICE guidance, what is the most appropriate next step in management?

A. Topical potent corticosteroid + vitamin D analogue
B. Topical potent corticosteroid
C. Refer for ultraviolet light therapy
D. Topical vitamin D analogue
E. Topical coal tar

A. Topical potent corticosteroid + vitamin D analogue

Topical potent corticosteroid + vitamin D analogue is first-line for chronic plaque psoriasis

The correct answer is **Topical potent corticosteroid + vitamin D analogue**. According to NICE guidelines, the first-line treatment for psoriasis in adults should be a combination of a topical corticosteroid and a vitamin D analogue. This combination has been shown to be more effective than using either treatment alone. The patient's presentation of a scaly rash on his elbows and knees is consistent with plaque psoriasis, and the use of a potent corticosteroid combined with a vitamin D analogue would provide both anti-inflammatory and keratolytic effects, helping to reduce symptoms and improve the appearance of the skin.

The option **Topical potent corticosteroid** alone may provide some relief from inflammation but would not address the abnormal keratinocyte proliferation seen in psoriasis. Additionally, using a corticosteroid alone increases the risk of skin atrophy and other side effects associated with longterm use.

Refer for ultraviolet light therapy is not the most appropriate next step as per NICE guidelines. Ultraviolet light therapy can be considered if topical treatments have failed or are contraindicated; however, this patient has not yet tried any targeted topical treatments for his psoriasis.

Using only a **Topical vitamin D analogue**, while it may help regulate keratinocyte proliferation, would not provide sufficient anti-inflammatory effects needed to manage this patient's symptoms effectively. As mentioned earlier, combining it with a potent corticosteroid provides better results.

Finally, **Topical coal tar** is an older treatment option for psoriasis that works by reducing inflammation and slowing down skin cell growth. However, it is less commonly used today due to its unpleasant smell, staining properties, and potential carcinogenic risks. It is also less effective than newer treatments such as topical corticosteroids and vitamin D analogues.

Question 84 of 182

A 64-year-old man attends with a severe facial skin rash. He describes recurrent redness on his face. This has been on and off for several years but has recently worsened and the rash is not going away. It is associated with burning and stinging sensations and occasional swelling around the eyes.

On examination, he has an erythematous rash over his cheeks, nasal bridge, and forehead. Within the erythema are numerous large pustules and some pitted scarring with interspersed papules and single plaque. He also has an erythematous rash over his neck and shoulders that is warm to the touch and has the appearance of sunburn.

Given the likely diagnosis, what would be the most appropriate treatment option for this patient?

A. Laser therapy
B. Topical brimonidine gel
C. Topical ivermectin
D. Topical ivermectin and oral doxycycline combination therapy
E. Topical ivermectin and oral doxycycline combination therapy and dermatology referral

D. Topical ivermectin and oral doxycycline combination therapy

Rosacea: a combination of topical ivermectin + oral doxycycline is first-line for patients with severe papules and/or pustules

The most likely diagnosis here is rosacea. Recurrent erythematous facial rash that comes and goes with the distribution described in the stem is typical of rosacea. It is commonly associated with flushing, papules, and pustules, in some cases, rhinophyma can develop. Another clue is that this patient has sunburn - the skin rash in rosacea is commonly exacerbated by sunlight and sunburn indicates significant sun exposure.

Topical ivermectin and oral doxycycline combination therapy is the correct answer. We have a persistent rash with a significant burden of papules and pustules, this would be deemed 'moderate to severe' so a combination of topical ivermectin and oral doxycycline would be advisable.

Topical ivermectin is incorrect. This would be a reasonable first-line option for patients with mild to moderate rash. 'Few' papules/pustules would be classed as 'mild', 'several' would be classed as 'moderate', and 'many' would be classed as 'severe' rosacea according to the National Rosacea Society. The presence of plaque also indicates 'severe' rosacea.

Laser therapy is incorrect. This would be guided by secondary care specialists and does not form part of the first-line management for rosacea, it is predominantly used for patients with extensive telangiectasia which is not a main issue for this patient.

Topical ivermectin and oral doxycycline combination therapy and dermatology referral is incorrect. It would be reasonable to trial optimal management in primary care before onward referral to dermatology specialists.

Topical brimonidine gel is incorrect. This topical alpha-adrenergic agonist is used to manage flushing associated with rosacea. It would not be of benefit in this case as it would not have efficacy in managing the pustules and papules. This patient has pustule and papule-predominant rosacea which is better managed with ivermectin, doxycycline, or alternative options such as metronidazole and topical azelaic acid.

Question 85 of 182

A 50-year-old woman attends your clinic with an itchy rash on her forearms. It constitutes several small violaceous polygonal papules, mainly clustered around the wrist flexors. Her background is notable for left ventricular failure, for which she was recently commenced on 5mg bisoprolol OD.

Bloods are unremarkable.

Which of the following is true in this condition?

A. Scalp lesions are common
B. Oral lesions have a better prognosis
C. Nail involvement is not seen
D. It is a type IV hypersensitivity reaction
E. Exhibits the Koebner phenomenon

E. Exhibits the Koebner phenomenon

Koebner phenomenon - Warts And ALL (warts, autoimmune, AIDS, lichen planus & lichen sclerosis)

This is the typical description of lichen planus. It is possible that bisoprolol has precipitated it - as can thiazide diuretics and anti-malarial drugs. Cutaneous lesions can take up to a year to fully heal and oral lesions can take much longer, with many requiring oral steroids and topical calcineurin inhibitors.

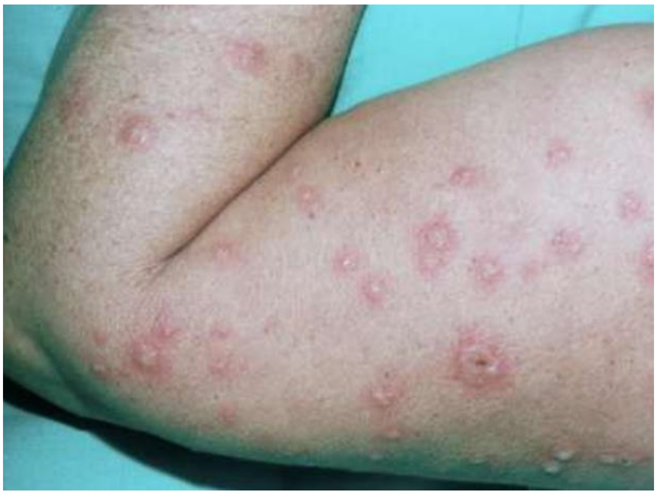
Lichen planus exhibits the Koebner phenomenon, in which minor trauma can cause new lesions. Other conditions that exhibit this phenomenon include viral warts, vitiligo, molluscum contagiosum and lichen sclerosis.

Nail involvement can be seen in lichen planus and is characterised by longitudinal grooving, which can be helpful at differentiating the condition from psoriasis.

Allergic contact dermatitis is a type IV hypersensitivity reaction and would have a more eczematous appearance.

Question 86 of 182

A middle aged man develops a non-pruritic rash after starting allopurinol therapy for gout. The rash develop within 24 hours and started on the back of his hands.



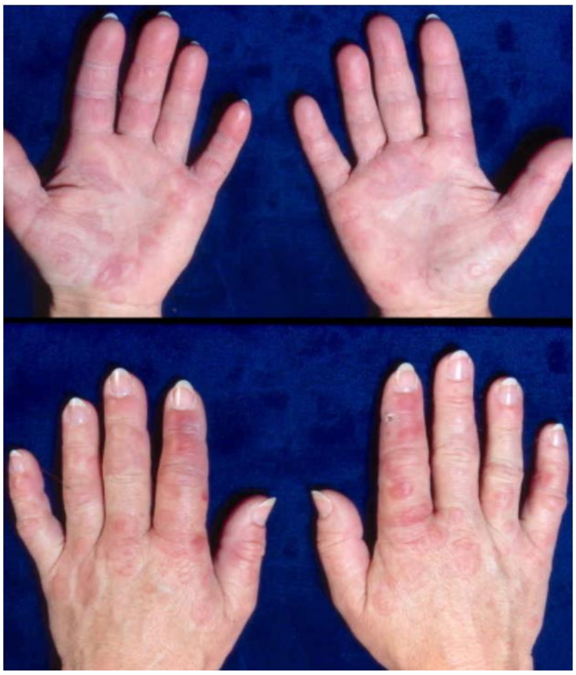
What is the most likely diagnosis?

A. A llopurinol-associated dermatitis
B. Plaque-type tophi
C. Erythema multiforme
D. Erythema marginatum
E. Eosinophilic folliculitis

C. Erythema multiforme

Question 87 of 182

A 40-year-old woman visits her general practitioner with a 2-day history of a new rash that has developed over her hands and forearms. She denies pain or itch and has no history of previous dermatological conditions. Over the last week, she reports feeling generally lethargic with lowgrade fevers and a dry cough. There is no past medical history of note and she takes no allergies. Her rash is examined, as shown below. There is no nail or mucosal involvement.



What is the most likely diagnosis?

A. Erythema marginatum
B. Erythema multiforme
C. Irritant contact dermatitis
D. Lichen planus
E. Plaque psoriasis

B. Erythema multiforme

This patient has multiple erythematous, round lesions on her hands. On closer inspection, some of these lesions have a characteristic appearance of a target lesion with an outermost erythematous ring and paler centre, in keeping with a diagnosis of erythema multiforme. Erythema multiforme is an acute, self-limiting skin eruption most commonly secondary to an infective trigger (e.g. herpes simplex virus or *Mycoplasma pneumoniae*). The history of low-grade fevers and a dry cough further support an infective component of this patient's rash. The rash appears abruptly and affects the upper limbs most often before spreading down towards the trunk. A history of lethargy and lowgrade fevers suggests a recent infection that may have triggered the onset of the rash.

Erythema marginatum is a manifestation of acute rheumatic fever. It is most commonly seen in children and is rare in adults. It presents as annular erythematous macules or papules that spread outwards with central clearance. The lesions are not itchy or painful and may be asymptomatic.

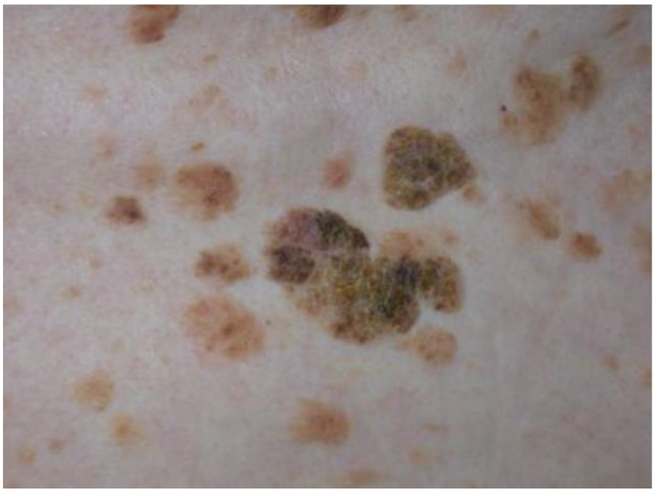
Irritant contact dermatitis is an inflammatory skin condition secondary to contact with irritants to the skin (e.g. detergents). The rash manifests as an erythematous and dry rash that may feel painful or itchy. There is no history of exposure to irritants in this question and the rash does not appear to be dry or flaky which makes irritant contact dermatitis less likely.

Lichen planus is a chronic inflammatory skin condition characterised by purplish papules and plaques commonly found on the front of the wrists. They are often shiny and may have fine white lines covering the surface (Wickham striae). This description does not match the rash in the photograph, making it the incorrect answer.

Plaque psoriasis is a chronic inflammatory skin condition that gives rise to well-defined red plaques with an overlying silver scale. Common features include itch and painful fissures. The rash in the image does not show the presence of erythematous plaques. Furthermore, this patient's rash has had an acute onset which is atypical of psoriasis that has a much slower onset.

Question 88 of 182

A 68-year-old man asks you to 'check his moles' during an admission. He was admitted three days ago with a non-ST elevation myocardial infarction. You look at the following area of skin on his back:



What is the most likely diagnosis?

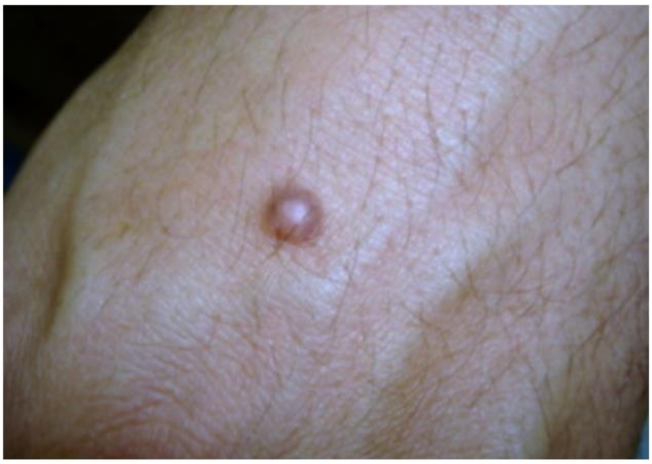
A. Actinic keratosis
B. Benign mole
C. Bowen's disease
D. Malignant melanoma
E. Seborrhoeic keratosis

E. Seborrhoeic keratosis

This lesion has the typical warty, 'stuck-on' appearance of a seborrhoeic keratosis.

Question 89 of 182

A 34-year-old man presents with a small lump on his hand. He says that it has been present for several months. He cannot remember a clear onset, although does remember a thorn-related injury on that hand whilst gardening. On examination, the lump appears as shown below:



It is approximately 8mm in diameter and not tender.

Given the most likely diagnosis, which of the following should happen next?

A. Aspiration
B. Biopsy
C. Cryotherapy
D. Excision

E. Observation

E. Observation

This photo is indicative of a dermatofibroma, commonly found in young people - more so on the legs, rather than on the hands as seen here. It is a solitary, firm papule, usually less than 1cm in diameter. It has a regular border, shape, colour and is symmetrical - there are no concerning features regarding its appearance. In this case, as the lesion is not tender or irritating, it can simply be observed for now and the patient reassured.

Aspiration is inappropriate - dermatofibromas are solid lesions, not fluid-filled.

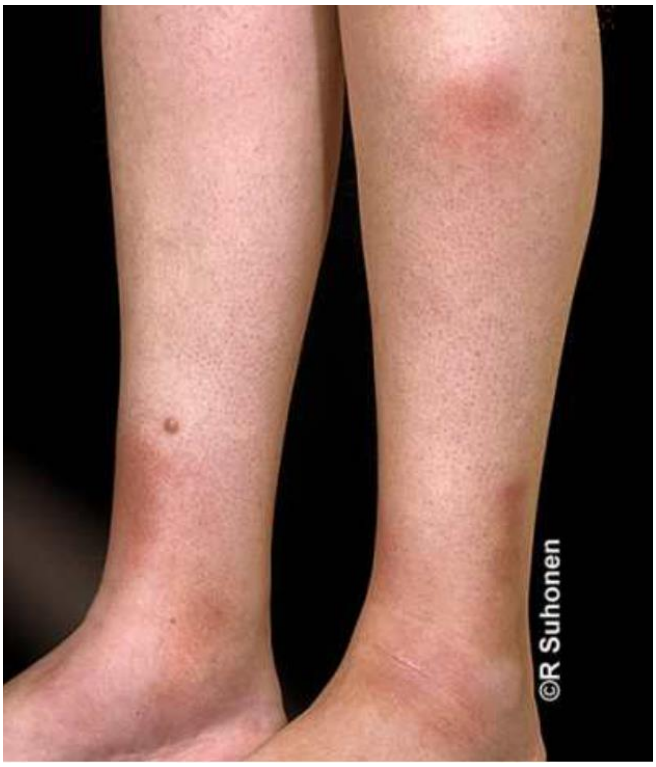
A biopsy may be undertaken if any atypical features trigger concern for a more serious diagnosis. However, in this instance, we can see the lesion looks entirely regular and typical.

Cryotherapy is a suitable option for treatment if the lesion is bothersome, according to the British Association of Dermatologists. In this scenario, there are no troublesome features mentioned and so the patient should be reassured at this stage.

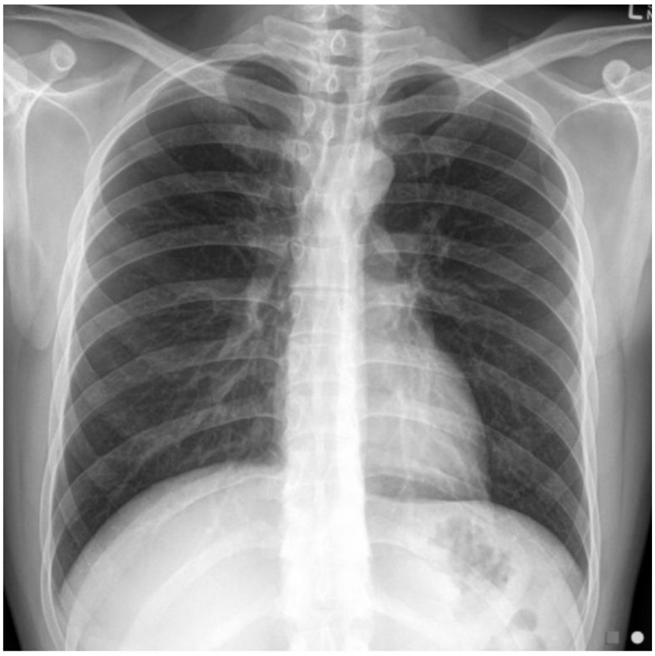
Excision is another suitable option for treatment if bothersome. However, in this scenario, the lesion causes no issues and so should simply be observed for now.

Question 90 of 182

A 30-year-old woman presents with a painful 'rash' on her shins



These have been present for the past 2 weeks. There is no past medical history of note although she had a course of penicillin V for a bout of tonsillitis around a month ago. She also takes Cerazette (a progestogen-only pill) for contraception. A chest x-ray is requested:



What is the most likely cause of the skin lesions?

- A. Lymphoma
- B. Sarcoidosis
- C. Progestogen-only pill
- D. Penicillin
- E. Tuberculosis

D. Penicillin

The likely diagnosis here is erythema nodosum (EN). The chest x-ray is completely normal making penicillin the likely culprit in precipitating skin lesions. The combined oral contraceptive pill is linked to EN rather than the progestogen-only pill.

Question 91 of 182

A 32-year-old man with autism spectrum disorder presents to the general medical clinic. He was referred by his GP for urgent review whilst awaiting a dermatology appointment. The patient has been experiencing a severe eczema flare which has not been controlled despite the use of emollients twice each day, strong topical corticosteroids for five days and non-sedating antihistamines. He has no other medical problems. He has become very concerned about the spreading rash and feels a high level of anxiety with it. On examination, there is spreading erythema from flexural folds on arms and legs.

What is the most appropriate treatment option whilst awaiting dermatology opinion?

- A. Admit for IV hydrocortisone 200mg QDS
- B. Start prednisolone 30mg OD for one week
- C. Start prednisolone 30mg OD long-term with bone protection
- D. Advise for bandaging
- E. Start urea-containing emollient

B. Start prednisolone 30mg OD for one week

Prednisolone treatment for eczema flares needs several weeks of treatment and then tapering off to prevent rebound

The most appropriate action for this patient is for a trial of oral prednisolone. NICE advises one week of 30mg OD whilst awaiting dermatology review, which can be extended as necessary, but this should be done under close review. This would be especially done for people who are suffering psychological distress from severe eczema. Admission is not necessary but would be if the patient was unstable or had eczema herpeticum. Bandaging would be a better approach for weeping or lichenified eczema. and urea-containing emollients are useful when greater hydration is needed for pruritic skin in the absence of severe inflammation.

Question 92 of 182

A 30-year-old lady was admitted with a painful ulcer on her right lower limb. At first, the patient described developing a painful erythematous area which then rapidly broke down to form a painful ulcer. The edges of the ulcer had a purple discolouration. She did recall recently knocking this area whilst riding her bike to work. She had recently been considering seeing her GP as she had been opening her bowels around eight times a day with some mucus and she had noticed some mild abdominal pain. She attributed this to irritable bowel syndrome which she is believed to have had since the age of 20 years.

Her past medical history included migraines and a right deep vein thrombosis after a flight to America. Her father had a family history of diabetes. She had a biopsy of the ulcer which showed heavy neutrophil infiltration.

What is the most likely diagnosis?

A. Pyoderma gangrenosum
B. Erythema nodosum
C. Necrobiosis lipoidica
D. Leishmaniasis
E. Venous ulcer

A. Pyoderma gangrenosum

This patient has Pyoderma gangrenosum with underlying undiagnosed inflammatory bowel disease.

Pyoderma gangrenosum is a rare, non-infectious, inflammatory disorder. It is an uncommon cause of very painful skin ulceration. It may affect any part of the skin, but the lower legs are the most common site. In 50% there is no underlying cause but in 10-15% it is associated with ulcerative colitis or Crohn's disease. Other associations include rheumatoid arthritis, myeloproliferative disorders, malignancy, and Wegener's granulomatosis.

Pyoderma gangrenosum is classified as a neutrophilic dermatosis. Neutrophilic dermatoses are skin conditions characterised by dense infiltration of neutrophils in the affected tissue and this is often seen on biopsy.

Pyoderma gangrenosum usually starts quite suddenly, often at the site of a minor injury as in this patient's case and this is known as pathergy. It may start as a small pustule, red bump or bloodblister. The skin then breaks down resulting in an ulcer which is often painful. The edge of the ulcer is often described as purple, violaceous and undermined.

Diagnosis of Pyoderma gangrenosum can be difficult. Diagnosis is often made by its characteristic appearance, associations with other diseases, the presence of pathergy, histology results and when other diseases have been ruled out. Histology is not specific and can vary depending on time and site of the specimen. It is helpful in ruling out other causes of an ulcer. The ulcer should be swabbed and cultured for micro-organisms and fungi.

Treatment is mainly steroid (0.5-2mg/kg) therapy which is slowly tapered over 1-2 months. Immunosuppressants are useful as a steroid sparing agent and maintenance therapy. These may include ciclosporin, methotrexate, mycophenolate mofetil and cyclophosphamide. Surgery should be postponed until the disease process is controlled on immunosuppression to risk worsening of the disease (pathergy).

Necrobiosis lipoidica is a skin disorder which can affect the shins. This most commonly occurs in patients with insulin dependent diabetics, although it may occur in non-diabetic patients. These lesions are characteristically yellowish brown patches which appear slowly over a few months. The patch is often pale, shiny and has telangiectasia present. They are often painless. Ulceration can occur if the patch has a minor injury to the area.

Erythema nodosum is often described as red lumps that form on the shins, but can also occur on the forearms and thighs. It is an inflammatory disorder affecting subcutaneous fat (panniculitis). Patients commonly develop these in association with bacterial infections (commonly mycoplasma pneumonia), streptococcal throat infections, sarcoidosis, tuberculosis, drugs such as the oral contractive pill, NSAIDS and salicylates, pregnancy and inflammatory bowel disease.

The lesions may appear in a range of sizes and number. The nodules are often painful, warm and red on first appearance. Later they may change to a purple colour and appear more like a bruise. This bruise like colour often evolves over the next 1-2 weeks and then subsides by 3rd to 6th week. The patient may also complain of a fever, arthralgia and malaise.

Question 93 of 182

A 33-year-old lady in her third trimester of her first pregnancy comes to see you regarding a rash she has developed. It started over her abdomen but has now spread over her upper thighs and buttocks. You examine her and see the rash is erythematous, and there are small papules evident which have coalesced into patches in some areas. Around her abdomen, the rash is most marked in areas related to her stretchmarks and around the umbilicus seems to be spared; there are no blisters evident.

What is the most likely diagnosis?

A. Polymorphic eruption of pregnancy
B. Atopic eruption of pregnancy
C. Pemphigoid gestationis
D. Psoriasis
E. Obstetric cholestasis

A. Polymorphic eruption of pregnancy

The answer here is the polymorphic eruption of pregnancy. This is a condition usually occurs in the third trimester, often only in a first pregnancy, and typically there are pruritic urticarial papules that

coalesce into plaques. These often start on the abdomen, particularly related to striae but may also extend elsewhere. Around the umbilicus is typically spared.

Atopic eruption of pregnancy is most common in patients that have eczema. It is most common in the first trimester and it is typically eczematous lesions that break out, unlike in this case. Pemphigoid gestationis is not the answer as it is a very rare condition that is characterised by initial erythematous urticarial papules that progress to form bullae especially over the abdomen. Obstetric cholestasis is not associated with a rash so this is unlikely. The history and lesions are not typical of psoriasis so this is not the diagnosis here.

Question 94 of 182

A 65-year-old Caucasian lady presents with a new skin lesion to the forearm which has been present for 4 weeks. She reports she first noticed it after sustaining a minor abrasion to the area, and it has quickly increased in size since. On examination, there is a 10mm raised, symmetrical nodular lesion, which has a large keratinised central core. The surrounding skin appears normal, with no other similar lesions.

What is the most likely diagnosis?

A. Basal cell carcinoma
B. Actinic keratosis
C. Pyogenic granuloma
D. Molluscum contagiosum
E. Keratoacanthoma

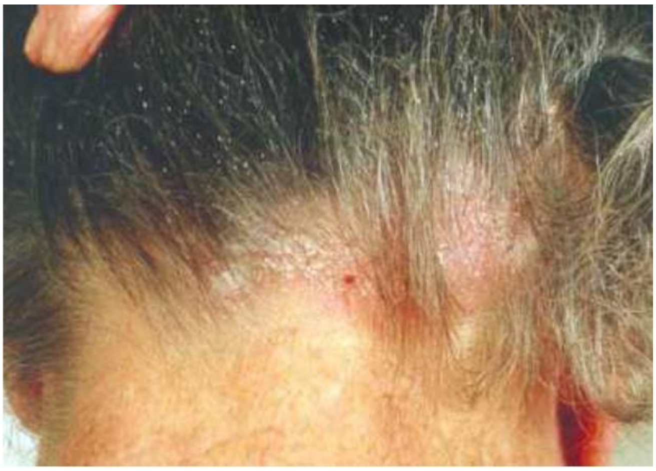
E. Keratoacanthoma

Keratoacanthoma are fast-growing skin lesions which may appear in areas of sun damaged skin. They may also develop after a minor skin injury. They typically start as a small, round fleshy nodule before developing a keratinised central core. Though they may spontaneously regress, they are difficult to distinguish clinically from a squamous cell carcinoma, and therefore should be referred for surgical removal.

Basal cell carcinomas tend to be slow growing lesions. Actinic keratoses tend to be scaly plaques. Pyogenic granuloma is another fast-growing lesion which occur at the site of minor skin injury, but are vascular, bleeding easily. Molluscum contagiosum are round lesions with a small central punctum caused by a pox virus that tend to appear in crops, mainly in children.

Question 95 of 182

A 47-year-old woman complains of an itchy neck and scalp:



This skin condition is though to occur as a result of a reaction to:

A. Trichophyton rubrum
B. Trichophyton schoenleinii
C. Microsporum audouinii
D. Candida albicans
E. Malassezia furfur

E. Malassezia furfur

Seborrhoeic dermatitis - an inflammatory reaction to *Malassezia furfur*

The correct answer to this question is ***Malassezia furfur***. This yeast-like fungus is a part of the normal skin flora but can overgrow in certain conditions, leading to various skin diseases including Pityriasis versicolor, seborrheic dermatitis and dandruff. The image provided shows signs of seborrheic dermatitis on the scalp and neck which is typically associated with an overgrowth of *Malassezia furfur*. It is thought that this organism causes irritation and inflammation in susceptible individuals, leading to the characteristic flaky, itchy skin.

The other options listed are all organisms that can cause skin infections, but they are not typically associated with the symptoms and presentation described in the question.

Trichophyton rubrum is a dermatophyte fungus that causes athlete's foot (tinea pedis), jock itch (tinea cruris) and ringworm (tinea corporis). These conditions present with a well-defined red, scaly rash often accompanied by itching. However, these rashes usually appear on the feet, groin or body rather than the scalp or neck.

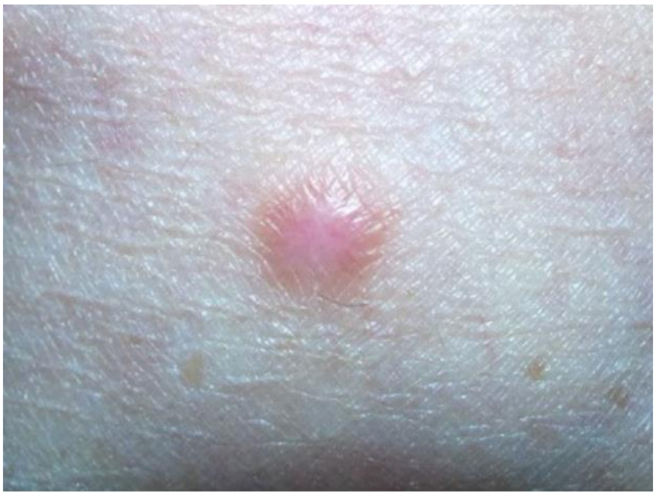
Trichophyton schoenleinii is another dermatophyte fungus, which primarily causes tinea capitis (scalp ringworm). While this condition does affect the scalp, it presents differently from seborrheic dermatitis. Tinea capitis typically causes patchy hair loss and a scaly scalp rather than generalised itching and flaking.

Microsporum audouinii, also a cause of tinea capitis, would similarly result in patchy hair loss rather than widespread itching and flaking. It's important to note that while both *T. schoenleinii* and *M. audouinii* can cause scalp infections, they are more commonly seen in children rather than adults.

Finally, ***Candida albicans***, a type of yeast fungus, can cause various infections including oral thrush and vaginal yeast infections. While it can affect the skin causing candidal intertrigo or diaper rash for example; it's less likely to be responsible for an itchy neck and scalp as described in this scenario.

Question 96 of 182

A 33-year-old woman asks you to look at a 'spot' on her arm that has been present for several months. It has not changed recently and is completely asymptomatic.



What is the most likely diagnosis?

A. Leiomyoma
B. Basal cell carcinoma
C. Amelanotic malignant melanoma
D. Dermatofibroma
E. Nodular prurigo

D. Dermatofibroma

The most likely diagnosis for the lesion presented in the image is a **Dermatofibroma**. Dermatofibromas are common benign skin nodules that often develop after minor skin injuries. They are typically asymptomatic, firm to touch, and can be brownish or purplish in colour. The patient's history of having a 'spot' on her arm for several months without any changes or symptoms is consistent with this diagnosis.

The first option, a **Leiomyoma**, is less likely as these are smooth muscle tumours that usually present as painful lesions when exposed to cold or pressure, which does not match the patient's presentation of an asymptomatic lesion.

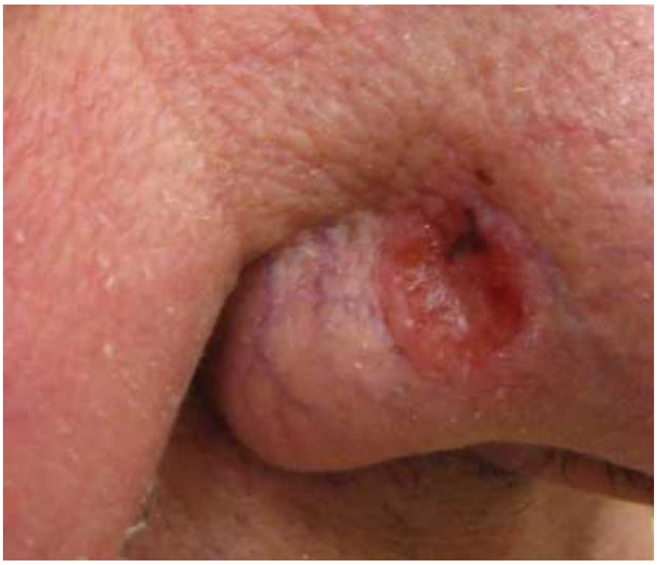
The second option, a **Basal cell carcinoma**, is also unlikely. Although it is one of the most common forms of skin cancer, it usually presents as a pearly nodule with telangiectasia (visible blood vessels) on sun-exposed areas. It may ulcerate and bleed but rarely metastasises. This does not fit with the clinical picture described here.

An **Amelanotic malignant melanoma**, the third option, is a type of skin cancer that lacks pigment. While it can appear similar to the lesion in question, amelanotic melanomas tend to change rapidly over weeks to months and may have irregular borders and surface characteristics. Given this woman's stable lesion over several months without any symptoms, an amelanotic melanoma seems unlikely.

Finally, **Nodular prurigo** could present as multiple intensely itchy nodules predominantly found on extensor surfaces such as arms and legs. However, given that this woman has no mention of itchiness or multiple lesions, nodular prurigo would be an unlikely diagnosis for her condition.

Question 97 of 182

A 62-year-old man presents with a lesion on the right side of his nose. He is unsure how long it has been there.



What is the most likely diagnosis?

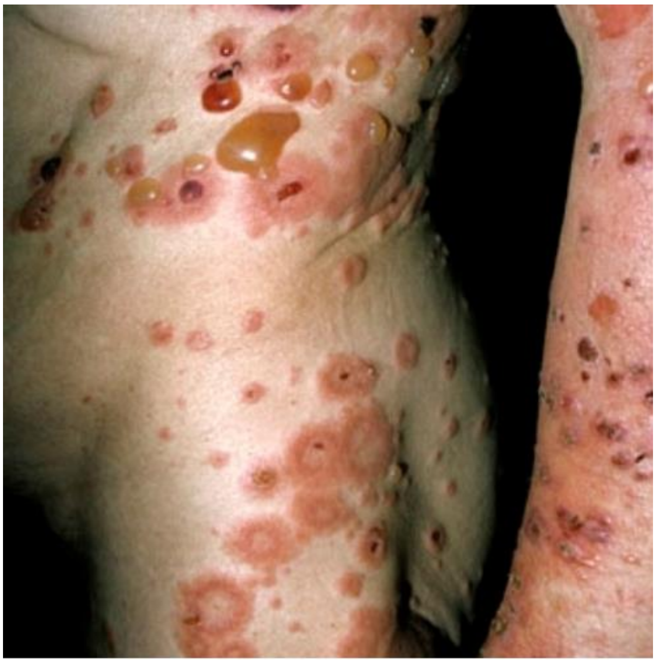
A. Desmoplastic trichoepithelioma
B. Squamous cell carcinoma
C. Impetigo
D. Basal cell carcinoma
E. Actinic keratosis

D. Basal cell carcinoma

The rolled, pearly edges with telangiectasia surrounding a central crater make basal cell carcinoma the most likely diagnosis.

Question 98 of 182

An elderly man develops a generalised pruritic rash:



Which one of the following is the mainstay of treatment?

A. Gluten free diet
B. Phototherapy
C. Oral corticosteroids
D. Long-term oral antibiotics
E. Potent topical corticosteroids

C. Oral corticosteroids

Question 99 of 182

A 59-year-old man with extensive small bowel stricturing Crohn's disease underwent a large small bowel resection. It was complicated by an anastomotic breakdown which required a further resection and jejunostomy formation. He was referred to a local intestinal failure unit and, after a period of assessment, was discharged home on parenteral nutrition. He gained weight and made good progress, although an intermittently high-output stoma persisted. When reviewed in clinic after a year on home parenteral nutrition, he complained of hair loss, a skin rash, and impairment of taste. Examination revealed a superficial scaling erythematous patchy rash that was most prominent in intertriginous areas and periorally.

Which is the most likely nutrient deficiency?

A. Niacin
B. Selenium
C. Vitamin A
D. Vitamin E
E. Zinc

E. Zinc

Zinc deficiency causes a characteristic skin rash (mainly at the intertriginous and perioral areas), alopecia, taste impairment, glucose intolerance, and diarrhoea

Zinc deficiency causes a characteristic skin rash (mainly affecting the intertriginous and perioral areas), alopecia, taste impairment, glucose intolerance, and diarrhoea. In addition to the above symptoms, deficiency also causes acne, visual problems, impaired ability to smell, subtle cognitive and memory changes, and increased susceptibility to respiratory infections. Secondary skin infections may develop with extensive skin rashes. Nail changes, including white spots, bands, lines, or leuconychia, may also be evident. Diarrhoea, stomal and fistula losses increase the loss of zinc.

In contrast to the other options, vitamin A deficiency causes night blindness and eventually xerophthalmia. It can also lead to impaired immune function, cancer, and birth defects. Vitamin E deficiency can lead to problems such as spinocerebellar ataxia and myopathies, and anaemia, due to oxidative damage to red blood cells. Selenium deficiency has been seen in patients with malabsorption and in those on total parenteral nutrition. The effects include myocardial necrosis leading to congestive cardiomyopathy. There is increased susceptibility to infection and can also cause disruption of thyroid metabolism (hypothyroidism). Niacin deficiency causes pellagra, dermatitis, alopecia, oedema, and glossitis. Psychological changes include emotional problems, aggression, insomnia, confusion, and dementia. Neurological signs include weakness, ataxia, paralysis, and peripheral neuritis. Diarrhoea and a dilated cardiomyopathy may also occur.

Question 100 of 182

A 82-year-old man presents to dermatology clinic with changes on his scalp. He is a bald man and has noticed that he has had thickened and abnormal skin. He has a long history of sun exposure from having been living in Spain for five years previously but has now returned to the UK permanently. He has also a history of smoking, but quit 15 years ago, and has also quit drinking. He has been diagnosed with COPD, fractured NOF, gout and hypertension. He normally uses ipratropium and seretide, as well as allopurinol, ramipril, amlodipine and alendronic acid.

On examination of his scalp he has erythematous skin with thickened plaques. It is mildly tender, and looks slightly irritated.

What is the most appropriate treatment?

A. Emollients
B. Topical hydrocortisone
C. Miconazole shampoo
D. Topical 5-FU
E. Salicylate cream

D. Topical 5-FU

Topical 5-FU, imiquimob or difclofenac can be used as first line treatment for actinic keratosis

This patient has a typical presentation of actinic keratoses. Actinic keratoses, also known as solar keratosis, is an area of sun-damaged skin which is considered an early form of cutaneous squamous cell carcinoma. There are several treatment options available, including topical 5-FU, topical diclofenac, cryotherapy and topical imiquimod.

Topical hydrocortisone and emollients are used for eczema. Miconazole shampoo is used for tinea and other infections. Salicylate creams can help with scales, especially in psoriasis.

Question 101 of 182

A 72-year-old man presents to the general medical clinic with his daughter. She is concerned about him because she has developed shingles and is concerned that he may catch shingles from her, and wonders if he could have a shingles vaccination. The patient is well and has no rash. He has a past medical history of type 2 diabetes which is diet controlled, high cholesterol, previous stroke without residual weakness, as well as a fractured hip repaired with hemiarthroplasty. He normally takes aspirin, atorvastatin and paracetamol.

He believes that he has had chicken pox when he was young but does not think that he has ever had shingles or a shingles vaccination.

What is the most appropriate plan?

A. Offer oral aciclovir

B. Offer shingles vaccination

C. Explain that he is not eligible for shingles vaccination and should monitor for symptoms of shingles

D. Arrange admission for IV aciclovir

E. Offer oral corticosteroids

B. Offer shingles vaccination

People aged between 70-79 years old are eligible for shingles vaccine

The patient is not at risk of catching shingles from another person with shingles, but is eligible for shingles vaccination. This is the most appropriate plan available. It could be argued that he should be asked to monitor for symptoms only as he is not of increased risk of shingles, but as he is eligible for vaccination and has inquired this should be offered.

Oral aciclovir can be used to treat acute shingles, whilst ophthalmic shingles would need hospital admission for IV aciclovir or ganciclovir.

Question 1 of 82

A 37-year-old gentleman is referred to the cardiology clinic with a 7-month history of bilateral foot pain. Initially, the pain only occurred towards the end of his daily commute; improving when he sat at his desk, but over the past 3 weeks his symptoms have progressed. The pain is now provoked by walking short distances and has occasionally occurred at rest. He describes being woken by the pain at night, although he is able to obtain relief by standing on the cool tiles in his bathroom. He eventually decided to see his GP when he developed similar pain in his right wrist 10 days ago.

His past medical history is unremarkable. There is no history of hypertension, dyslipidaemia or diabetes. He is a current smoker with a 20 pack year history. He drinks alcohol in moderation.

On examination, both feet are noted to be smooth and hairless. The right dorsalis pedis is difficult to feel and the medial 3 toes are cold and dusky. Urgent angiography is performed and shows a number of distal stenoses in the right limb affecting the anterior and posterior tibial arteries as well as the distal fibular artery. A number of similar stenoses are seen in the contralateral limb with 'corkscrew' collateral formation.

Blood tests are as follows:

Hb	130 g/l	Na +	139 mmol/l
Platelets	322*10 /l 9	K +	4.1 mmol/l
WBC	9.1*10 /l 9	Urea	5.3 mmol/l
Neuts	6.2*10 /l 9	Creatinine	113 µmol/l
Lymphs	2.1*10 /l 9	CRP	19 mg/l
Eosin	0.1*10 /l9		

MPO	negative
PR3	negative
anti-cardiolipin	negative

What is the most likely diagnosis?

A. Peripheral vascular disease
B. Microscopic polyangiitis
C. Takayasu arteritis
D. Thromboangiitis obliterans
E. Polyarteritis nodosa

D. Thromboangiitis obliterans

The patient presents with symptoms of arterial insufficiency; however, his age, lack of vascular risk factors and upper limb involvement should alert you to the fact this may not be a simple case of peripheral vascular disease.

Both microscopic polyangiitis and polyarteritis nodosa are multisystem vasculitic disorders characterised by constitutional symptoms such as weight loss, fever, anorexia, and fatigue. Renal involvement and skin rash are common, as is an association with p-ANCA (MPO) antibodies and elevation of the inflammatory markers.

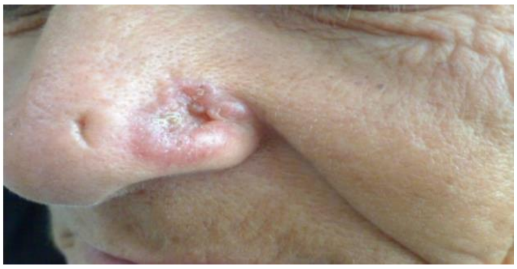
Takayasu arteritis is a large vessel vasculitis that affects the aorta and its branches. It is more common in females and would not typically cause the isolated small and medium vessel stenoses described above.

Thromboangiitis obliterans is an inflammatory disorder of the small to medium-sized arteries and superficial veins in the distal extremities. Segmental arterial inflammation and thrombus formation lead to peripheral limb ischaemia, with the disease often pursuing an aggressive course. The aetiology is unclear but the condition is strongly associated with smoking, and disease progression is closely linked to continued tobacco use. It most commonly affects men aged 20-40.

The diagnosis is made on the basis of a characteristic history and examination, angiographic findings and the exclusion of proximal emboli and vasculitic disorders. Typical findings on angiography include segmental occlusions of the distal arteries in the hands and feet, 'corkscrew' collateral vessels and the lack of widespread atherosclerotic disease. Thromboangiitis obliterans is, therefore, the most appropriate answer to the question.

Question 2 of 82

A 66-year-old man presents to the GP with the following lesion on his nose, which he says has been growing over the course of several years:



He is otherwise well in himself, and takes amlodipine for hypertension.

Given the likely diagnosis, which of the following is the most appropriate, definitive management?

A. Conventional surgery
B. Cryotherapy
C. Fluorouracil
D. Imiquimod
E. Mohs surgery

E. Mohs surgery

The most appropriate option is Mohs surgery. The lesion shown here is a basal cell carcinoma (BCC), which are characterised by slow growth and local invasion. BCCs are typically found on sunexposed sites, such as the nose in this scenario. The picture here depicts the typical features of a BCC - it is a papule with 'pearly, rolled edges' and a depressed, crater-like central area which has followed ulceration. BCCs often have associated telangiectasia, which is not so obvious in this photo. Definitive management involves surgical removal. Mohs surgery is the preferable option for cosmetically challenging locations such as the face, removing very small amounts at a time, thus leaving the smallest scar.

Conventional surgery almost always results in complete cure. However, it should be reserved for areas where tissue sparing is not important, as it is likely to result in significant scarring. For sensitive areas such as the face, Mohs surgery is more appropriate.

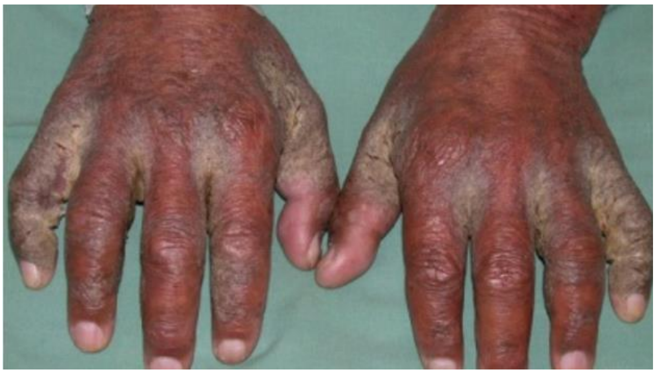
Cryotherapy is a potential option if the BCC is not advanced and does not extend deeply upon palpation. This BCC, however, appears to have ulcerated and left a crater visible in the photo, which suggests it is more advanced. Furthermore, the question asks for 'definitive' management - surgery is the most definitive route for BCCs.

Fluouracil is a topical option, often used when multiple BCCs are present. It can significantly reduce the size and appearance of the lesions over time, with repeated application. It is not, however, the most definitive management.

Imiquimod is another topical option and has more evidence supporting its efficacy than fluouracil. It has a good cure rate, although is not as definitive or successful as surgery.

Question 3 of 82

A 45 year old man with mild learning difficulties and newly diagnosed advanced HIV (CD4 count 65 /mm3) attends A&E from his residential home. He has an intensely itchy rash on his hands, arms, groin, legs and feet. He was recently commenced on Atripla (Emtritcitabine, Tenofavir, Efavirenz) and co-trimoxazole.



There is extensive crusted scaling on his arms, groins and hands. On closer examination there are grey burrow marks between the webs of his fingers and toes. There are itchy nodules extensively over the palms and backs of his hands.

What is the most appropriate treatment?

A. Isolate and apply topical malathion cream for 24 hours
B. Isolate and stop co-trimoxazole
C. Discharge with topical steroids
D. Change his antiretroviral therapy to a second line regimen
E. Isolate and give ivermectin orally

E. Isolate and give ivermectin orally

The correct answer is **Isolate and give ivermectin orally**. This patient has a clinical presentation consistent with scabies, which is caused by the mite *Sarcoptes scabiei*. Immunocompromised patients are at risk of developing crusted scabies (formerly known as Norwegian scabies). It typically begins as poorly defined red patches that then develop into thicker, scaly plaques between the fingers, under the nails, or diffusely over palms and soles. Mites can also potentially collect in nail beds, causing the nail plates to split.

In patients with advanced HIV, such as this patient with a CD4 count of 65/mm3, scabies can be more severe and difficult to treat. Ivermectin is an effective oral treatment for scabies and is particularly useful in cases where topical treatments may be less effective or challenging to apply.

Isolate and apply topical malathion cream for 24 hours would be an appropriate treatment option for uncomplicated scabies in an immunocompetent individual. However, given the severity of this patient's infection and his immunocompromised state due to advanced HIV, oral ivermectin would be a more suitable choice.

Isolate and stop co-trimoxazole is not an appropriate management plan because stopping cotrimoxazole will not address the underlying cause of the rash - scabies. Co-trimoxazole was likely prescribed as prophylaxis against opportunistic infections due to the patient's low CD4 count.

Discharge with topical steroids would not effectively treat the underlying scabies infection. Topical steroids may provide temporary relief from itching but do not eradicate the mites causing the infection.

Change his antiretroviral therapy to a second-line regimen is not indicated in this scenario. There is no evidence to suggest that changing antiretroviral therapy would impact this patient's scabies infection or improve his symptoms. The focus should be on treating the scabies infection with appropriate medication, such as oral ivermectin.

Question 4 of 82

A 52-year-old gentleman presents with a lesion on his tongue. He has noticed feeling 'something odd'in his tongue and noticed a white rash on the side of the tongue which he is unable to wipe away. He has a past medical history of recurrent herpes simplex sores, HIV, hypertension and an ankle fracture requiring surgery. He takes only losartan. On examination, there is a thickly furrowed white lesion on the side of his tongue.

What is the most appropriate treatment that would help resolve the lesion?

A. Antifungal treatment
B. Antiretroviral treatment
C. Long-term antibiotics
D. Oral steroids
E. Surgical resection

B. Antiretroviral treatment

The correct answer is antiretroviral treatment. This patient with is described as having leukoplakia. A white lesion on the side of the tongue is most commonly candida or lichen planus, but the fact that the lesion can't be rubbed off makes leukoplakia a more likely diagnosis, especially in the context of HIV. A biopsy should be done to exclude a squamous cell cancer. Despite the lesion being caused by EBV, treating the underlying HIV causes improvement.

Question 5 of 82

A 55-year-old gentleman was referred to the urgent outpatient dermatology clinic with a flare up of long standing psoriasis. HIs GP had diagnosed him with psoriasis five years ago. It usually affected the extensor surfaces of his elbows and was well controlled with a combination of topical vitamin D analogue and topical corticosteroid. For the last four weeks, however, the rash had become extensive across his chest and back. Despite an intensive trial of topical high potency corticosteroid and further topical vitamin D analogue, his rash had seemed to be worsening, leading to his referral.

His past medical history comprised hypercholesterolaemia and hypertension which were diagnosed at a well man check by his GP three months ago. As he also suffered from palpitations which were thought to be induced by anxiety, he was commenced on propranolol modified release 80mg OD, as well as simvastatin 40mg OD. He also suffered from chronic low back pain for the last few years and used naproxen 500mg BD with lansoprazole 30mg OD for the last five years with good effect. He also admitted to using over the counter aspirin 75 mg OD for the last nine years as his friend was prescribed this by her doctor.

Examination revealed a widespread rash comprising of multiple scaly erythematous discrete plaques across his chest, abdomen, back and extensor surfaces of his elbows and knees. He was otherwise systemically well.

Which is the single most likely causative agent responsible for the deterioration?

A. Propranolol
B. Simvastatin
C. Naproxen
D. Lansoprazole
E. Aspirin

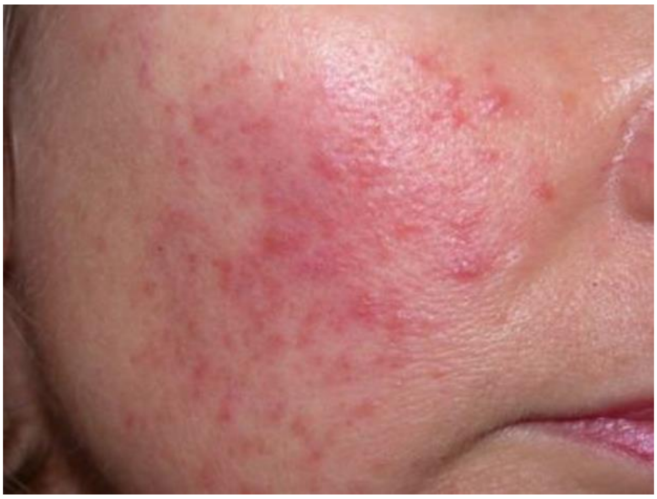
A. Propranolol

Beta-blockers are known to exacerbate plaque psoriasis

Psoriasis may be exacerbated by a variety of causes. With respect to drugs, the most common suspects are lithium and beta blockers. Other agents include antimalarials, ACE inhibitors and non-steroidal anti-inflammatories. The patient was indeed using naproxen and aspirin. However, he was commenced on propranolol recently with a subsequent exacerbation of his psoriasis. The most suitable answer, therefore, is propranolol.

Question 6 of 82

A 49-year-old woman complains of 'spots' on her cheeks. She has tried using her daughter's 'Clearasil' but this has had no effect.



What is the most likely diagnosis?

A. Seborrhoeic dermatitis
B. Systemic lupus erythematous
C. Perioral dermatitis
D. Late-onset acne vulgaris
E. Acne rosacea

E. Acne rosacea

Rosacea features:

- nose, cheeks and forehead
- flushing, erythema, telangiectasia → papules and pustules

The correct answer to this question is **Acne rosacea**. This condition, also known as rosacea, is a common skin disease that often begins with a tendency to blush or flush more easily than other people. The redness can slowly spread beyond the nose and cheeks to the forehead and chin. Even the ears, chest, and back can be red all the time. The image shows typical features of Acne rosacea: erythema (redness) of the cheeks with some papules (small bumps) and pustules. It's important to note that this condition is different from acne, which typically includes blackheads and whiteheads - these are not present in rosacea.

Seborrhoeic dermatitis is an incorrect option because it usually presents with greasy-looking, flaky skin in areas rich in sebaceous glands such as the scalp, eyebrows, sides of the nose, behind the ears and middle of the chest. It does not typically present with spots on cheeks.

Systemic lupus erythematosus (SLE) could potentially cause a malar rash ('butterfly' rash) on cheeks but this would usually also involve the bridge of the nose which isn't mentioned in this case. Additionally, SLE-related rashes are photosensitive and there was no mention of sunlight exacerbating symptoms in this scenario.

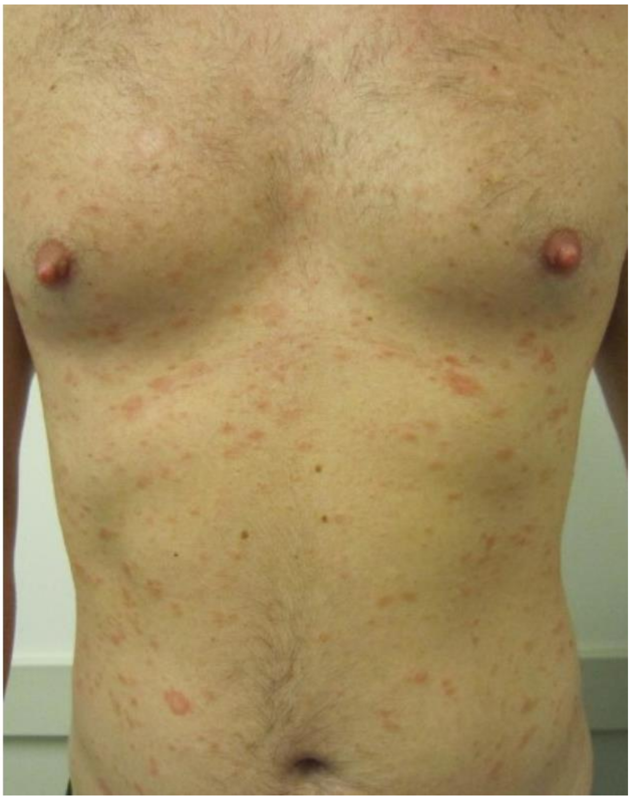
Perioral dermatitis, as its name suggests, tends to occur around the mouth area (although sometimes it can affect areas around the eyes or nose). It presents as groups of itchy or tender small red papules. It's unlikely in this case due to the location being described as 'cheeks'.

Lastly, **Late-onset acne vulgaris**, while possible at any age including adulthood ('late-onset'), would typically include comedones (blackheads & whiteheads), which were not mentioned here. Furthermore, over-the-counter treatments like Clearasil often have some effect on acne vulgaris but none on rosacea according to the patient's history.

Question 7 of 82

A 19-year-old man is referred to the dermatology clinic by his GP with a 2-week history of a rash over his torso. He has tried applying topical emollients but has seen no improvement in his symptoms. The rash is not painful and only mildly itchy. He denies any preceding illness or recent travel and there is no past medical history of note and no known allergies.

On examination, his observations are recorded within normal limits. His rash is examined, as shown below:



Given the likely diagnosis, what is the recommended management for this patient?

A. Oral phenoxymethylpenicillin
B. Reassurance and discharge
C. Topical 1% hydrocortisone
D. Topical ketoconazole
E. UVB phototherapy

B. Reassurance and discharge

Reassurance and discharge is correct. This patient has multiple small, oval-shaped, red plaques that are located on the trunk. Looking closely at these lesions, some appear to have a fine peripheral scale. This patient has a diagnosis of pityriasis rosea, a self-limiting rash that is characterised by a large round 'herald patch', usually found on the chest, abdomen, or back. It mostly affects children and young adults and is thought to be precipitated by bacterial and viral infections (e.g. human herpes virus 6 and 7).

Oral phenoxymethylpenicillin is incorrect. This is used in the treatment of Streptococcal infections (e.g. tonsillitis). Streptococcal infections are associated with guttate psoriasis that presents as an eruption of teardrop-shaped erythematous, scaly lesions. In contrast, the lesions of pityriasis rosea have a fine scale confined to the peripheries of the lesion. Furthermore, given the lack of signs of a streptococcal throat infection, phenoxymethylpenicillin is unlikely to be of any benefit.

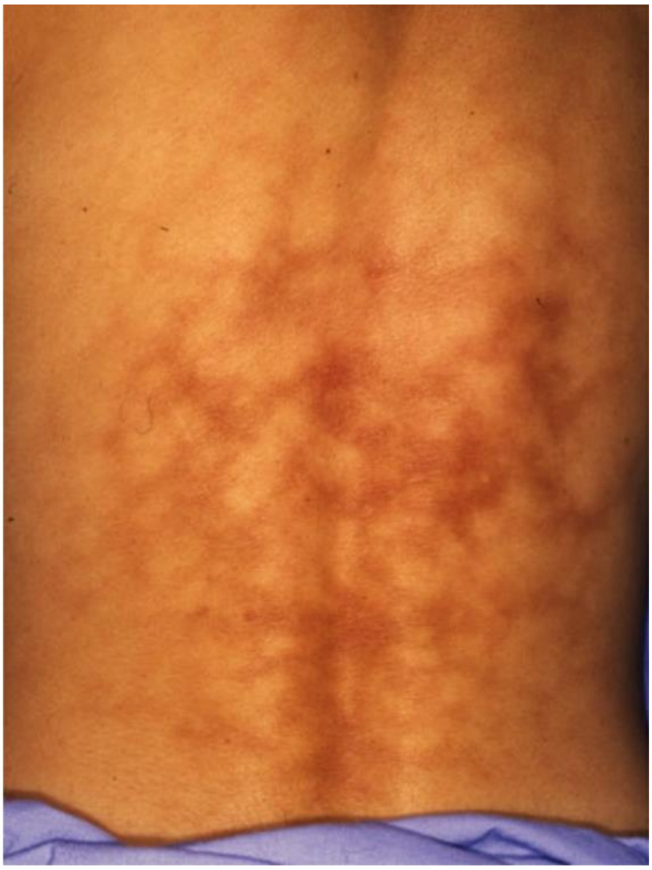
Topical 1% hydrocortisone is incorrect. Topical corticosteroids are usually used in the treatment of eczematous diseases that typically present as a dry, itchy and scaly rash which is not seen here. They can also be used in the management of localised chronic plaque psoriasis. However, it plays no role in the management of pityriasis rosea.

Topical ketoconazole is incorrect. Topical ketoconazole is used in the treatment of fungal infections such as pityriasis versicolor. The rash is mostly seen on the trunk, neck and upper limbs. The patches can vary in colour from pink, brown to pale (typically paler than the surrounding skin). They are usually asymptomatic but can occasionally be itchy. Heat and moisture are risk factors for developing the rash.

UVB phototherapy is incorrect. This is used in the management of chronic plaque psoriasis and guttate psoriasis that cannot be controlled with initial topical management. However, it is not used in the management of pityriasis rosea.

Question 8 of 82

A 34-year-old man with a long history of back pain asks you to have a look at his back. His wife has noticed a rash.



What is the most likely diagnosis?

A. Pityriasis rosea
B. Erythema multiforme
C. Erythema ab igne
D. Pityriasis versicolor
E. Cold urticaria

C. Erythema ab igne

This is a typical erythema ab igne rash. He may have been applying a hot water bottle to his lower back to try and relieve the pain.

Question 9 of 82

A 22-year-old female with a background history of iron deficient anaemia and eczema presents with a skin rash. She takes ferrous sulphate 200mg twice daily but no other medication. On examination, she has an itchy bullous rash consisting of papules and blisters on the knees and elbows. Direct immunofluorescence of a skin biopsy shows immunoglobulin A (IgA) deposition in a granular pattern within the upper dermis.

Which of the following would be the most appropriate treatment?

A. Emollients and topical hydrocortisone
B. Dapsone and a gluten-free diet
C. Oral steroids
D. Emollients and a vitamin D analogue
E. A gluten-free diet and topical hydrocortisone

B. Dapsone and a gluten-free diet

Dermatitis herpetiformis is typically treated with a gluten-free diet and topical dapsone

The clue here is the history of a young person who is iron-deficient and develops a rash which is not typical of eczema or psoriasis. Coeliac disease can often present with iron deficiency and no bowel manifestations and practitioners are lucky if their patient develops the characteristic rash of dermatitis herpetiformis, pointing them to the diagnosis.

Question 10 of 82

A 82-year-old female is brought into hospital after she was witnessed by her carer to 'twitch all 4 limbs' and lose consciousness for about 5 minutes. She is known to have previously had a stroke, resulting in mild right sided weakness 5 years previously and is a type 2 diabetic. She is diagnosed with a first generalised seizure and is prescribed lamotrigine. Four days after her admission, whilst awaiting a new package of care, she complains of a sore throat. The next day, you note peeling skin from her bottom lip and a new erythematous, well-defined macule on her trunk.

What is the most likely diagnosis?

A. Stevens-Johnson syndrome
B. MRSA cellulitis
C. Impetigo
D. Scabies
E. Necrobiosis lipoidica

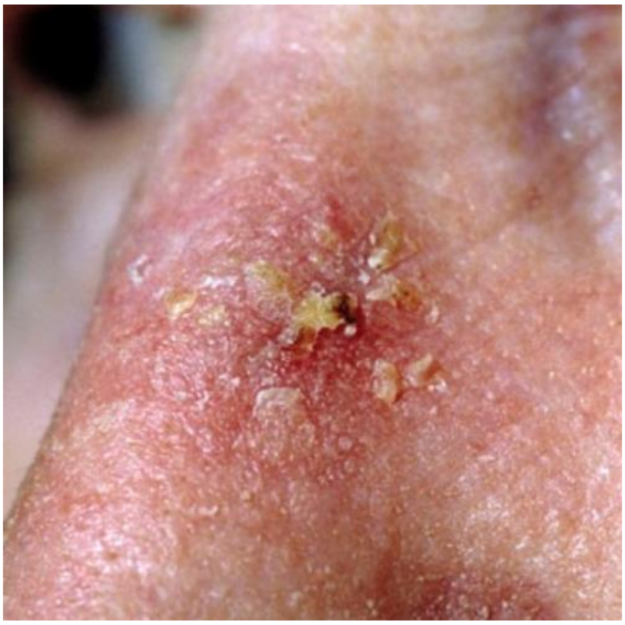
A. Stevens-Johnson syndrome

The clinical syndrome of a sore throat, macular erythematous rash and mucous involvement is suggestive of Stevens-Johnson/ toxic epidermal necrolysis spectrum disorder.

Although Stevens-Johnson syndrome is a classic, well-recognised side effect of lamotrigine, it must be remembered that rashes commonly occur in up to 7% of all patients starting lamotrigine but only a small proportion develop Stevens-Johnson syndrome.

Question 11 of 82

A 67-year-old man presents with a rough, scaly lesion on his nose. He has a long history of sunrelated damage to his skin and has had similar lesions on his temples treated previously:



Which one of the following is he at an increased risk of developing if the lesion is not treated?

A. Pyoderma gangrenosum
B. Seborrhoeic keratosis
C. Malignant melanoma
D. Basal cell carcinoma
E. Squamous cell carcinoma

E. Squamous cell carcinoma

Actinic keratoses are premalignant lesions which may develop into squamous cell carcinomas if not treated.

Question 12 of 82

A 45-year-old woman is admitted with hallucinations. She has a long history of alcohol dependency and is being treated by her GP for hypothyroidism. Further questioning of her husband reveals a 3-month history of diarrhoea, difficulty swallowing and an itchy rash on her arms. Prior to this she had been irritable and suffered from regular bouts of vomiting.

The examination is limited as the patient is aggressive . There is a pigmented, scaly rash on her arms and neck. Heart sounds are normal, her chest is clear and her abdomen soft. Neurological examination reveals generalised weakness.

Blood tests show:

Hb	142 g/l
Platelets	200 * 10 /l9
WBC	5.3 * 10 /l9
Na +	140 mmol/l
K +	4.2 mmol/l
Urea	6 mmol/l
Creatinine	84 µmol/l
TSH	4.0 U/mL
Free T3	3.1 pg/mL
Free T4	1.5 ng/L

What is the most likely diagnosis?

A. Beriberi
B. Thyroxine toxicity
C. Systemic lupus erythematosus (SLE)
D. Pellagra

D. Pellagra

Niacin (B3) deficiency is characterised by dermatitis, diarrhoea and dementia, a condition known as pellagra

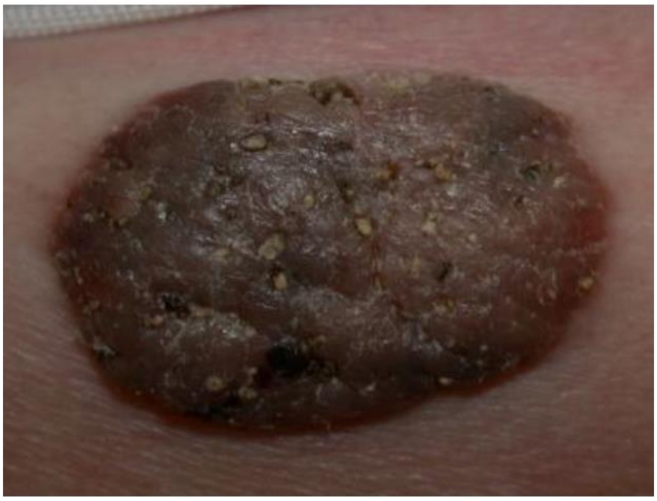
This lady has pellagra, caused by niacin (vitamin B3) deficiency. It occurs primarily in countries such as India and China, in which corn is a staple food. In the UK it is uncommon, and largely seen in patients with alcohol dependency or anorexia nervosa. Niacin is absorbed from foods such as beans and eggs and is also converted from amino acid tryptophan. Pellagra may manifest in carcinoid syndrome, in which tryptophan is converted to serotonin.

Over-treatment or deliberate overdose of thyroxine could cause some of this patient's symptoms, but her thyroid function tests are normal. SLE and Darier's disease both cause a light-sensitive rash, but would not cause the gastrointestinal symptoms. Cognitive disturbance may be seen in SLE.

Pellagra is distinguished from beriberi by the presence of a rash and gastrointestinal symptoms. Like beriberi, it can lead to confusion and memory deficits. Alcoholic patients may, of course, present with both. Other signs include dilated cardiomyopathy, oesophagitis and ataxia.

Question 13 of 82

A 60-year-old man presents with a lesion on his back which has increased in size over the past year. His past medical history includes ischaemic heart disease and spinal stenosis. There is no personal or family history of skin cancer.



What is the most likely diagnosis?

A. Malignant melanoma
B. Seborrhoeic keratosis
C. Bowen's disease
D. Dermatosis papulosa nigra
E. Actinic keratosis

B. Seborrhoeic keratosis

Question 14 of 82

A 36-year-old presents with a 4 months history of episodic generalised abdominal discomfort, nausea and vomiting. He reports no gastrointestinal symptoms prior to this period. He denies eating any unusual foods or recent travel within the past 2 years. His diarrhoea appears to be watery and he denies any blood stools. Eight months ago, he underwent a bone densimetry scan after breaking his hip and both femurs playing football, revealing a T-score of <-2.8. On examination, you notice brown papules, measuring 2 to 3 mm on each lower leg. When you press along the lesion and the surrounding skin, you note a red raised line is elicited. Abdominal examination reveals hepatosplenomegaly. His admission blood tests are as follows:

Hb	98 g/l
Platelets	195 * 10 /l9
WBC	4.9 * 10 /l9
ESR	70 mm/hr
Na +	138 mmol/l
K +	4.6 mmol/l
Adjusted calcium	2.81 mmol/l
Phosphate	1.3 mmol/l
CRP	22 mg/l
Serum tryptase 379 ng/ml (< 20)	
Complement	normal
C1 inhibitor	normal
Serum gastrin	normal
24 hour urinary 5-HIAA	normal

What is the most likely unifying diagnosis?

A. Zollinger-Ellison syndrome
B. Carcinoid syndrome
C. Hereditary angioedema
D. Cutaneous mastocytosis
E. Systemic mastocytosis

E . Systemic mastocytosis

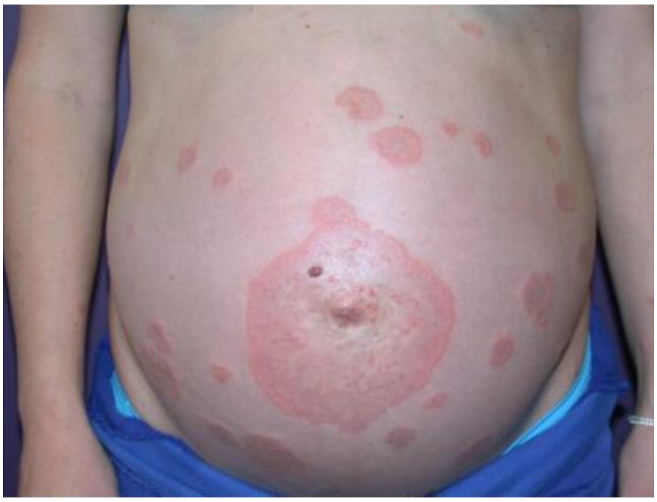
Localised erythema and urticaria on scratching, rubbing or stroking of the skin as described is classically known as Darier's sign, a manifestation of mast cell mediator release following physical irritation, classically seen in mastocytosis, a disorder of excessive mast cells. The next distinction is whether this represents symptoms limited to the skin or involves extracutaneous sites, hence the classification of cutaneous and systemic mastocytosis respectively. Systemic symptoms are a result of mast cell mediator and IgE release, which can cause gastrointestinal, neuropsychiatric and anaphylactic symptoms. A mild anaemia, as in this patient, is common in half of all systemic mastocytosis patients. Infiltration of spleen, liver and lymph nodes are noted in physical examinations as organomegaly. Excessive bleeding can also be an issue as a result of excess heparin release from mast cells. Osteoporosis in young patients should make you suspicious of bone marrow involvement.

Diagnosis of cutaneous mastocytosis is made upon signs and symptoms alone. Systemic mastocytosis is diagnosed according to a WHO criteria of major and minor symptoms: the major criterion involves the presence of mast cells in extracutaneous organs such as the liver and bone marrow, while minor criteria relies on serum tryptase over 20, surface markers of mast cells, atypical bone marrow mast cell morphology and a specific kit mutation. In the case of this patient, serum tryptase is significantly elevated in association with systemic involvement.

An important differential is that of hereditary angioedema, caused by a deficiency of C1 inhibitor deficiency and transient painful episodes of skin, laryngeal and bowel oedema. In this case, C1 inhibitor and complement are normal. Similarly, carcinoid syndrome should produce increased levels of urinary 24 hour 5HIAA secondary to excessive serotonin release. Lastly, Zollinger-Ellison syndrome only rarely presents with diarrhoea. Serum tryptase is almost always normal with elevated gastrin levels.

Question 15 of 82

A 27-year-old woman who is 34 weeks pregnant presents with an itchy, blistering rash over her abdomen. Initially she had a red rash around her umbilicus but it later spread.



What is the most likely diagnosis?

A. Pemphigoid gestationis
B. Seborrhoeic dermatitis
C. Polymorphic eruption of pregnancy
D. HELLP syndrome
E. Pompholyx

A. Pemphigoid gestationis

The correct diagnosis for this patient is **Pemphigoid gestationis**. This condition, also known as Herpes gestationis, is a rare autoimmune blistering disorder that occurs in pregnancy. It typically presents during the second or third trimester with pruritic, urticarial plaques and tense vesicles or bullae. The rash often starts around the umbilicus and then spreads to other parts of the body, which matches the description provided in the question. There may be remissions and exacerbations throughout pregnancy, with flares often occurring at delivery.

Seborrhoeic dermatitis is an incorrect answer. While it can cause an itchy rash, it typically affects areas of the body rich in sebaceous glands such as the scalp, eyebrows, sides of the nose and behind ears rather than the abdomen. Moreover, its presentation does not include blisters.

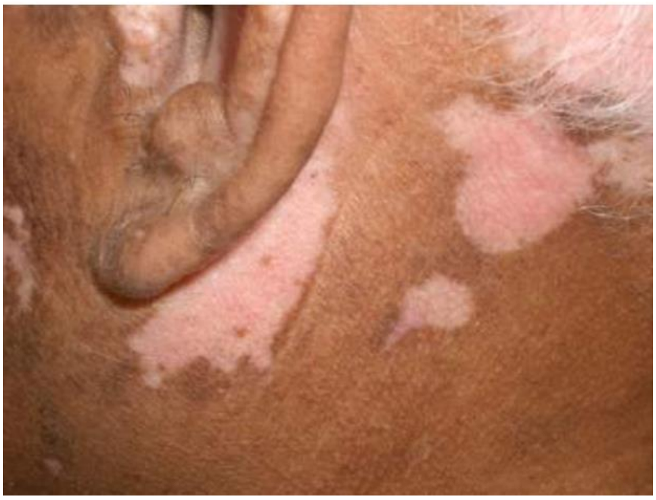
Polymorphic eruption of pregnancy, formerly known as PUPPP (pruritic urticarial papules and plaques of pregnancy), is another incorrect option. Although it does present with intense itching during late pregnancy, its distinguishing feature is that it usually spares the umbilical area - unlike in this case where the rash started from around the umbilicus.

HELLP syndrome (Hemolysis Elevated Liver enzymes Low Platelet count) is also not correct. HELLP syndrome is a severe form of pre-eclampsia characterised by haemolysis, elevated liver enzymes and low platelet count. It may sometimes present with epigastric or right upper quadrant pain due to liver swelling but a blistering rash would not be a typical presentation.

Lastly, **Pompholyx**, also known as dyshidrotic eczema, primarily affects hands and feet causing small blisters along the sides of fingers or toes as well as palms or soles - not the abdomen or around the umbilicus which makes it an unlikely diagnosis for this case scenario.

Question 16 of 82

Please look at the image below:



Which one of the following is LEAST likely to have a role in the management of this patient?

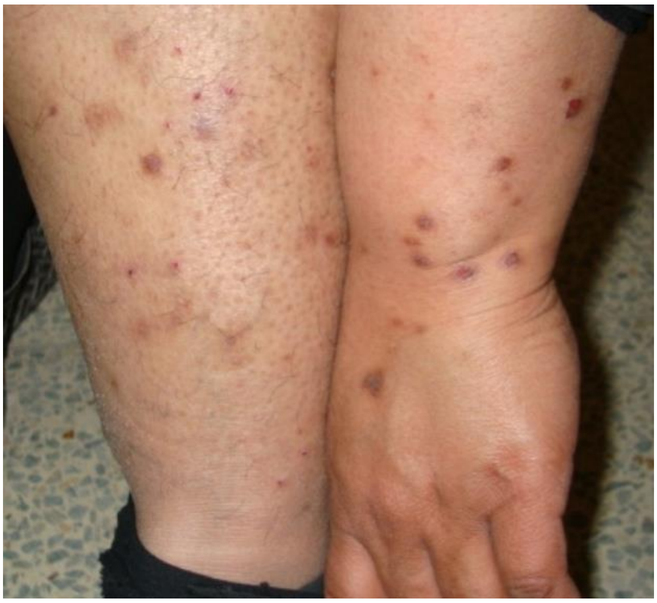
A. Sun block
B. Topical tacrolimus
C. Phototherapy
D. Topical ketoconazole
E. Topical corticosteroids

D. Topical ketoconazole

There is no role for antifungal therapy in vitiligo.

Question 17 of 82

A 63-year-old woman presents with an itchy rash on her arms and legs and also mentions that she has a white discolouration on her tongue and cheeks. The rash has been present for the last 2 months and over-the-counter emollients have not helped. This woman works in a bakery and wears gloves but she took the last 2 weeks off work. Also, she has been in a stable relationship since her divorce 10 years ago.



What is the most likely diagnosis?

A. Eczema
B. Lichen planus
C. Lichen simplex
D. Prurigo nodularis
E. Syphilis

B. Lichen planus

The image shows a typical lichen planus rash. The image shows a plaque-like erythematous rash distributed on the hand, arm, and leg. There are some small areas of desquamation where the skin appears peeled and exposes the dermal layer (most prominently here on the proximal arm). Lichen planus can also be described as having shiny red or purple papules although it is difficult to tell if any lesions are raised in this image.

Lichen planus - this is the correct answer. This typically affects people over 40 years old and about 50% of cases affect the oral mucosa. Fine white or grey lines or dots may be seen overlying the rash and oral mucosal lesions, otherwise named Wickham's striae. The cause is not well understood but it is thought to be a T-cell-mediated immune disorder. The diagnosis is mainly clinical but a skin biopsy will show globular deposits and T-cell infiltration. Most cases resolve spontaneously within a year but topical steroids can help with symptoms.

Eczema - this is incorrect as eczema can appear with excoriations and lichenification, there is often more involvement on the flexor surfaces. Topical steroids and emollients are the treatment. It might be expected that emollient use or staying away from working at the bakery would help (contact allergen) instead of the history in the stem.

Lichen simplex - this is incorrect. In lichen simplex, one or more plaques with lichenification will appear in an area that is heavily scratched. The itch/scratch cycle perpetuates the rash. Topical steroids and scratch avoidance are the treatment.

Prurigo nodularis - this is incorrect as this will appear as pruritic nodules often on the extremities. This is a chronic skin condition characterised by very itchy firm lumps. It can appear anywhere on the body but is most common in a symmetrical distribution on the arms, legs, back, and torso. There is a correlation between prurigo nodularis with atopy and internal disease.

Syphilis - this is incorrect. Syphilis is caused by the spirochete *Treponema pallidum*. It is primarily sexually transmitted and can cause many signs and symptoms similar to other diseases and so is nicknamed 'the great imitator'. This kind of rash is more typical of secondary infection which follows an incubation period of 10-90 days. One would expect other symptoms to accompany this stage like fever, headache, malaise, myalgia, arthralgia, and lymphadenopathy. There is no likely history of any sexual transmission or other systemic symptoms in the stem, making this answer less likely.

Question 18 of 82

A 57-year-old man has returned to the emergency department after struggling to cope with pain from shingles, diagnosed two days ago. He was started on aciclovir, paracetamol and codeine, but was still struggling and therefore yesterday was started on neuropathic analgesia with gabapentin, but has found this to be ineffective. He has a past medical history of oesophagitis, atrial fibrillations and gout. He normally takes omeprazole, warfarin, bisoprolol and allopurinol.

What would be the most appropriate plan?

A. Admit for IV aciclovir
B. Admit for IV ganciclovir
C. Stop all opiates
D. Add an NSAID
E. Add prednisolone

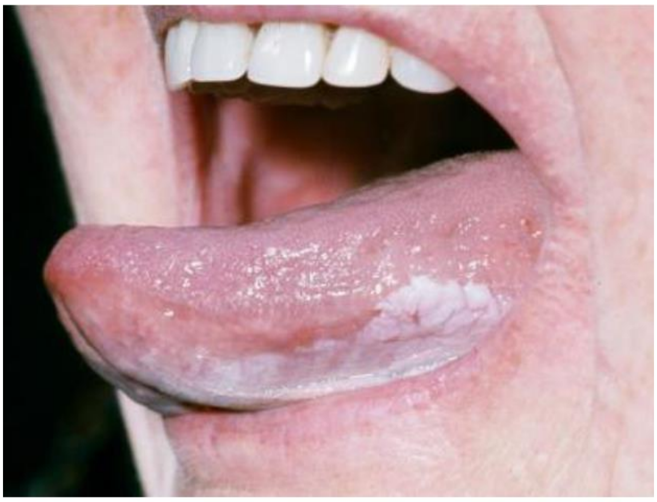
E. Add prednisolone

Corticosteroids can be used in refractory pain in shingles if simple analgesia and neuropathic analgesia do not help, but only for acute shingles

This patient has been suffering with severe pain due to acute shingles despite management with paracetamol, codeine and neuropathic agent. Adding an NSAID would be inappropriate due to this history of gastritis, whilst IV antiviral treatment would not make any difference in regards to the pain management. NICE suggests prednisolone can be used to help in the management of pain in acute shingles, and this can be offered for this patient.

Question 19 of 82

A 52-year-old man asks you to look at the side of his tongue. The white patches have been present for the past few months and are asymptomatic. He is a smoker who is known to have type 2 diabetes mellitus.



What is the most likely diagnosis?

A. Candidiasis
B. Squamous cell carcinoma
C. Lichen sclerosus
D. Oral leukoplakia
E. Geographic tongue

D. Oral leukoplakia

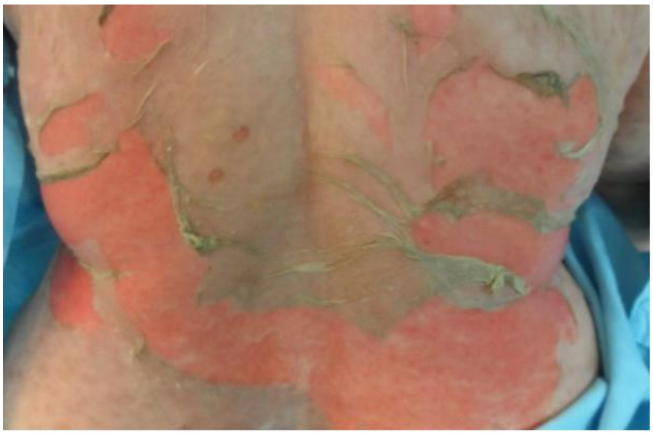
The asymptomatic and prolonged nature of the symptoms goes against a diagnosis of candidiasis. Lichen planus (rather then sclerosus) is a differential diagnosis but tends to have a slightly different appearance - typically a symmetrical white lace-like pattern on the buccal mucosa. Squamous cell carcinoma is not the most likely diagnosis as only around 1% of oral leukoplakias become malignant.

This patient should be referred for a biopsy to confirm the diagnosis.

Question 20 of 82

A 42-year-old female originally presents to her GP with a small skin lesion on her forearm after being bitten by her new kitten 4 days previous. There was some redness with minimal discharge at the site, but the patient denied any systemic symptoms. Her GP send off a swab of the area and started the patient on a course of amoxicillin.

Initial the patient felt the wound appeared to be healing but after a few further days, she became systemically unwell with fever, sweating and feeling weak. She noticed her skin appeared to be peeling all over her body (see below) and her considered family rushed her into hospital. On review of her GP records, the wound swab culture grew *Staphylococcal aureus*.



Other than supportive care what other management has been shown to have the most benefit for this patient's condition long term?

- A. Corticosteroids
- B. IV antibiotics
- C. Intravenous immunoglobulin
- D. Skin graft
- E. Surgical debridement

C. Intravenous immunoglobulin

This patient has presented with toxic epidermal necrolysis (TEN) most likely secondary to

amoxicillin started by her GP. The specific pathophysiology of TEN is unknown but it is thought to be due to an immune response and a drug precipitate is attributed to 80-95% of cases. Patients are systemically unwell and the epidermis separates resulting in a peeling like appearance as seen in this case. Management involves stopping the precipitating drug and supportive care, often requiring intensive care. Recent research has shown intravenous immunoglobulin therapy is effective in reducing mortality and morbidity and so is commonly used as first-line management. Other treatments options including immunosuppressive agents and plasmapheresis have also be used but are normally second-line.

Although the patient had a previous skin infection it is not the cause of their acute deterioration. The rapid onset following starting a new drug (in this case an antibiotic) is in keeping with a TEN reaction. IV antibiotics would be required in the differential diagnosis of staphylococcal scaled skin syndrome (SSSS) however this is less likely in this case despite the patients confirmed *Staphylococcal aureus* infection. SSSS is rarely seen in adults and is less severe than TEN. Also in SSSS the cleavage site is the intraepidermal as opposed to the TEN which involves necrosis of the full epidermal layer as seen in this patient. Antibiotics are sometimes used prophylactically in TEN and are often required later as patients are at high risk of infection, but they are not required initially.

Immunosuppressive medication such as corticosteroids have been used in TEN but intravenous immunoglobulin is more effective and therefore is commonly used as first-line.

Skin grafts may be required much later in the course of TEN to promote healing if there is extensive skin disruption however it is not required in all cases and the benefits on mortality and morbidity are unclear.

Surgical debridement is not commonly required as TEN is not due to an infection. Secondary infection can occur but again debridement is rarely required.

Question 21 of 82

An 18-year-old male university student presents to the emergency department due to itching. He has been experiencing worsening itching of his hands and arms after two months of living in student accommodation with two other students. He has found the itching to be progressively worse and not manageable with over the counter chlorphenamine. He has had no other medical problems and takes no regular medications. He is an economics student and has no exposure to any chemicals. On examination there are linear burrows on the sides of some of his fingers on both right and left sides. In additions, there is evidence of lots of scratching, but does not appear infected. He is prescribed permethrin 5% as treatment.

What advise should be given in its application?

- A. Apply once to whole body
- B. Apply once to whole body and repeat in one week
- C. Apply once to whole body and repeat in one week and advise household contacts to dosame
- D. Apply daily to whole body for one week
- E. Apply daily to whole body for one week and advise household contacts to do same

C. Apply once to whole body and repeat in one week and advise household contacts to dosame

This patient likely has scabies. Scabies is more common in unkempt environments, which can occur in student housing. The diagnosis is strongly supported by severe, persisting pruritus in the presence of linear burrows. Treatment is with permethrin 5% but care must be given to ensure that the patient understands the treatment protocol or treatment failure is likely.

In scabies, advise all close contacts to be treated as well as the patient twice, with applications one week apart

Question 22 of 82

A 32-year-old lady attends with a facial rash for several weeks. She has an erythematous rash which looks greasy and has a fine scale over her face affecting her cheeks, nasolabial folds, eyebrows, nasal bridge and scalp.

What is the most likely diagnosis?

- A. Acne rosacea
- B. Systemic lupus erythematous (SLE)
- C. Eczema
- D. Seborrhoeic dermatitis
- E. Psoriasis

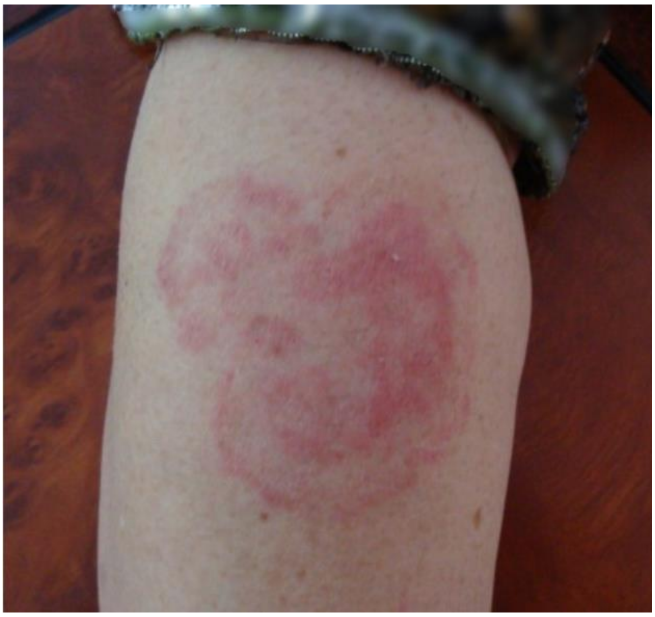
D. Seborrhoeic dermatitis

An itchy rash affecting the face and scalp distribution is commonly caused by seborrhoeic dermatitis

The description describes seborrhoeic dermatitis. The involvement of the nasolabial folds differentiates it from acne rosacea which typically spares this area and tends to include telangiectasia and pustules.

Question 23 of 82

A 26-year-old man presents with a lesion on his leg that he thinks has been present for a couple of weeks. It is somewhat itchy. He is otherwise fit and well, has no significant past medical history and takes no regular medications. The rash is shown below:



Given the likely diagnosis, what is the definitive management?

- A. Oral doxycycline
- B. Topical emollient
- C. Topical fusidic acid
- D. Topical hydrocortisone
- E. Topical ketoconazole

E. Topical ketoconazole

The rash here is characteristic of tinea corporis, colloquially known as ringworm. This is a fungal infection affecting the trunk and limbs. It has a characteristic appearance of a circular red patch with a raised edge and central hyperpigmentation as seen here, leading to the 'ring' appearance. Given its fungal nature, the most appropriate treatment is therefore topical ketoconazole. If the rash were significantly widespread, an oral antifungal agent may be more appropriate.

Oral doxycycline would be an appropriate treatment for Lyme disease. There was no history of a tick bite in this question, and the lesions are much more indicative of ringworm than of erythema migrans, which would instead present with a red papule or macule that gradually enlarges to form a bull's eye-like ring.

Topical emollient is insufficient. Whilst this may relieve the itch associated with the rash, it will not treat the fungal cause of ringworm.

Topical fusidic acid is inappropriate. This is an antibiotic and would be used for bacterial infections, such as mild impetigo or a mildly infected wound. It would not help in treating ringworm.

Topical hydrocortisone may be used short-term to relieve inflammation. The lesion in this photo does not look particularly inflamed. It is not the definitive management for this condition; an antifungal cream is required. In fact, prolonged use of steroid creams can actually worsen fungal rashes.

Question 24 of 82

A 24-year-old woman presents with new skin lesions.

She was the recipient of a renal transplant a year ago following IgA nephropathy. After several modifications to her immunosuppressive therapy, her graft function is stable with an eGFR of 80ml/min/1.73m². She also has a past history of hypothyroidism for which she takes levothyroxine.

She had first noticed the lesions 3 months ago. She had noted them a few years previously but on that occasion, they had disappeared of their own accord. They are not itchy.

On examination she has well demarcated depigmented patches on her arm, her shoulders and her upper back; the lesions shine a yellow-green colour under Woods lamp.

What is the most likely diagnosis?

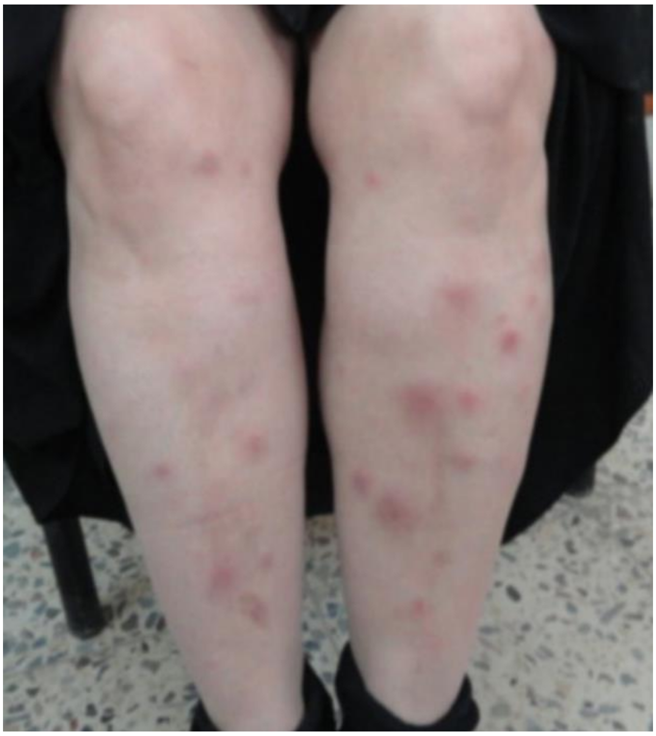
- A. Vitiligo
- B. Pityriasis alba
- C. Idiopathic guttate hypomelanosis
- D. Pityriasis versicolor
- E. Seborrhoeic dermatitis

D. Pityriasis versicolor

The yellow-green fluorescence under Woods lamp is the key factor here; none of the other answers fluoresces in this way. Hence vitiligo is not correct and the history of hypothyroidism (an autoimmune illness that may be associated with vitiligo) is irrelevant. The description is not consistent with seborrhoeic dermatitis, and the distribution of the rash is not consistent with either pityriasis alba or seborrhoeic dermatitis which typically affect the face.

Question 25 of 82

A 33-year-old woman presents with several days of tender lesions overlying her shins. She feels generally well in herself, aside from feeling slightly feverish. She has a past medical history of depression, anxiety, acid reflux, and ulcerative colitis, including a recent exacerbation that required oral prednisolone. She recently completed a course of doxycycline for a chest infection. Her regular medications include sertraline, azathioprine, and the combined oral contraceptive pill. Her rash appears as follows:



Given the likely diagnosis, which of the following is the most likely cause?

A. Azathioprine
B. Combined oral contraceptive pill
C. Doxycycline
D. Prednisolone
E. Sertraline

B. Combined oral contraceptive pill

The diagnosis here is erythema nodosum. This patient has the typical appearance of multiple erythematous, nodular lesions over the shins which appear inflamed. They are also described as being tender. These usually resolve within 6 weeks without scarring. There are several causes, including some medications - of the list above, the combined oral contraceptive pill is most strongly associated with the development of erythema nodosum.

Erythema nodosum is associated with inflammatory bowel disease. There have been a few case studies of azathioprine hypersensitivity being one possible explanation for this association. However, the combined oral contraceptive pill remains a much more likely option.

Doxycycline is not known to trigger erythema nodosum. Many antibiotics are, however, implicated in the condition, including penicillins and sulphonamides.

Prednisolone is not linked to the development of erythema nodosum. It is sometimes used to aid the resolution of the condition if symptoms persist.

Sertraline is a selective serotonin reuptake inhibitor used for anxiety and depression. Newer antidepressants are rarely linked to erythema nodosum, with fluoxetine, paroxetine, and venlafaxine being more strongly implicated than sertraline (although still relatively rarely linked compared to the combined pill).

Question 26 of 82

A 17-year-old male presents with a new skin condition which his mum noticed when they were on holiday in Spain. On examination, he has skin type V, with multiple small patches of depigmentation to the upper back. The patches appear mildly flaky but they are asymptomatic. He is usually well and has never had this condition before.

Which of the following is the most likely diagnosis?

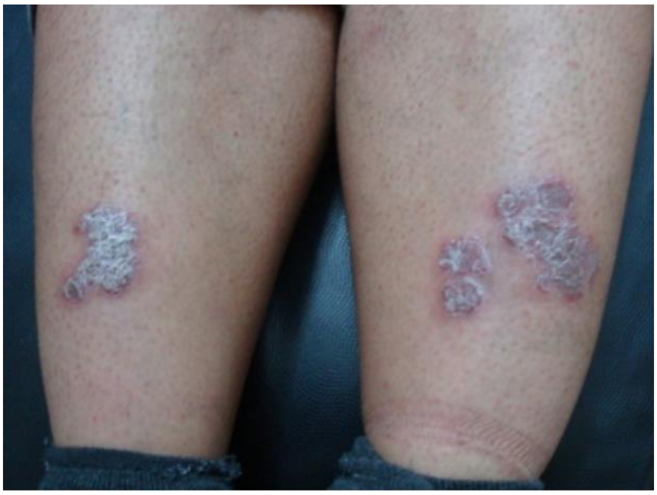
A. Pityriasis rosea
B. Atopic eczema
C. Vitiligo
D. Guttate psoriasis
E. Pityriasis versicolor

E. Pityriasis versicolor

This is a typical history of pityriasis versicolor, a skin condition caused by an overgrowth of Malassezia yeast. It is most common in young people, especially males. It causes multiple patches of skin discoloration, mainly to the trunk. The patches may appear pale brown, pink, or may appear depigmented especially in patients with dark skin. They may also be mildly flaky and itchy. The condition can often present after spending time in sunny, humid environments. It is treated with topical antifungals eg. ketoconazole shampoo.

Question 27 of 82

A 32-year-old woman presents with a rash over her shins. It has gradually been getting worse, despite moisturising. The rash is shown below:



She is otherwise fit and well and has no significant past medical history. She takes the combined oral contraceptive pill and uses a salbutamol inhaler for asthma.

Which of the following is the most likely diagnosis?

A. Chronic plaque psoriasis
B. Discoid lupus
C. Erythema nodosum
D. Lichen planus
E. Tinea corporis

A. Chronic plaque psoriasis

The correct answer is chronic plaque psoriasis, which is the most common presentation of psoriasis. The photo demonstrates a typical example of this condition - erythematous plaques covered with a silvery-white scale. There is a clear delineation between the plaques and the surrounding normal skin. What is slightly atypical about this photo is the location - generally, it presents on extensor surfaces such as elbows and knees. These lesions appear to be on the shins.

Discoid lupus would appear somewhat similar, but lesions would be less scaly and more regularly shaped. It is localised to above the neck in 80% of patients, or generalised across the body in the remaining 20% - unlike this presentation on the shins.

Erythema nodosum is inflammation of subcutaneous fat, presenting as tender red nodules on the shins - whilst the location here is correct, the appearance is not. The combined oral contraceptive pill is a known causative factor but, although this patient is taking the pill, the appearance is far more likely to be psoriasis.

Lichen planus is characterised by shiny, flat-topped, violaceous papules which are often clustered around the wrists and ankles. Rather than appearing scaly as in this photo, the papules are crossed by fine white lines called Wickham striae.

Tinea corporis is a fungal infection of the skin, affecting any part of the body. It is colloquially known as ringworm. Its appearance differs from the photo here - rather than scaly plaques, it has a red, ring-shaped appearance with central hypopigmentation.

Question 28 of 82

A 54-year-old female presented to the dermatology clinic with a history of worsening itchy rash. She has a history of psoriasis which had been quite well controlled but had worsened significantly in the last week. On examination, there are multiple well-demarcated oval, red/pink elevated lesions with overlying silvery scales over her elbows, knees, legs and scalp. She revealed that her GP had started her on a new tablet 2 weeks ago.

Which of the following drugs is likely to have resulted in the above presentation?

A. Citalopram
B. Lithium
C. Omeprazole
D. Ranitidine
E. Cimetidine

B. Lithium

Psoriasis: lithium may trigger an exacerbation

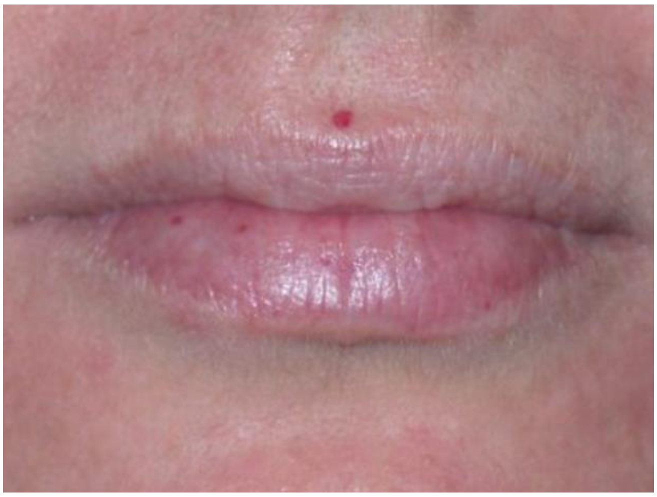
Psoriasis can be exacerbated by certain drugs such as:

- lithium
- beta blockers
- antimalarials
- non-steroidal anti-inflammatory drugs
- ACE-inhibitors
- antibiotics such as tetracycline and penicillin

Withdrawal of systemic steroids can also exacerbate psoriasis.

Question 29 of 82

This 21-year-old woman has a history of recurrent epistaxis:



What is the most likely underlying diagnosis?

A. Idiopathic thrombocytopenic purpura
B. Peutz-Jeghers syndrome
C. Anorexia nervosa
D. Combined oral contraceptive pill use
E. Hereditary haemorrhagic telangiectasia

E. Hereditary haemorrhagic telangiectasia

The correct answer is **Hereditary haemorrhagic telangiectasia**. This condition, also known as Osler-Weber-Rendu syndrome, is a genetic disorder that leads to abnormal blood vessel formation in the skin, mucous membranes and often in organs such as the lungs, liver and brain. Recurrent epistaxis (nosebleeds) are a common symptom because of the fragile blood vessels in the nasal lining.

Idiopathic thrombocytopenic purpura is incorrect. It's an autoimmune disorder where platelets are destroyed by antibodies leading to purpura (small red or purple spots caused by bleeding into the skin), but not typically recurrent nosebleeds. Epistaxis can occur but it's usually accompanied by other signs of bleeding like petechiae or ecchymosis.

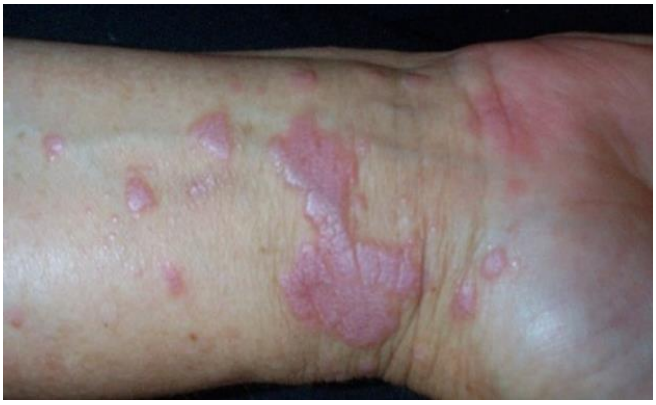
Peutz-Jeghers syndrome is also incorrect. This genetic condition results in the development of polyps in the digestive tract and hyperpigmented macules on lips, oral mucosa and digits. While these patients have an increased risk for intestinal bleeding, they do not typically present with recurrent epistaxis.

Next, **Anorexia nervosa** doesn't fit this clinical picture either. Although patients with anorexia nervosa may experience nosebleeds due to dry nasal passages from dehydration, it is not a characteristic feature of this eating disorder.

Lastly, **Combined oral contraceptive pill use** can increase risk of thromboembolic events due to increased oestrogen levels which promote coagulation but it does not cause recurrent epistaxis.

Question 30 of 82

A 43-year-old man presents with a three week history of an itchy rash on the flexor surfaces of his arms. He is generally fit and well and has no history of skin problems.



What is the most likely diagnosis?

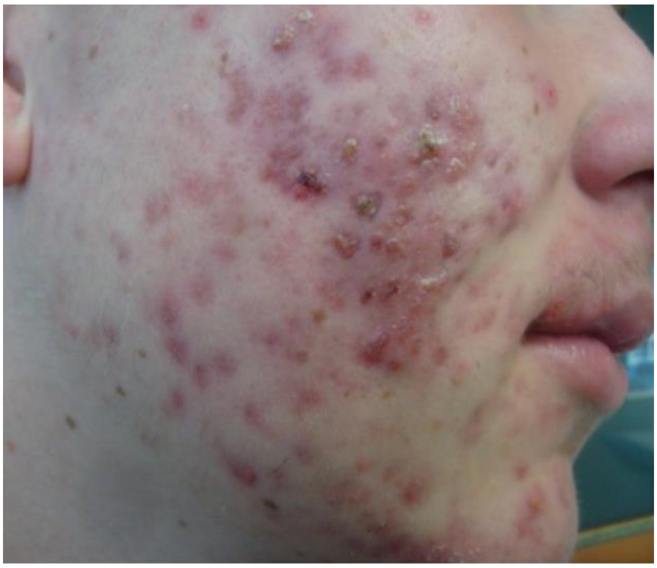
A. Morphea
B. Lichen sclerosus
C. Lichen planus
D. Psoriasis
E. Idiopathic urticaria

C. Lichen planus

Question 31 of 82

A 17-year-old boy presents to the dermatology clinic with a facial rash. He reports that the rash has been worsening over the past 6 weeks despite regular facial washing and multiple treatments including topical benzoyl peroxide and clindamycin. He now feels uncomfortable going outside due to feeling uncomfortable with his appearance. His current medications include oral lymecycline which was prescribed by his GP that he has been taking for the last 3 months.

His rash is examined, as shown below:



Given the underlying diagnosis, what is the first-line recommended management for this patient?

A. Continue oral lymecycline for further 3 months
B. Oral isotretinoin
C. Topical corticosteroids
D. Topical fusidic acid
E. Topical isotretinoin

B. Oral isotretinoin

Oral isotretinoin is correct. This patient has a diagnosis of acne vulgaris given the presence of inflammatory macules, papules and pustules in the photograph of this young male. Acne vulgaris is very common, particularly in adolescence. Associated features include comedones which are skin-coloured papules that can either be open (blackheads) or closed (whiteheads). Comedones are associated with increased sebum production and are formed when sebaceous ducts and hair follicles become blocked by debris. Looking closely at this patient's face, the areas of erythema are localised around a pilosebaceous unit. In those with acne vulgaris that has not responded to firstline measures and that are at risk of scarring, NICE guidelines recommend the use of oral isotretinoin.

Continue oral lymecycline for further 3 months is incorrect. Guidelines recommend that oral antibiotics should only be continued in the management of acne if the patient is seeing some improvement in their symptoms. As this patient is seeing a progression of symptoms despite antibiotics, an alternative treatment is needed.

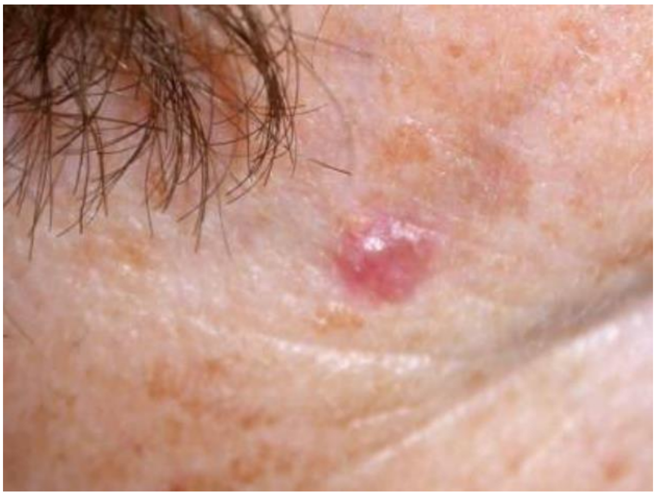
Topical corticosteroids is incorrect. This is used in the management of inflammatory skin lesions such as eczema or psoriasis. It is not used in the management of acne vulgaris.

Topical fusidic acid is incorrect. This is used in the management of superficial bacterial infections such as impetigo and mild cellulitis. Although topical antibiotics can be used in the management of acne vulgaris, fusidic acid is not recommended as per NICE guidelines.

Topical isotretinoin is incorrect. This is used in the initial stages of acne management and would not be recommended for the clearance of severe acne that has failed to respond to topical and oral antibiotics.

Question 32 of 82

A 78-year-old woman presents with a raised skin lesion on her face:



What is the most likely diagnosis?

- A. Keratoacanthoma
- B. Basal cell carcinoma
- C. Actinic keratosis
- D. Squamous cell carcinoma
- E. Malignant melanoma

B. Basal cell carcinoma

The correct answer is **Basal cell carcinoma**. It is the most common type of skin cancer and typically presents in elderly individuals on sun-exposed areas, such as the face.

Keratoacanthoma is an incorrect choice. Although it can appear similar to basal cell carcinoma, Keratoacanthomas tend to grow rapidly over weeks to months and then involute, leaving a scar. They also often have a central keratin-filled crater which is not apparent in this image.

The option **Actinic keratosis** is also incorrect. Actinic keratoses are precancerous lesions that result from chronic sun exposure and present as rough, scaly patches on sun-exposed skin. They are typically flat rather than raised and lack the pearly appearance seen in this image.

Squamous cell carcinoma would be an incorrect answer too. While Squamous cell carcinomas can present as raised lesions on sun-exposed skin, they more commonly appear as erythematous scaly plaques or ulcerated nodules rather than the pearly nodule shown here.

Finally, **Malignant melanoma** is unlikely given this presentation. Malignant melanomas generally present as pigmented lesions with asymmetry, irregular borders, colour variation and diameter greater than 6mm (the 'ABCD' criteria). This lesion does not exhibit these characteristics.

Question 33 of 82

A 30-year-old cleaner presents with a four-week history of recurrent vesicular lesions on her hands. She describes these lesions as initially appearing on the sides of her fingers before progressing to more generalised vesicles on her palms. They then break down and become intensely itchy, dry and cracked. She has tried using over the counter moisturisers but these have not helped.

She finds that the cleaning products she works with makes the rash worse and has been wearing rubber gloves to try and avoid this happening. She has also taken the past two weeks off work due to the cracked and inflamed skin on her hands.

She has no past medical history of note but does describe an allergy to nickel at the age of 14 around the time of her first ear piercings.

She currently takes the oral contraceptive pill.

On examination, you find linear 1-2mm vesicles along most of her digits with evidence of lichenification, cracking and inflamed skin. There is no evidence of any other skin rash elsewhere.

What is the most likely diagnosis?

- A. Digital Herpes Simplex
- B. Irritant contact dermatitis
- C. Pompholyx
- D. Pustular psoriasis
- E. Allergic contact dermatitis

C. Pompholyx

This is a classic history of pompholyx eczema. It typically affects the hands (80% of the time) or the feet (12%), or both and presents with small vesicles along the digits and palms/soles. These then de-roof causing intense itching and drying of the skin.

Pompholyx eczema has been associated with a nickel allergy.

The other answers can also present with vesicular eruptions on the hands but the clinical presentations are different.

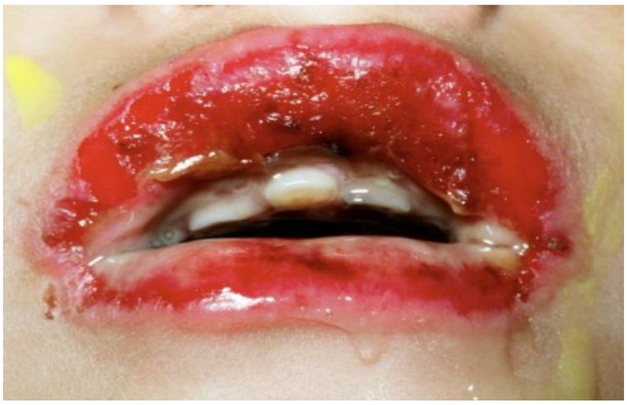
Herpetic whitlow would lead to a painful outcrop of vesicles and would be unlikely to cause lesions at multiple sites in an immunocompetent person.

Pustular psoriasis is an acute form of psoriasis which leads to widespread pustules with systemic upset.

Irritant and allergic contact dermatitis can present similarly to pompholyx eczema but are as a result of contact with an irritant or allergen. As a cleaner and with a nickel allergy she could be susceptible to both these conditions. However the fact that she has been wearing rubber gloves and has removed herself from potential contacts suggests that a specific chemical is unlikely to be the cause of her symptoms.

Question 34 of 82

A 27-year-old man presents as he is feeling generally unwell. Around 5 days ago he started having a sore throat associated with myalgia and lethargy. Yesterday he developed a fever and over the course of the past 24 hours a rash has appeared. His past medical history includes anxiety and atopic eczema. On examination he has a widespread erythematous rash, with many of the lesions having a 'target' appearance. Some of the lesions are becoming bullous. His pulse is 120/min and temperature 38.4º. He also has conjunctivitis and some ulceration and sloughing around the mouth:



What is the most likely diagnosis?

A. Eczema herpeticum
B. Pemphigus vulgaris
C. Erythema multiforme major
D. Impetigo
E. Necrotizing fasciitis

C. Erythema multiforme major

The correct answer in this case is **Erythema multiforme major**. Erythema multiforme is an acute, immune-mediated skin condition that typically presents with target-like lesions on the skin and mucous membranes. In this patient, the history of a sore throat followed by fever, myalgia, and lethargy along with the appearance of a widespread erythematous rash with target lesions and mucosal involvement (conjunctivitis and oral ulceration) strongly suggest erythema multiforme major. This condition can be triggered by infections (commonly herpes simplex virus or mycoplasma pneumoniae) or medications.

Eczema herpeticum is an incorrect option as it is a complication of atopic eczema where there is an extensive infection with herpes simplex virus. It presents with clusters of painful vesicles on an erythematous base that may rupture and form erosions. Although the patient has a history of atopic eczema, the presentation with target lesions and mucosal involvement makes erythema multiforme major more likely.

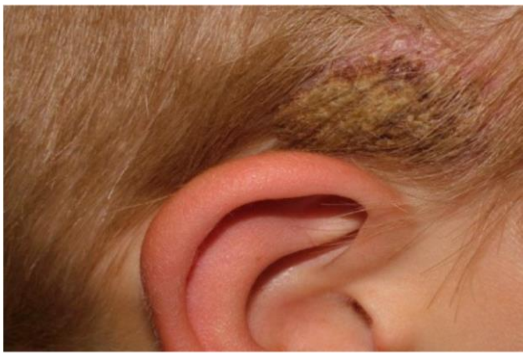
Pemphigus vulgaris is an autoimmune blistering disorder characterized by intraepidermal blisters involving both the skin and mucous membranes. The clinical presentation may include bullae that rupture easily, leaving painful erosions. However, the sudden onset of symptoms following a sore throat and fever in this case make it less likely than erythema multiforme major.

Impetigo is a superficial bacterial skin infection caused mainly by *Staphylococcus aureus* or *Streptococcus pyogenes*. It presents as honey-colored crusted lesions or small fluid-filled blisters that may rupture. The widespread rash involving multiple areas of the body along with systemic symptoms such as fever and myalgia make erythema multiforme major a more appropriate diagnosis.

Lastly, **necrotizing fasciitis** is a rapidly progressive bacterial infection involving the subcutaneous tissue and fascia. It presents with severe pain, erythema, and edema that rapidly progress to necrosis and systemic symptoms such as fever and hypotension. The presence of target lesions, mucosal involvement, and the absence of severe pain or rapid progression of symptoms in this case make erythema multiforme major more likely than necrotizing fasciitis.

Question 35 of 82

A 12-year-old boy is brought with a persistent 'scab' above his right ear. His mother reports that it has slowly developed over the past few weeks and initially started out as a patch of 'dandruff'. He is systemically well and their is no past medical history of note. The lesion is shown below:



What is the most likely diagnosis?

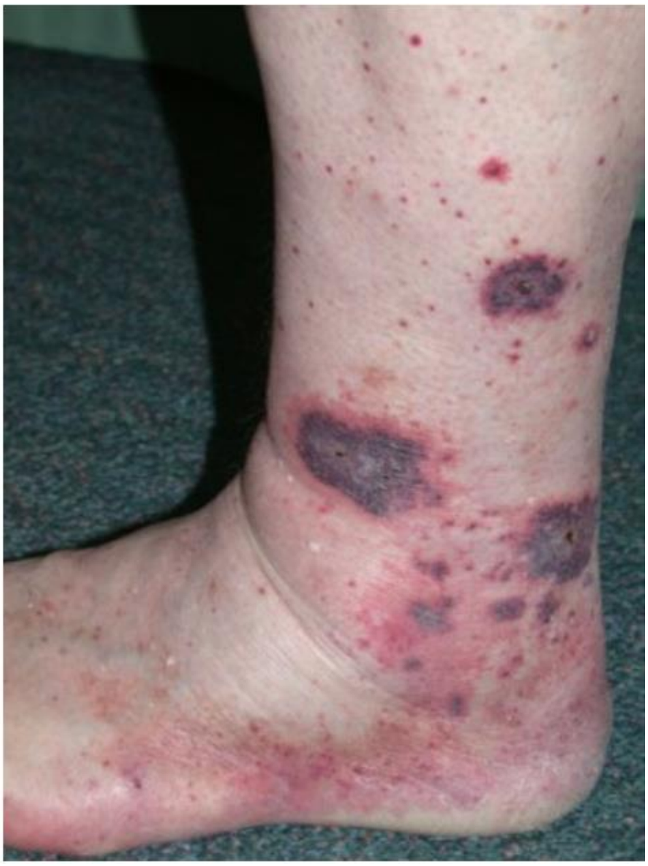
A. Seborrhoeic dermatitis
B. Trichotillomania
C. Impetigo
D. Scalp psoriasis
E. Kerion

E. Kerion

The kerion has developed as a result of an untreated tinea capitis infection. Systemic antifungals are usually required.

Question 36 of 82

A 64-year-old man presents with a 'rash' on his legs which has developed over the past few days:



He complains of feeling generally 'run-down' but review of systems is unremarkable.

What is the most likely underlying cause?

A. Vasculitis
B. Erythema multiforme
C. Necrotising fasciitis
D. Kaposi sarcoma
E. Venous eczema

A. Vasculitis

Kaposi sarcoma may cause similar skin changes to the larger lesions but would not typically cause petechiae.

Vasculitis is commonly limited to the skin and may be caused by infections, drugs, autoimmune disorders and malignancy.

Question 37 of 82

A 20-year-old woman presents to the medical clinic for review. She had been started by her GP on bisoprolol following an episode of palpitations and has subsequently developed a rash affecting her elbows, knees, navel genital area. It has been itchy but not painful, and she has not had any further episodes of palpitations. She has previously had eczema as a young child but this disappeared before the age of five. She has no allergies as far as she knows. On examination, she has a well defined erythematous rash of extensor surfaces of her elbows, knees, umbilicus and groin.

What is the most likely diagnosis?

A. Allergy to bisoprolol
B. Psoriasis
C. Topical dermatitis
D. Eczema
E. Cellulitis

B. Psoriasis

Flexural psoriasis is characterised by well defined, erythematous, non-painful rash

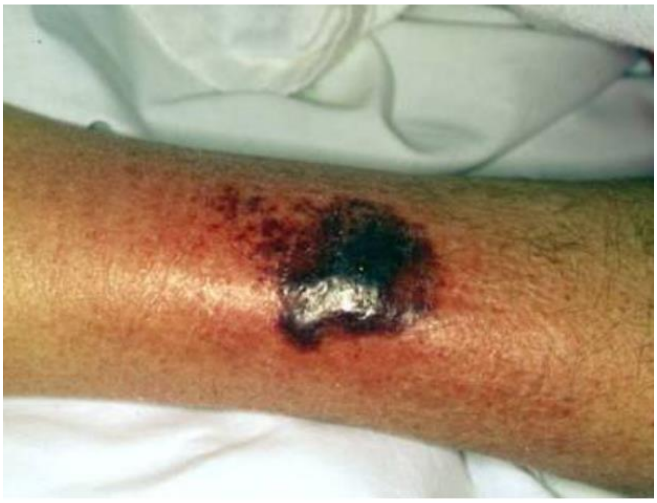
This is a patient who has developed a well-defined erythematous and pruritic rash of extensor surfaces following the use of a beta-blocker. The most likely explanation is psoriasis. In the progression of the condition, the typical plaques can form. For this patient, the first presentation has been triggered by beta-blockers; this is a known effect of beta-blockers which limits their use for people with psoriasis.

This is a very unlikely description of a drug allergy. The onset is faster with a systemic rash involving the trunk which is macular and poorly defined.

In topical dermatitis, there are defined areas of inflammation in areas of contact with an irritant. Eczema is also unlikely; eczema affects flexural rather than extensor surfaces.

Question 38 of 82

A 24-year-old man with a history of ulcerative colitis presents due to an expanding 'blood blister' on his lower leg:



What is the most likely diagnosis?

A. Pyogenic granuloma
B. Arterial leg ulcer
C. Necrotising fasciitis
D. Venous leg ulcer
E. Pyoderma gangrenosum

E. Pyoderma gangrenosum

The correct answer is **Pyoderma gangrenosum**. Pyoderma gangrenosum is a rare, inflammatory skin condition often associated with systemic diseases such as inflammatory bowel disease (IBD), which includes ulcerative colitis. The patient's history of ulcerative colitis and the appearance of the lesion - a rapidly enlarging, painful ulcer with a violaceous border - are characteristic features of pyoderma gangrenosum. It is also important to note that pyoderma gangrenosum can be precipitated by minor trauma or surgical procedures.

Pyogenic granuloma, although it can appear similar to pyoderma gangrenosum, typically presents as a small, red, vascular lesion that bleeds easily. They are usually solitary and occur after minor trauma. While they can occur anywhere on the body, they most commonly appear on the hands and face.

An **Arterial leg ulcer** would be an unusual presentation in such a young patient without risk factors for peripheral arterial disease (PAD). These ulcers typically present on the lateral aspect of the ankle or foot and are characterised by severe pain, especially at night or with elevation of the limb. Additionally, there would often be signs of peripheral arterial disease such as absence of pulses or claudication.

Necrotising fasciitis is a life-threatening soft tissue infection causing rapidly progressive skin necrosis and systemic toxicity. Although it could theoretically present similarly to this case, it would likely have been accompanied by severe systemic symptoms like fever and hypotension which are not mentioned in the scenario.

A **Venous leg ulcer** tends to occur in older patients with a history of chronic venous insufficiency or deep vein thrombosis (DVT). The ulcers usually develop around the medial malleolus and are often accompanied by other signs of chronic venous insufficiency such as varicose veins, oedema and skin changes like hyperpigmentation or lipodermatosclerosis.

Question 39 of 82

A 20-year-old man is reviewed in dermatology clinic. He has been suffering from severe worsening of his eczema symptoms. He normally manages with emollients and topical steroids of moderate to severe strength. Recently he has had a severe flare, which has not even responded to a trial of oral prednisolone over one week. He is suffering from severe pruritus and irritation of his skin. On examination, his flexural surfaces on his arms and legs are inflamed and show evidence of scratch marks.

What non-steroidal option may help control his flare?

A. Alitretinoin
B. Topical tacrolimus
C. Oral tacrolimus
D. IV tacrolimus
E. Topical salicylic acid

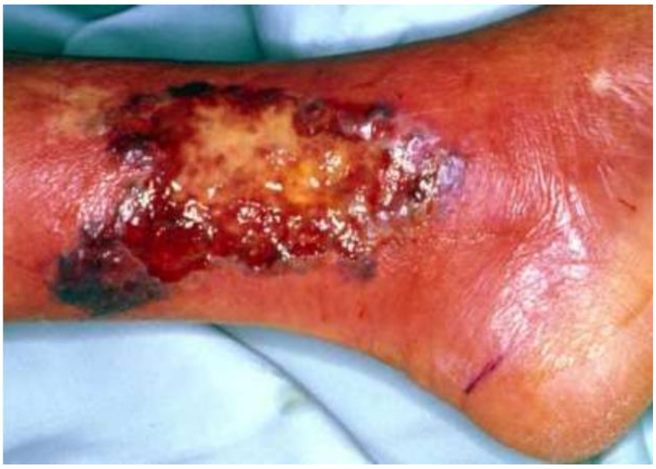
B. Topical tacrolimus

Calcineurin inhibitors are an alternative to topical steroids in eczema

This patient has a severe flare of eczema not responding to emollients and strong steroid therapy as evidence by failure of response to prednisolone. Calcineurin inhibitors, such as tacrolimus, can be used by dermatologists for this. Topical tacrolimus is preferred, as oral and IV tacrolimus are used to prevent and treat organ rejection rather than to treat eczema. Salicylic acid is used for scales in psoriasis, whilst alitretinoin would only be used for severe refractory hand eczema.

Question 40 of 82

The lesion below started as a small red papule which grew in size before starting to ulcerate:



Which one of the following conditions is most associated with this skin condition?

A. Rheumatoid arthritis
B. Sarcoidosis
C. Primary herpes simplex virus infection
D. Tuberculosis
E. Thyrotoxicosis

A. Rheumatoid arthritis

Question 41 of 82

A 50-year-old male patient with a history of severe psoriasis has previously tried treatment with topical corticosteroids, vitamin D analogue therapy and phototherapy with little effect.

On examination he has multiple well circumscribed indurated erythematous plaques with overlying white scale over the majority of the trunk and forearms.

Blood tests reveal:

Hb	135 g/l
Platelets	405 * 10 /l9
WBC	8.2 * 10 /l9
Bilirubin	12 µmol/l
ALP	70 u/l
ALT	27 u/l
Albumin	35 g/l
Na +	140 mmol/l
K +	5.1 mmol/l
Urea	8.2 mmol/l

Creatinine	112 µmol/l

What is the most appropriate therapy?

A. Infliximab
B. Adalimumab
C. Ciclosporin
D. Methotrexate
E. Etanercept

D. Methotrexate

NICE CG154 addresses the approach to systemic therapy for psoriasis and is outlined below:

Offer systemic non-biological therapy to people with any type of psoriasis if:

- It cannot be controlled with topical therapy and
- It has a significant impact on physical, psychological or social wellbeing and one or more of the following apply:

psoriasis is extensive (for example, more than 10% of body surface area affected or a PASI score of more than 10) or psoriasis is localised and associated with significant functional impairment and/or high levels of distress (for example severe nail disease or involvement at high-impact sites) or phototherapy has been ineffective, cannot be used or has resulted in rapid relapse (rapid relapse is defined as greater than 50% of baseline disease severity within 3 months).

Choice of drugs:

- Offer methotrexate as the first choice of systemic agent for people with psoriasis who fulfil the criteria for systemic therapy (above)
- Offer ciclosporin as the first choice of systemic agent for people who fulfil the criteria for systemic therapy (above) and who:

need rapid or short-term disease control (for example a psoriasis flare) or have palmoplantar pustulosis or

are considering conception (both men and women) and systemic therapy cannot be avoided.

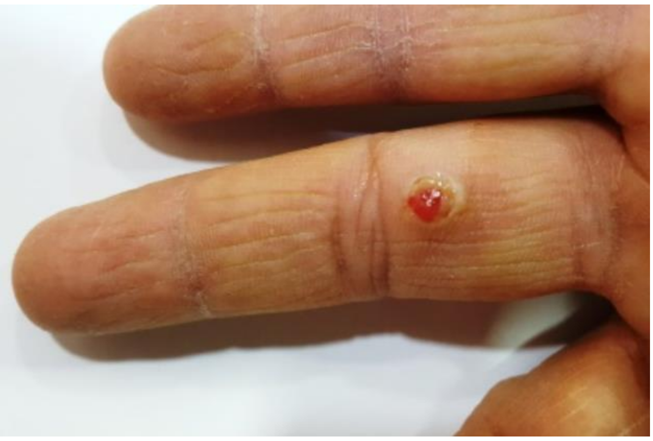
- Consider changing from methotrexate to ciclosporin (or vice-versa) when response to the first-choice systemic treatment is inadequate.
- Consider acitretin for adults, and in exceptional cases only for children and young people, in the following circumstances:

if methotrexate and ciclosporin are not appropriate or have failed or for people with pustular forms of psoriasis.

Question 42 of 82

You are reviewing a 33-year-old woman with a lesion on her finger. The lesion has been present for 6 weeks, initially starting small before quickly growing in size. There is no history of trauma. There is no past medical history and her only regular medication is folic acid. She is 28 weeks pregnant with her second child and has had no complications during her pregnancy.

An image of the lesion is shown below.



What is the most appropriate management for the lesion?

A. Cauterisation
B. Cryotherapy
C. Curettage
D. Excision
E. Watch and wait

E. Watch and wait

The image shows a well-defined, ulcerated papule alongside a history of rapid growth, in keeping with a pyogenic granuloma. These are found to be more common after trauma, in pregnancy, and in young adults. Given that the above scenario does not allude to any trauma, the likely cause for this lesion is pregnancy.

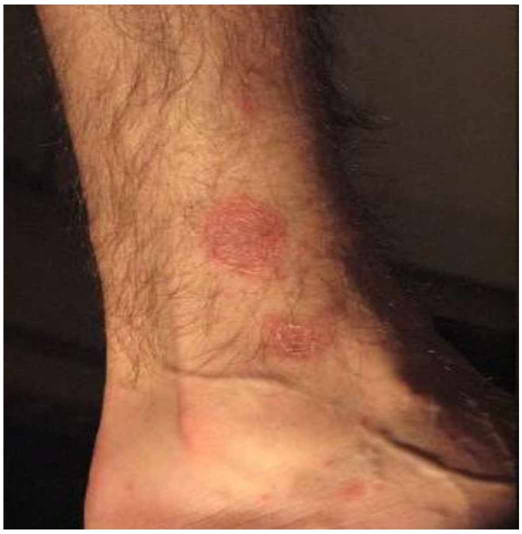
Traumatic pyogenic granulomas can be treated with cauterisation, cryotherapy, curettage, or excision.

The above scenario is a non-traumatic pyogenic granuloma likely secondary to pregnancy and so the most appropriate initial step in management is 'watch and wait' as lesions often self-resolve in pregnancy.

Question 43 of 82

A 32-year-old man presents to the dermatology clinic with a rash on his lower legs. He reports that an initial lesion appeared 2 weeks ago, followed by further smaller lesions over his body. There is no history of itch or pain and he denies having a fever. His past medical history includes anxiety for which he takes propranolol and he has no known allergies.

His rash is examined, as shown below:



What is the recommended management for this patient?

A. Reassurance and discharge
B. Topical 1% hydrocortisone
C. Topical fusidic acid
D. Topical ketoconazole
E. UVB phototherapy

A. Reassurance and discharge

This patient has multiple small, oval-shaped, red plaques that are located on the lower limbs.

Looking closely at these lesions, some appear to have a fine peripheral scale. This patient has a diagnosis of pityriasis rosea, a self-limiting rash that is characterised by a large round 'herald patch', usually found on the chest, abdomen, or back. It mostly affects children and young adults and is thought to be precipitated by bacterial and viral infections (e.g. human herpes virus 6 and 7) although this has not definitely been proved yet.

Reassurance and discharge is correct. Pityriasis rosea is a self-limiting rash and treatment is not usually required.

Topical 1% hydrocortisone is incorrect. Topical corticosteroids are usually used in the treatment of eczematous diseases that typically present as a dry, itchy and scaly rash which is not seen here. They can also be used in the management of localised chronic plaque psoriasis. However, it plays no role in the management of pityriasis rosea.

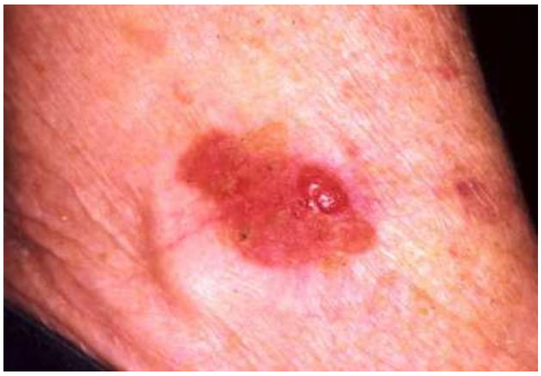
Topical fusidic acid is incorrect. This is used in treating superficial bacterial infections including insect bites, stings and impetigo. However, there is no surrounding erythema or pustular discharge to suggest that this rash is bacterial in nature.

Topical ketoconazole is incorrect. Topical ketoconazole is used in the treatment of fungal infections such as pityriasis versicolor. The rash is mostly seen on the trunk, neck and upper limbs. The patches can vary in colour from pink, brown to pale (typically paler than the surrounding skin). They are usually asymptomatic but can occasionally be itchy. Heat and moisture are risk factors for developing the rash.

UVB phototherapy is incorrect. This is used in the management of chronic plaque psoriasis and guttate psoriasis that cannot be controlled with initial topical management. Importantly, this patient is taking propranolol which is known to exacerbate psoriasis. Psoriasis has a similar appearance to pityriasis rosea. However, psoriasis has a coarser silvery scale with surrounding lichenification. However, the history of an isolated herald patch before the onset of the remaining rash is suggestive for pityriasis rosea for which UVB phototherapy is not a treatment.

Question 44 of 82

A 59-year-old man presents with a new skin lesion which has developed over the past few months:



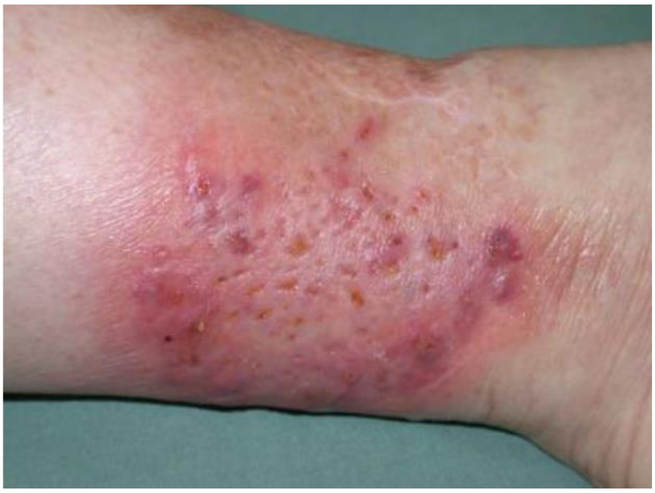
You plan to refer the patient to dermatology. What is the most likely diagnosis?

A. Malignant melanoma
B. Actinic keratosis
C. Bowen's disease
D. Basal cell carcinoma
E. Seborrhoeic keratosis

C. Bowen's disease

Question 45 of 82

You review a 31-year-old woman who has had Crohn's disease for the past 12 years. She is currently on infliximab therapy.



What is the most likely diagnosis?

A. Pyoderma gangrenosum
B. Acute febrile neutrophilic dermatosis
C. Squamous cell carcinoma
D. Pyogenic granuloma
E. Behcet's disease

A. Pyoderma gangrenosum

The correct answer is **Pyoderma gangrenosum**. Pyoderma gangrenosum is a neutrophilic dermatosis that commonly occurs in patients with inflammatory bowel disease, such as Crohn's. It presents as painful, necrotic ulcers often found on the lower extremities. The pathophysiology involves an abnormal immune response leading to neutrophil infiltration of the skin, resulting in ulceration. Management typically involves systemic corticosteroids and immunosuppressants like infliximab.

Acute febrile neutrophilic dermatosis, also known as Sweet's syndrome, is incorrect. Although it is also a neutrophilic dermatosis like pyoderma gangrenosum, it usually presents with fever and elevated inflammatory markers alongside the abrupt onset of tender erythematous skin lesions. It can be associated with malignancies and infections but less commonly with Crohn's disease.

Squamous cell carcinoma is not the most likely diagnosis in this case. While patients with chronic inflammatory conditions may have an increased risk for squamous cell carcinoma over time, the acute presentation of painful necrotic ulcers is more indicative of pyoderma gangrenosum.

The option **Pyogenic granuloma** is incorrect as well. Pyogenic granulomas are benign vascular lesions that present as rapidly growing red papules or nodules, often after minor trauma or during pregnancy. They do not typically present with ulceration and are not associated with Crohn's disease.

Finally, **Behcet's disease** could potentially cause similar skin lesions due to its vasculitis component; however, other symptoms such as oral aphthous ulcers, genital ulcers and ocular inflammation would likely be present too. Furthermore, Behcet's disease has no established association with Crohn's disease, unlike pyoderma gangrenosum.

Question 46 of 82

A 21-year-old woman presents to the emergency department with an itchy rash. It developed over the course of the day which she spent at the beach with friends.

She complains of an itching and burning sensation on her upper arms, trunk and thighs.

On examination there are crops of 3mm pink papules over the symptomatic areas, sparing her face and her hands.

What is the most likely diagnosis?

A. Scabies
B. Systemic lupus erythematosus
C. Xeroderma pigmentosum
D. Photoallergic contact dermatitis
E. Polymorphic light eruption

E. Polymorphic light eruption

Photoallergic contact dermatitis is a toxic or allergic reaction that occurs when certain chemicals are applied to the skin and subsequently exposed to the sun. It is unlikely to spare the hands and face.

Xeroderma pigmentosum is a rare hereditary defect of the enzyme system that repairs DNA after damage from ultraviolet rays, resulting in extreme sensitivity to sunlight and a tendency to develop skin cancer. It typically presents in youth with multiple basal cell carcinomas and other skin malignancies.

The photosensitive rash of systemic lupus erythematosus classically includes the the butterflyshaped rash that appears over the bridge of the nose and both cheeks.

The rash associated with scabies often appears as erythematous papules on the trunk and limbs with vesicles on palms and soles and irregular tracks in the web spaces between the fingers.

Question 47 of 82

A 27-year-old man was seen in the dermatology clinic with an itchy, vesicular rash over buttocks and proximal forearms. He was otherwise well.

A subsequent skin biopsy and direct immunofluorescence demonstrate granular IgA at the dermal-epidermal junction. Given the most likely diagnosis, he was started on dapsone and given specific diary advice.

Six weeks later he complains of worsening fatigue. What is the most important investigation?

A. Full blood count
B. Echocardiogram
C. ECG
D. Urine protein:creatinine ratio
E. Creatine kinase

A. Full blood count

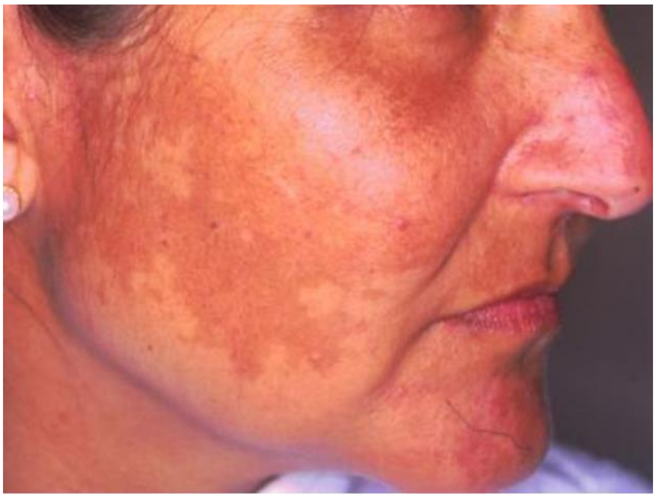
The patient has dermatitis herpetiformis - an inflammatory cutaneous condition closely associated with gluten sensitive enteropathy (coeliac disease).

Dapsone is an antibacterial agent that can provide temporary symptomatic relief as a gluten-free diet is established. The main side effect is that of haemolytic anaemia - so regular full blood counts are essential. Other side effects include peripheral neuropathy and rarely agranulocytosis.

The remaining options are clearly not correct if the candidate is aware of the side effects of dapsone - a MRCP favourite - as is the presentation of dermatitis herpetiformis without overt diarrhoea.

Question 48 of 82

This woman complains of a 'rash' on her cheeks. She has recently started taking hormone replacement therapy for menopausal symptoms.



What is the most likely diagnosis?

A. Vitiligo
B. Seborrhoeic dermatitis
C. Acne rosacea
D. Melasma
E. Systemic lupus erythematosus

D. Melasma

The correct answer is **Melasma**. Melasma, also known as chloasma, is a common skin condition of adults in which light to dark brown or greyish pigmentation develops, mainly on the face. The image shows hyperpigmented patches on the cheeks, a typical presentation of melasma. It is more common in women and often related to hormonal changes such as pregnancy or hormone treatments like hormone replacement therapy (HRT).

Vitiligo is incorrectly identified here because it presents with depigmented patches rather than hyperpigmented. Vitiligo is an autoimmune condition that causes loss of melanocytes leading to white patches on the skin.

Seborrhoeic dermatitis would be incorrect as well. Seborrhoeic dermatitis typically presents with a red, scaly, itchy rash usually located on the scalp, eyebrows, nasolabial folds and chest. It does not cause hyperpigmentation.

The diagnosis of **Acne rosacea** would be unlikely given the absence of papules, pustules or rhinophyma which are characteristic for this condition. Rosacea generally affects middle-aged women and presents with flushing and persistent erythema along with telangiectasia.

Lastly, **Systemic lupus erythematosus (SLE)** can indeed present with a facial rash known as malar rash or 'butterfly' rash but this tends to be erythematous and sparing nasolabial folds, unlike melasma which often involves these areas. Additionally, SLE usually comes with other systemic symptoms like joint pain and fatigue which were not mentioned in this scenario.

Question 49 of 82

A 74-year-old male presents to the acute medical take with left sided chest pain, worse on inspiration. On examination, you note his nails are yellow and clubbed with bilateral non-pitting oedema. Examination of his chest reveals reduced air entry of his left lung to mid zone, dull to percussion, with no wheeze.

He has a known past medical history of bronchiectasis diagnosed 2 years ago, for which he has been admitted 3 times in the past 5 months. He reports weight loss of about 8kg in the past 9 months. He last underwent an echocardiogram 2 years ago, during which a left ventricular ejection fraction of 56% was demonstrated.

A chest radiograph demonstrates a large left pleural effusion and a mark has been made by ultrasound for a pleural tap.

Pleural fluid analysis results are as follows:

pH	7.42
Protein	40 g/L (serum 58)
LDH	130 IU/L (serum 181)
Glucose	3.5 mmol/l (serum 6.2)
Amylase	22 u/l (serum 32)
Triglycerides	1.90 mmol/L (serum 2.2)
Cytology	awaited
AFB	awaited

What is the unifying diagnosis?

A. Parapneumonic effusion
B. Yellow nail syndrome
C. Malignant pleural effusion
D. Oesophageal rupture
E. Congestive cardiac failure

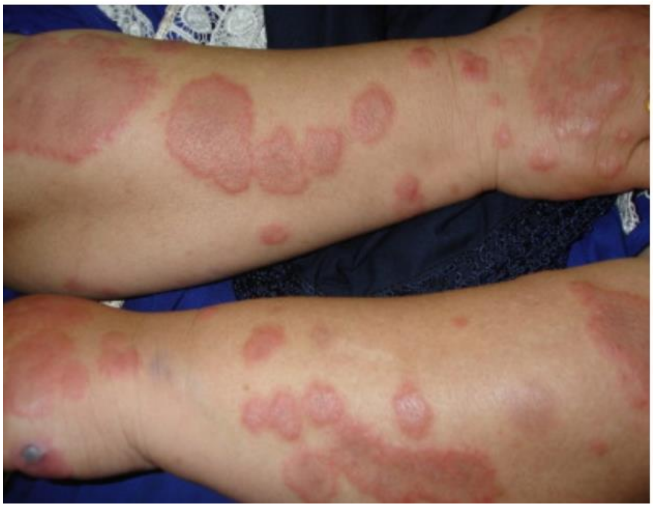
B. Yellow nail syndrome

Diagnosis here is dependent on subtle details in the history and pleural fluid analysis: the patient has bronchiectasis, pleural effusion (exudate), lymphoedema (not pitting oedema), chylothorax (note the significantly raised triglycerides in the pleural fluid) and of course, yellow nails! The patient has yellow nail syndrome, characterised by nail dystrophy or discolouration, lymphoedema and pleural effusions. A parapneumonic and malignant effusion are reasonable differentials but do not explain the triglycerides. Oesophageal rupture classically increases pleural amylase. Lastly, congestive cardiac failure classically produces a transudate.

Question 50 of 82

A 34-year-old woman presents to the general practitioner with a 2-day history of an erythematous rash over her upper limbs. She describes waking up yesterday morning with multiple lesions over her arms. The rash is not itchy or painful and has not resolved despite regular emollient use. She has no past medical history of note.

On examination, she appears well. There is a crusted cold sore on her top lip. Her chest is clear and her heart sounds are normal. She has a soft abdomen. Her rash is examined and appears as shown below:



What is the most likely diagnosis?

A. Eosinophilic granulomatosis with polyangiitis
B. Erythema marginatum
C. Erythema multiforme
D. Plaque psoriasis
E. Urticaria

C. Erythema multiforme

This patient has multiple well-demarcated, round target lesions with an outermost erythematous ring and paler centre in keeping with a diagnosis of erythema multiforme. Erythema multiforme is an acute, self-limiting skin eruption most commonly secondary to an infective trigger (e.g. herpes simplex virus or *Mycoplasma pneumoniae*). The rash appears abruptly and affects the upper limbs most often before spreading down towards the trunk. One of this patient's examination findings included a cold sore, suggesting a recent infection with herpes simplex virus, the likely trigger of her rash.

Urticaria presents as an itchy rash with multiple weals over the skin. They usually appear pale or light pink and may be surrounded by a red flare. The most common trigger is an allergic reaction, although viral infections may also precipitate urticaria. Urticaria does not cause the target lesions seen in the above image, making it an unlikely diagnosis.

Eosinophilic granulomatosis with polyangiitis is a small-vessel vasculitis with symptoms including asthma, allergic rhinitis and constitutional symptoms of weight loss, fevers and night sweats. Skin involvement can manifest in up to 50% of patients and include blisters, petechiae and ulceration. This is not seen in the image above. Furthermore, there is nothing in this patient's clinical history to suggest an underlying diagnosis of vasculitis.

Erythema marginatum is a manifestation of acute rheumatic fever. It is most commonly seen in children and is rare in adults. It presents as annular erythematous macules or papules that spread outwards with central clearance. The lesions are not itchy or painful and may be asymptomatic.

Plaque psoriasis is a chronic inflammatory skin condition that gives rise to well-defined red plaques with an overlying silver scale. Common features include itch and painful fissures. The rash in the image does not show the presence of erythematous plaques. Furthermore, this patient's rash has had an acute onset which is atypical of psoriasis that has a much slower onset.

Question 51 of 82

A 72-year-old gentleman presents with a peeling and erythematous rash on both of his hands. He has noticed slight tingling in the same area but denies pain. He has a past medical history of colorectal cancer which was managed surgically with an anterior resection. He developed local recurrence of his cancer five months post-operatively. He is now on palliative chemotherapy with capecitabine and oxaliplatin every two weeks in order to control progression. His last treatment was one week ago. He has a history of type two diabetes mellitus, depression and has had a cholecystectomy when he was younger. On examination he appears frail and cachectic, but systemically well. His hands are shown to have patchy palmar erythema with mild desquamation. A similar rash is present on the soles of his feet.

Observations:

Saturations	97%
Respiratory rate	17/min
Blood pressure	132/73mmHg
Heart rate	71/min
Temperature	37.3°C

What is the most likely diagnosis?

A. Erythromelalgia
B. Palmoplantar psoriasis
C. Palmar-plantar erythrodysesthesia
D. Paraneoplastic syndrome
E. Cellulitis

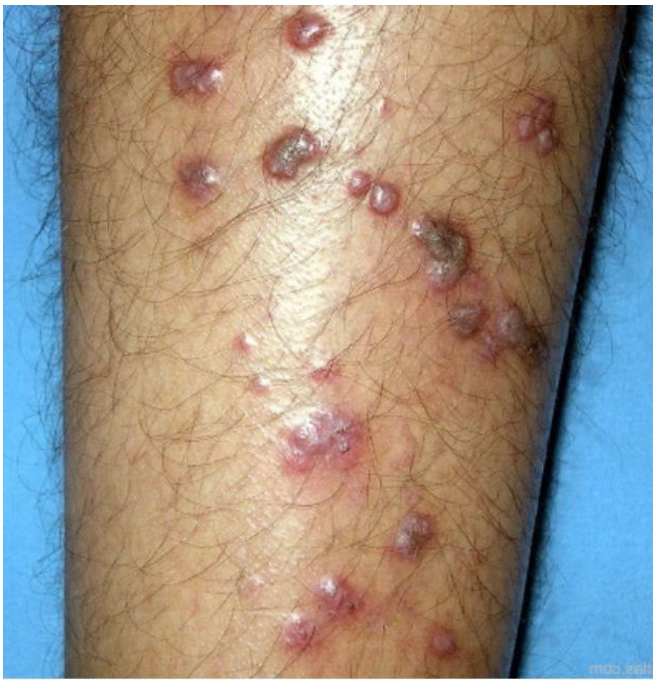
C. Palmar-plantar erythrodysesthesia

The answer is palmar-planter erythrodysesthesia. The distribution of a dysesthesic erythematous rash with desquamation of the palms and soles is a classic description of palmar-plantar erythrodysesthesia during chemotherapy. Cellulitis, paraneoplastic syndromes, and erythromelalgia do not fit this distribution, and palmoplantar psoriasis is associated with itching.

Question 52 of 82

A 53-year-old woman is seen in the dermatology clinic with a 4-week history of an itchy rash on her lower legs. She has tried various antihistamines and a cold compress, but these have not relieved her symptoms. There is no history of pain or bleeding and she is systemically well. Her past medical history includes chronic hepatitis C infection. She takes no regular medication.

On examination, her rash appears as shown below.



What is the most likely diagnosis?

A. Bullous pemphigus
B. Lichen planus
C. Lichen sclerosus
D. Molluscum contagiosum
E. Pemphigus vulgaris

B. Lichen planus

The photograph above shows multiple round, well-circumscribed, raised purple lesions. On closer inspection, subtle white markings can be visualised on top of the lesions, otherwise known as Wickham striae. The clinical history and appearance of the rash are in keeping with a diagnosis of lichen planus. Lichen planus is typically an itchy rash that appears as flat-topped plaques. The colour of the rash is dependent on skin tone. However, in fairer skin tones, the rash is more likely to look purple in colour. Rarely, nail involvement can be seen which includes thinning of the nail bed to onycholysis. Infection with hepatitis C is a risk factor for developing lichen planus. The treatment of choice is potent topical corticosteroids.

Bullous pemphigus is an autoimmune blistering disease commonly seen in those over 60 years. Typically a non-specific rash is seen for several weeks before the development of tense blisters between the dermis and epidermis. Any part of the skin can be affected, although the flexor aspects are more commonly affected.

Lichen sclerosus is most commonly diagnosed in women over the age of 50. It is a chronic dermatological disorder of the genital and peri-anal skin. It is possible for lichen sclerosus to overlap with other skin conditions such as lichen planus or psoriasis. However, the absence of vulval symptoms in this patient makes the diagnosis less likely.

Molluscum contagiosum is a viral condition that is commonly seen in childhood or the immunocompromised. It presents as clusters of round papules with an umbilicated centre and each papule contain a thick creamy material. There is nothing in this patient's history to suggest immunosuppression and therefore molluscum contagiosum is unlikely.

Pemphigus vulgaris is an autoimmune disease characterised by painful blisters and erosions on the skin. Mucous membranes are also involved and are usually the first site to be affected during the onset of the disease, followed by epidermal involvement. It typically arises in those aged between 30-60 years. Unlike bullous pemphigus, pemphigus vulgaris presents as flaccid blisters which easily rupture to cause painful erosions. These are not seen in the image above making the diagnosis less likely.

Question 53 of 82

A 32-year-old man attends his GP with pruritus of the genital area. Additionally, he reports painful intercourse with his long-term partner. Examination reveals a whitish scarred meatus with a white plaque on phimotic foreskin.

What is the most likely diagnosis?

A. Candidiasis
B. Vitiligo
C. Lichen planus
D. Lichen sclerosus
E. Erythroplasia of Queyrat

D. Lichen sclerosus

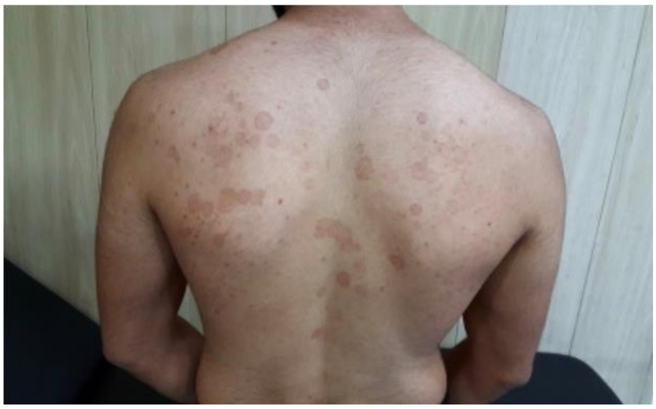
Candidiasis will typically cause erythema on the meatus and discharge. Vitiligo would not be expected to cause painful intercourse or result in phimosis.

Penile lichen planus usually presents with purple papules in a ring around the glans. Comparatively, lichen sclerosus usually affects the glans and foreskin, resulting in white papules or plaques. It can cause phimosis.

Erythroplasia of Queyrat, also known as an in-situ squamous cell carcinoma of the penis, is a penile intraepithelial neoplasia. It typically occurs in men above 50 years of age, with symptoms including erythema, pain, bleeding and ulcers.

Question 54 of 82

A 21-year-old man presents to the dermatology clinic with a 10-day history of a widespread rash over his torso, neck and upper limbs. He reports that the rash developed during a backpacking holiday in South East Asia. There is no history of fever, pain or itch and other than a mild gastrointestinal illness whilst abroad, has been well in himself. He thinks he may have had a similar rash before last summer on a family holiday to Portugal. His rash is examined, as shown below:



What is the most likely diagnosis?

A. Guttate psoriasis
B. Pityriasis rosea
C. Pityriasis versicolor
D. Tinea corporis
E. Urticaria

C. Pityriasis versicolor

This patient has a diffuse hyperpigmented rash consisting of multiple round lesions mostly over the trunk. This is consistent with the diagnosis of **pityriasis versicolor**, a superficial cutaneous fungal infection caused by *Malassezia furfur*. The patches can vary in colour from pink, brown to pale (typically paler than the surrounding skin) and therefore explains the name 'versicolor'. The upper limbs and neck are also commonly affected. The rash is usually asymptomatic but can occasionally be itchy. Heat and moisture are risk factors for developing the rash, and the exposure to the heat seems to coincide with this patient's rash.

Guttate psoriasis is incorrect. Guttate psoriasis is a subtype of psoriasis that typically affects children and young adults following infection with *Streptococcus sp.*. The rash presents acutely with multiple small scaly and erythematous patches of skin appearing over the trunk and limbs.

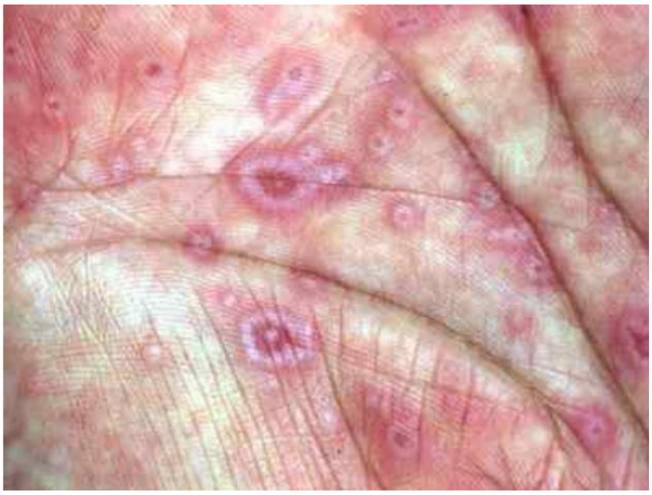
Pityriasis rosea is incorrect. Pityriasis rosea is a self-limiting rash, characterised by a large round 'herald patch', usually found on the chest, abdomen, or back. It mostly affects children and young adults and is thought to be precipitated by bacterial and viral infections (e.g. human herpes virus 6 and 7).

Tinea corporis is incorrect. Tinea corporis is a superficial fungal infection of the skin that can affect any part of the body. However, the infection often spares the hands, feet, scalp, face and groin. The lesions associated with tinea corporis are characteristic ring-shaped lesions that are not seen here.

Urticaria is incorrect. Urticaria presents as an erythematous, raised rash that is often described as being intensely itchy. This is not in keeping with this patient's presentation.

Question 55 of 82

A 55-year-old man develops a rash two days after starting a new medication. The rash is mildly pruritic and mainly affects the arms, torso and neck. The palms of his hand are shown below:



Which one of the following drugs is most likely to have been started?

A. Levetiracetam
B. Olanzapine
C. Carbamazepine
D. Fluoxetine
E. Diazepam

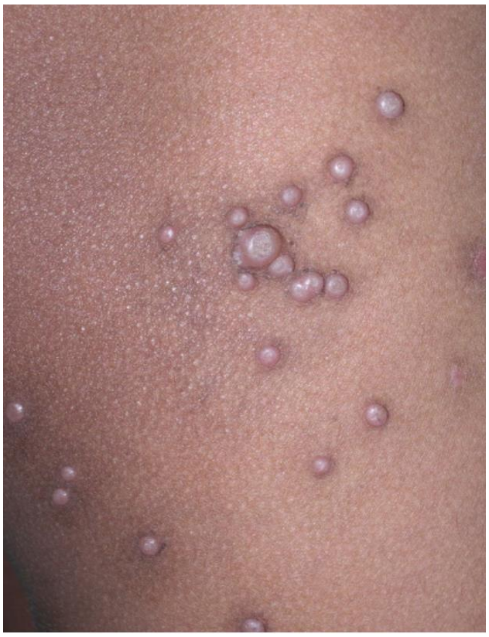
C. Carbamazepine

This patient has developed erythema multiforme which is a known complication of carbamazepine use.

Question 56 of 82

An 8-year-old boy presents with his mother, who is concerned about a rash that has developed on her son's torso. It has gradually developed over the past few weeks. He is otherwise healthy and well, with no significant medical history, nor family history.

On examination, the rash appears as shown below:



Given the likely diagnosis, what is the most appropriate management?

A. Cryotherapy
B. Piercing
C. Reassurance
D. Topical fusidic acid
E. Topical hydrocortisone

C. Reassurance

The image above depicts molluscum contagiosum in a child. The clustered lesions have the typical appearance of pearly papules with umbilicated centres. This is an incredibly common infection that is highly contagious and often spreads between children in close contact. The mother should be reassured that it is a self-limiting condition, and symptoms usually resolve within 18 months - and so reassurance is the most appropriate option.

Cryotherapy may be an option used in older children or adults, if lesions are concerning, for instance catching on clothing or in a cosmetically sensitive place. However, this is a young child, and the lesions and described as being limited to the torso.

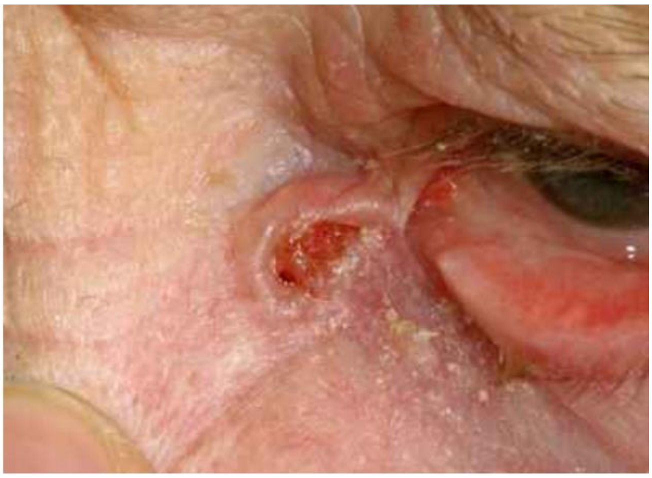
Piercing with an orange stick, or squeezing with fingernails, may be tried following a bath. This should, however, be limited to a few lesions at one time. This is not generally recommended if lesions are not problematic - in a straightforward case such as this, reassurance should be given and the lesions left alone.

Topical fusidic acid would be used if there were any signs of secondary infection - oedema, erythema, or crusting. The photo above does not demonstrate any of these signs and so an antibiotic is not necessary.

If there are any signs of inflammation, or any itching, a mild topical steroid such as hydrocortisone may be used. Again, in this photo, the lesions do not appear inflamed, nor is any description given of problematic itching.

Question 57 of 82

Please look at the skin lesion shown below:



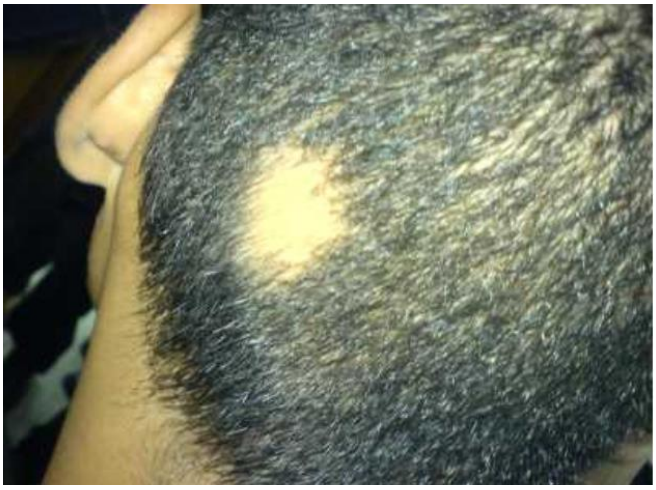
What is the most likely diagnosis?

A. Infected chalazion
B. Actinic keratosis
C. Indurated dacryocystitis
D. Keratoacanthoma
E. Basal cell carcinoma

E. Basal cell carcinoma

Question 58 of 82

A 23-year-old man presents as he is concerned about recent hair loss. Examination reveals the following:



What is the most likely diagnosis?

A. Telogen effluvium
B. Alopecia areata
C. Tinea capitis
D. Male-pattern baldness
E. Discoid lupus erythematous

B. Alopecia areata

Question 59 of 82

A 73-year-old woman attended dermatology clinic for review of a skin lesion on her right cheek. The patient had recently returned to the United Kingdom having been resident in southern Spain for the previous 20 years. She described the development of a lump just under her right eye over approximately the past six months. She also recalled having a area of slightly dry and sore skin in a similar location prior to the emergence of the lesion, although she had not sought medical attention for this. The patient denied having any symptoms from the lesion, although was very concerned and upset about the unsightly appearance it caused.

The patient's medical history included rheumatoid arthritis, type 2 diabetes mellitus, hypertension and intermittent episodes of gout. She had no previous dermatological condition. Her regular medications were methotrexate 15 mg weekly, metformin 1000 mg twice daily, ramipril 2.5 mg daily and naproxen 500 mg as required. She denied any previous treatments for cancer.

Examination of the patient demonstrated an approximately spherical nodule 11 mm in diameter arising from the patient's cheek 15 mm inferior to her eyelid. Crusting was noted on the surface of the nodule, but there was no hyperkeratosis, induration or ulceration.

A biopsy of the lesion is taken during clinic assessment with histology demonstrating squamous cell carcinoma.

What is the appropriate technique for treatment of the patient's lesion?

A. Electrodessiccation
B. Wide local excision with 4 mm margin of normal skin
C. Mohs micrographic surgery
D. Wide local excision with 6 mm margin of normal skin
E. Radiotherapy

C. Mohs micrographic surgery

The patient has a facial cutaneous squamous cell carcinoma in a functionally and cosmetically important region. Her history of immunosuppression with methotrexate could also lead to the tumour being considered high risk, although the increased risk of squamous cell carcinoma is most well characterised in those individuals highly immunosuppressed to prevent transplant rejection.

Mohs micrographic surgery is a specialised technique reserved for use in high risk tumours or those in functionally or cosmetically important areas. The technique involves histological examination of the tumour during the procedure to ensure adequate margins and complete tumour clearance. The technique provides a high cure rate and maximum tissue conservation.

In less sensitive areas of the body, wide local excision is the treatment of choice. Low risk tumours with diameter < 2 mm require margins of 4 mm, with 6 mm margins being required in high-risk or larger tumours.

Radiotherapy is an alternative treatment option for individuals not suitable for surgery but has a higher recurrence rate than surgical excision. Electrodessiccation (curettage and cautery) is occasionally used for low risk cutaneous squamous cell carcinomas on the extremities or trunk.

Question 60 of 82

A 67-year-old man presents with a five week history of skin rash. He states that the rash erupted suddenly and progressed over five weeks.

His past medical history includes type 2 diabetes mellitus. He is obese with a BMI of 39kg/m² and drinks alcohol to excess. An ultrasound scan four years ago confirmed cirrhosis.

On examination, there are over 60 raised, oval lesions with tan pigmentation over his back and chest, ranging from 5mm to 25mm diameter, and have a warty texture and stuck-on appearance.

What would be the most appropriate next step for this patient?

A. Cryotherapy
B. Curettage
C. Full malignancy screen
D. Imiquimod
E. Reassurance and discharge

C. Full malignancy screen

The abrupt appearance of multiple seborrhoeic keratoses suggests underlying cancer (LeserTrelat sign)

The question gives a classic description of seborrhoeic keratoses.

These lesions are common and are benign although the rapid development of large numbers of them is cause for concern. This is termed the Leser-Trelat sign and is most commonly associated with gastrointestinal adenocarcinomas and hepatic cancers.

Full malignancy screen: a full malignancy screen is correct given the development of the LeserTrelat sign. Bloods including cancer markers as well as endoscopy / further imaging would be recommended to investigate for underlying malignancy.

Cryotherapy: cryotherapy and curettage are options for improvement of cosmetic appearance, but seborrhoeic keratoses usually do not require any specific treatment.

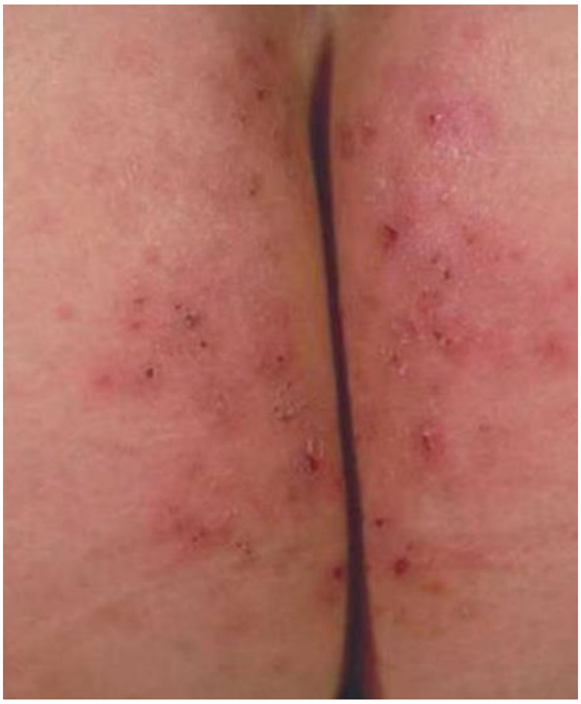
Imiquimod: Imiquimod is used for actinic keratoses rather than seborrhoeic keratoses.

Curettage: is an option for the treatment of seborrhoeic keratoses but with such high numbers would be unsuitable. Also, given the 'Leser-Trelat' sign, this patient requires investigation for underlying malignancy.

Reassurance and discharge: this is not appropriate in this case as the Leser-Trelat is associated with malignancy. If there were fewer lesions, or they had developed over a much longer time scale, it may be appropriate to reassure your patient.

Question 61 of 82

A 27-year-old man with a history of depression and coeliac disease presents with an itchy rash on his buttocks:



What is the most likely diagnosis?

A. Linear IgA dermatosis
B. Neurotic excoriations
C. Scabies
D. Dermatitis herpetiformis
E. SSRI-associated dermatitis

D. Dermatitis herpetiformis

The correct answer is **Dermatitis herpetiformis**. Dermatitis herpetiformis is a chronic, intensely pruritic skin disease characterised by grouped erythematous papules, vesicles and bullae. It is associated with coeliac disease, which the patient has a history of. The rash typically involves extensor surfaces such as the buttocks, elbows and knees. The diagnosis can be confirmed by skin biopsy showing granular IgA deposits at the dermo-epidermal junction.

Linear IgA dermatosis is an uncommon autoimmune blistering disorder that presents with tense blisters on normal or erythematous skin. It is not specifically linked to coeliac disease and while it can affect any body site, it favours the trunk and lower extremities rather than specifically the buttocks.

Neurotic excoriations refer to self-inflicted skin lesions produced by repetitive scratching. They are often seen in patients with psychiatric conditions including depression but tend to be more widespread and do not have the characteristic appearance of dermatitis herpetiformis.

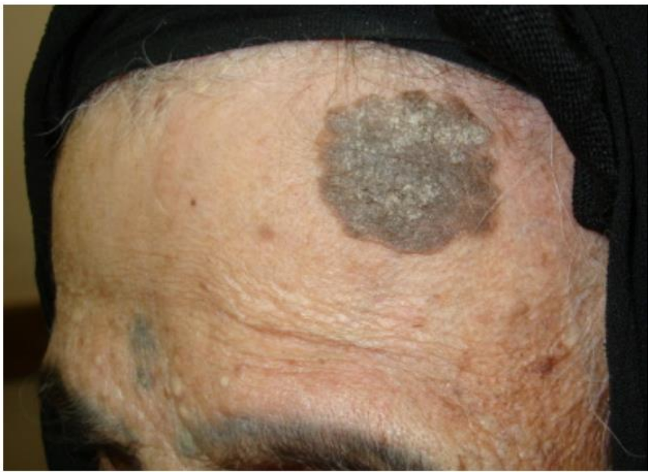
Scabies could present with an itching rash on the buttocks, however, scabies tends to cause more generalised itch especially in web spaces of fingers, wrists and ankles. The clinical picture would also usually include burrows or nodules which are not described here.

Lastly, **SSRI-associated dermatitis** refers to skin reactions related to selective serotonin reuptake inhibitors (SSRIs), a class of drugs commonly used in treating depression. While SSRIs can cause various skin reactions including rashes and pruritus, these tend to be more diffuse rather than localised solely on the buttocks as in this case scenario.

Therefore based on the clinical presentation and the patient's history of coeliac disease, Dermatitis herpetiformis represents the most likely diagnosis.

Question 62 of 82

A 68-year-old woman presents with the lesion below on the forehead. She explains that it has been present for several years and slowly growing.



It causes her no symptoms and she is otherwise well in herself. She has no significant past medical history except for hypertension, for which she takes ramipril.

Given the likely diagnosis, what is the most appropriate management?

A. Conventional surgery
B. Mohs surgery
C. Reassurance
D. Topical fluorouracil
E. Topical imiquimod

C. Reassurance

The correct answer is reassurance. This lesion has the characteristic appearance of seborrhoeic keratosis. This is a benign epidermal lesion seen in older people. They vary significantly in appearance - some have a more raised, 'stuck-on' appearance akin to a barnacle stuck on the skin, whereas some appear flat. The one above appears somewhat flatter. The uniformity of its colour and regular, well-demarcated border point toward seborrhoeic keratosis rather than malignant melanoma. For an asymptomatic patient, only reassurance is needed. If any itch, a topical corticosteroid may be used.

Conventional surgery is unwarranted. This would be used for a malignant lesion such as a melanoma, which would appear more irregular and have patchy colouring.

Mohs surgery is a technique used to remove malignant lesions from cosmetically-sensitive areas such as the face. This is often used for basal cell carcinomas of the face, which would not appear like the photo above - these are typically small, round, protruding lesions with pearly rolled edges and telangiectasia.

Topical fluorouracil may be used in the treatment of squamous cell carcinoma. These present as scaly, crusted, irregular lesions that often ulcerate and grow over weeks to months. For those in situ (known as Bowen's disease), topical treatments such as fluorouracil are a suitable initial option.

Topical imiquimod is an alternative to fluorouracil, also used in the treatment of squamous cell carcinoma in situ. It plays no role in the management of seborrhoeic keratosis, which is the most likely diagnosis given the picture above.

Question 63 of 82

A 21-year-old university student presents with an itchy skin rash. The rash came on at the start of the new school year around his groin, and a few weeks later he developed an intense itch all over his body.

On examination, he had an erythematous rash in the distribution described with wheals and papules and a mild scale. He has excoriated areas all over his body.

His flatmate complains of a similar rash on his hands.

Given the likely diagnosis, what would be the treatment of choice?

A. Malathion 0.5% to all skin for 12 hours, including the scalp, repeated after 14 days
B. Malathion 0.5% to the scalp, and permethrin 5% to the rest of the skin, for 12 hoursrepeated after 7 days
C. Permethrin 5% to all skin for 12 hours, including the scalp, repeated after 14 days
D. Permethrin 5% to all skin for 12 hours, including the scalp, repeated after 7 days
E. Permethrin 5% to all skin for 24 hours, excluding the scalp, repeated after 7 days

D. Permethrin 5% to all skin for 12 hours, including the scalp, repeated after 7 days

Scabies - permethrin treatment: all skin including scalp + leave for 12 hours + retreat in 7 days

The likely diagnosis here is scabies. The delayed itching is due to the delayed type IV hypersensitivity reaction to the mites and eggs. The rash is commonly found on the hands, flexor aspects of the wrists, groin, and around the genitals. It is spread by skin contact and so is common in households.

Permethrin 5% to all skin for 12 hours, including the scalp, repeated after 7 days is the correct answer. Permethrin should be applied to all the skin including the scalp and left for 12 hours before washing off. Patients should be advised to make sure their skin is clean and dry before applying and to ensure coverage in difficult-to-reach areas and skin creases. This process should then be repeated after 7 days.

Malathion 0.5% to all skin for 12 hours, including the scalp, repeated after 14 days is incorrect. Malathion 0.5% would be a second-line treatment option.

Permethrin 5% to all skin for 12 hours, including the scalp, repeated after 14 days is incorrect. According to the BNF, the treatment should be reapplied after 7 days.

Permethrin 5% to all skin for 24 hours, excluding the scalp, repeated after 7 days is incorrect. According to the BNF, the treatment should be washed off after 12 hours, the treatment area should also include the scalp.

Malathion 0.5% to the scalp, and permethrin 5% to the rest of the skin, for 12 hours repeated after 7 days is incorrect. Combination therapy like this is not recommended. If permethrin 5% was not successful in clearing the infestation, malathion 0.5% could be tried.

Question 64 of 82

A 50-year-old woman presents with a painful burning rash one week after starting chemotherapy. She describes a tingling sensation that started three days previously, which then progressed to swelling and redness of both her hands. She now finds that is impacting on what she able to do at home. Over the last day, she has noticed a blister as well. She has otherwise been suffering from fatigue and nausea since starting chemotherapy. She has a past medical history of left breast cancer managed with wide local excision and axillary node clearance following adjuvant radiotherapy and chemotherapy with docetaxel, as well as endocrine therapy.

What is the most appropriate management?

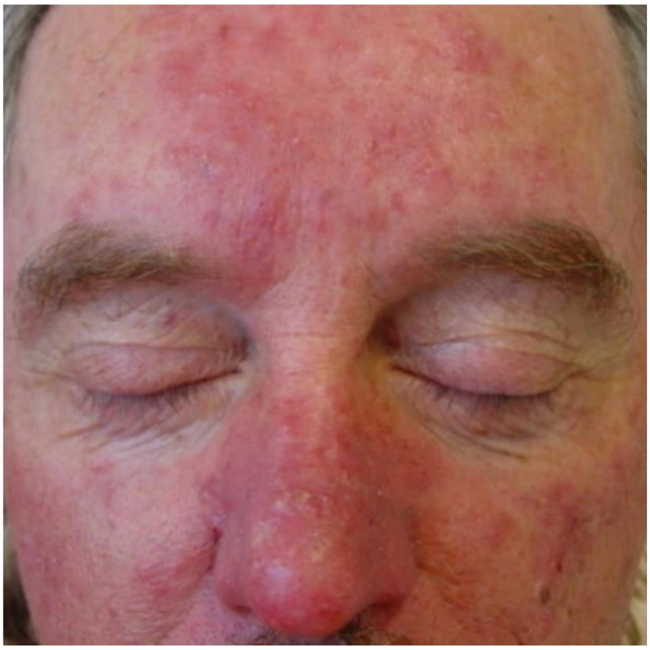
A. Topical hydrocortisone
B. Prednisolone
C. Flucloxacillin
D. Stop endocrine treatment
E. Dose reduction of docetaxel

E. Dose reduction of docetaxel

The answer is dose reduction of docetaxel. This history describes palmar-plantar erythrodysesthesia which is severe enough to limit daily activities. Whilst all cases can benefit from supportive management with emollients, cooling therapy and skin protection, severe reactions which cause an impact on the quality of life will usually be managed with dose reduction in chemotherapy. Steroids are not helpful in this condition, and there is no evidence of infection and therefore antibiotics are not appropriate. This explains why answers A, B and C are incorrect. Her endocrine treatment would not cause this problem and modifying it would be of no benefit as well, which is why D is incorrect.

Question 65 of 82

A 54-year-old man presents with a facial rash of several months. He explains that, initially, it started with redness across the face, before progressing to its current appearance as shown below:



He also mentions that it worsens in sunlight. He is otherwise fit and well, with no significant past medical history, nor any regular medications.

Given the likely diagnosis, which of the following is the most appropriate treatment?

A. Topical adapalene
B. Topical hydrocortisone
C. Topical ketoconazole
D. Topical ivermectin
E. Topical tacrolimus

D. Topical ivermectin

The correct answer is topical ivermectin - the diagnosis here is that of rosacea. The photo shows significant erythema across the forehead, nose and cheeks. Many papules and, to a lesser extent, pustules can also be seen across these same areas. The rosacea in this photo is not severe - rhinophyma of the nose would also be expected. The patient does appear to have some erythema and papules overlying the nose, which may be the start of rhinophyma. In severe rosacea, the rhinophyma would be more obvious than what is seen here. From the options above, topical ivermectin is the most appropriate treatment option in this case.

Topical adapalene is more commonly associated with the treatment of mild acne vulgaris, rather than rosacea. Typically, comedones would be present in acne vulgaris, colloquially referred to as 'whiteheads' and 'blackheads' depending on their appearance, which are not seen in this photo. Adapalene has been described in the literature as a potential alternative to topical metronidazole, although it is not recommended in guidelines for this purpose.

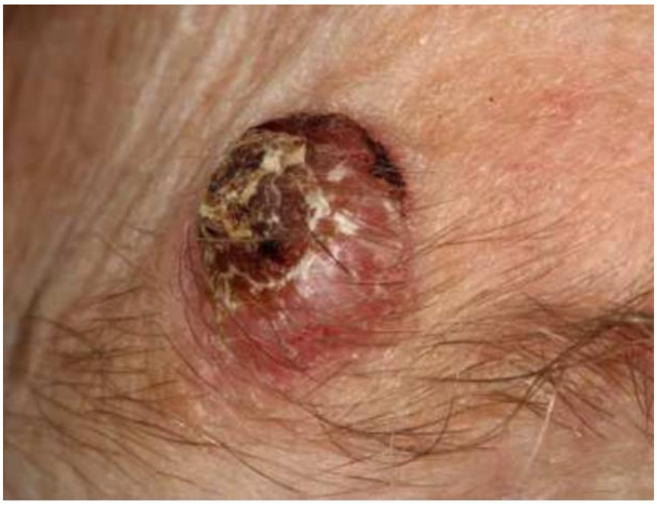
Hydrocortisone would be used for the treatment of facial eczema, not rosacea. Eczema would present with erythema and dryness, but not papules and pustules as seen in this photo. A mild corticosteroid may help to alleviate the appearance of erythema temporarily, but would not address the underlying issue.

Topical ketoconazole is an antifungal and would be used to treat seborrhoeic dermatitis rather than rosacea. This would present with erythema, but greasy, flaky scale rather than papules and pustules.

Tacrolimus can be used topically for steroid-resistant facial eczema, rather than stepping up to more potent steroids for the face. It is not routinely used in the management of rosacea.

Question 66 of 82

A 62-year-old man asks you to look at a lesion on his face:



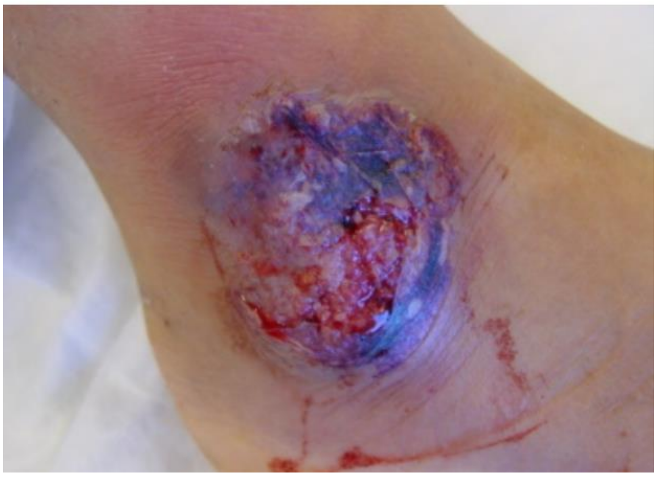
What is the most likely diagnosis?

A. Keratoacanthoma
B. Seborrhoeic keratoses
C. Actinic keratosis
D. Basal cell carcinoma
E. Pyoderma gangrenosum

Not answered

Question 67 of 82

A 67-year-old woman attends with a skin lesion. She described falling whilst walking in the Scottish Highlands and sustaining a small cut on her leg. This initially seemed to heal, but the woman then noted a blood-filled blister which has since burst and left the painful lesion shown below:



What is the most likely diagnosis?

A. Abscess
B. Cutaneous vasculitis
C. Pyoderma gangrenosum
D. Sweet's syndrome
E. Venous insufficiency ulcer

C. Pyoderma gangrenosum

The photo shows a typical pyoderma gangrenosum lesion with a deep ulcer and surrounding violaceous pigmentation.

Pyoderma gangrenosum is the correct answer. The diagnosis is often made on the characteristic appearance and history.

Cutaneous vasculitis is incorrect. This is a differential to consider, but is rare and is usually more widespread. In this case, there are also no systemic symptoms that you might expect with vasculitis.

Abscess is incorrect. This would be a fluctuant swelling, often with overlying cellulitis and would usually be associated with systemic symptoms.

Sweet's syndrome is incorrect. It is also known as acute febrile neutrophilic dermatosis and is a rare condition. It usually causes rashes on the upper body and face. It is an important differential but is not the most likely diagnosis here given the distribution of the rash and its rarity.

Venous insufficiency ulcer is incorrect. With venous insufficiency, you would expect to see associated skin changes and longer duration. This patient has no history of peripheral vascular disease which makes venous insufficiency ulcer even less likely.

Question 68 of 82

A 38-year-old man presents with a sudden onset rash. He is otherwise well in himself and has no notable past medical history. You see from his notes he has had a recent tonsillitis for which he received amoxicillin. On examination, there are multiple papules on his trunk and proximal extremities. There is a fine scale on several of these lesions.

What is the most likely diagnosis?

A. Drug eruption
B. Pityriasis rosea
C. Nummular dermatitis
D. Guttate psoriasis
E. Treponema pallidum

D. Guttate psoriasis

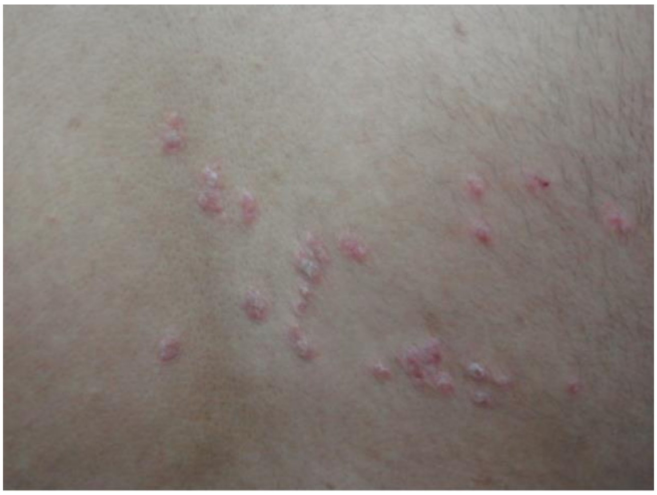
Acute onset of tear-drop scaly papules on trunk and limbs → ?guttate psoriasis

Guttate psoriasis usually presents in children and adults younger than 30 years of age. It can occur as the first presentation of psoriasis or as an acute exacerbation of plaque psoriasis, particularly after acute streptococcal infection (usually of the throat) or viral infection.

Lesions are small, round or oval (2 mm to 1 cm in diameter) scaly papules. They may be pink or red, but this can vary depending on the person's skin colour. Lesions occur all over the body, usually in large numbers and particularly on the trunk and proximal limbs (although the distal limbs can also be involved). Guttate psoriasis can occur on the face, ears, and scalp, but is rarely seen on the soles of the feet.

Question 69 of 82

A 19-year-old man presents with the following rash. He feels well in himself and has no significant past medical history. The patient does mention a sore throat that occurred several weeks ago and resolved itself after a few days.



Given the appearance above, what is the most likely diagnosis?

A. Guttate psoriasis
B. Lichen planus
C. Mycosis fungoides
D. Pityriasis rosea
E. Pityriasis versicolor

A. Guttate psoriasis

Acute onset of tear-drop scaly papules on trunk and limbs → ?guttate psoriasis

The photo above is typical of guttate psoriasis. Small, red, scaly plaques are visible. Some of the lesions in this photo have a 'tear-drop' appearance which is typical of guttate psoriasis. It classically follows a streptococcal throat infection several weeks prior. Most cases resolve spontaneously within 2-3 months. Standard psoriasis treatment may be used if needed to help resolve symptoms and appearance.

Lichen planus appears different from the photo above, with flat-topped, shiny, violaceous, polygonal papules, typically clustered around the wrists and ankles. They are overlaid by fine lines called Wickham striae, not the generalised scales seen here.

Mycosis fungoides is the most common type of primary cutaneous T-cell lymphoma. Rather than small, tear-drop lesions as seen here, it presents with poorly-defined, larger, more widespread patches, often with atrophic skin. It often occurs around sun-exposed sites.

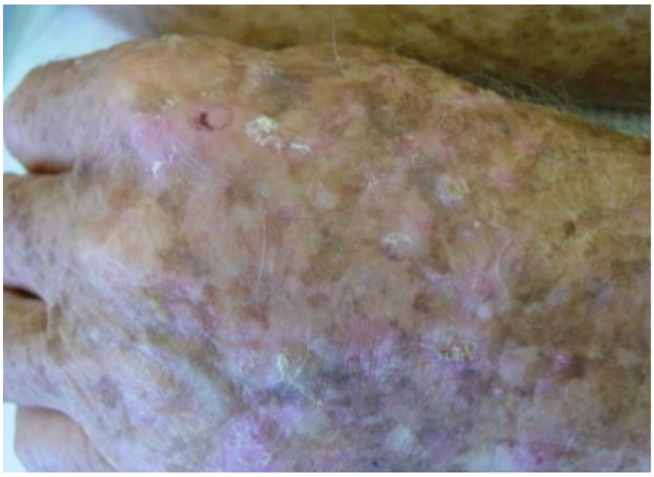
Pityriasis rosea is a reasonable differential - many patients report a preceding respiratory tract infection, but with regards to exam questions, this is not common. There is no mention of a herald patch in the question, which precedes the main pityriasis rosea rash by 1-2 weeks. The distribution of lesions typically follows a 'fir-tree' pattern, whereas, in the photo above, the distribution is relatively random.

Pityriasis versicolor is a fungal infection. Rather than the guttate lesions seen here, it leads to patchy, hypopigmented areas.

Question 70 of 82

A 67-year-old man presents to his general practitioner with skin lesions over his arms. They are not causing any itchiness or discomfort and have been developing over the past 6 months. He is otherwise well and his only past medical history of note includes hypertension and osteoarthritis.

The man reports he spends his time between the United Kingdom and a holiday home in Spain. He drinks approximately 10 units of alcohol per week and has a 20 pack-year smoking history.



What is the diagnosis?

A. Actinic keratoses
B. Basal cell carcinoma
C. Seborrhoeic dermatitis
D. Seborrhoeic keratosis
E. Squamous cell carcinoma

A. Actinic keratoses

The picture in this question depicts actinic keratoses which is the correct answer here. Sufferers often have several scaly/crusty lesions on sun-exposed areas such as the arms or head. As this man spends significant time in Spain, he is at an increased risk for developing these lesions.

Basal cell carcinomas classically present as a single pearly lump. There are several lesions in this instance and these are not consistent with this appearance. Basal cell carcinoma is therefore an incorrect answer.

Seborrhoeic dermatitis is a form of dermatitis triggered by Malassezia yeasts. This typically causes erythematous regions over the scalp, face, chest, and body creases. The distribution of the rash here as well as the scaly and crusty appearance is consistent with a diagnosis of actinic keratoses rather than seborrhoeic dermatitis.

Seborrhoeic keratoses are brown papules or plaques with a waxy appearance of unclear aetiology. The red and pink appearances of these lesions here are not consistent with this pathology.

Squamous cell carcinoma (SCC) will usually present as a solitary lesion and can arise from preexisting actinic keratoses. An SCC will typically be larger than a lesion in actinic keratoses and may become tender or ulcerated. As these features are not present here, actinic keratoses is the correct answer.

Question 71 of 82

A 24-year-old man who is normally fit and well presents with a new skin rash. He has no personal or family history of skin conditions. It started a couple of weeks ago with a lesion he noted on the hip, which is a patch approximately 4cm in diameter, mildly erythematous, with some mild scaling around the edge. He awoke this morning to find multiple smaller similar lesions, mainly on his back.

The lesions are asymptomatic.

How should this condition be managed?

A. Topical antifungal eg. ketoconazole shampoo
B. Mild topical steroid
C. No treatment required
D. Refer for phototherapy
E. Oral steroids

C. No treatment required

This is a typical history of pityriasis rosea, a self-limiting skin condition which most often occurs in teenagers and young people. The cause is unclear but thought to be viral in nature. An initial solitary 'herald patch' is followed some days to weeks later by multiple smaller lesions to the trunk. It is usually asymptomatic, in which case no treatment is required, but may cause a mild itch, in which case topical steroids and oral antihistamines could be considered. Referral to dermatology for phototherapy may be considered in extensive disease (some limited evidence of benefit).

Question 72 of 82

A 67-year-old man presents with a facial rash, which is more noticeable in the summer months. He describes flushing following sun exposure in the garden and eating spicy foods.

On examination, he has an erythematous, papular rash around his cheeks and forehead. There are visible pustules around his forehead and cheeks. There are no comedones and the rash is isolated to the face.

Which of the following would be the most appropriate first-line treatment?

A. Topical hydrocortisone
B. Topical ivermectin
C. Oral tetracycline
D. Azelaic acid
E. Emollient cream

B. Topical ivermectin

Rosacea: topical ivermectin is first-line for patients mild papules and/or pustules

This rash is typical of rosacea. This can present as flushing, erythema, telangiectasia and rhinophyma (enlarged nose).

For mild symptoms, topical therapy such as ivermectin gel is first-line. Azelaic acid can also be used but is usually not as well tolerated, especially for patients with sensitive skin.

For moderate or severe symptoms, an oral tetracycline or erythromycin can be used.

Question 73 of 82

A 25-year-old woman attends dermatology clinic for review of eczema. She has been suffering from eczema since she was young and has found the recent weather has been making her skin extremely dry and she finds that despite emollient application four times each day her skin is not improving. She also has asthma but this is well controlled and she rarely needs her inhaler. Apart from lotion emollients she is not using any creams currently. In the past she has needed topical steroids to manage her eczema when becomes very irritated. On examination the skin on over her flexural folds is very dry but does not appear irritated.

What can be advised to help manage the dry skin?

A. Advise to wear wool
B. Advise strong topical steroid use
C. Advise to change to cream rather than lotion emollient
D. Prescribe topical tacrolimus

E. Advise to change to a urea containing emollient

E. Advise to change to a urea containing emollient ×

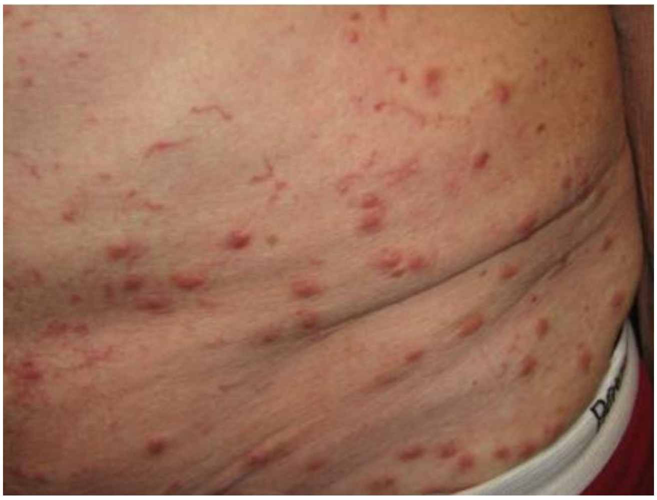
Adding urea to emollients increases moisturising effect, but can be inflammatory

Advise to change to a urea containing emollient Asking her to change to a urea containing emollient can help control dryness and itch as this can provide a greater moisturizing effect. Using urea containing emollients can increase inflammation and so in a acute inflammatory flare this would be inappropriate and such patients should be treated with topical steroids.

Changing to cream emollients would be appropriate for weeping skin. Tacrolimus can be used by dermatologists for refractory eczema.

Question 74 of 82

A 41-year-old man presents with an itchy rash over his arms and abdomen. It has got gradually worse over the past three days.



What is the most likely diagnosis?

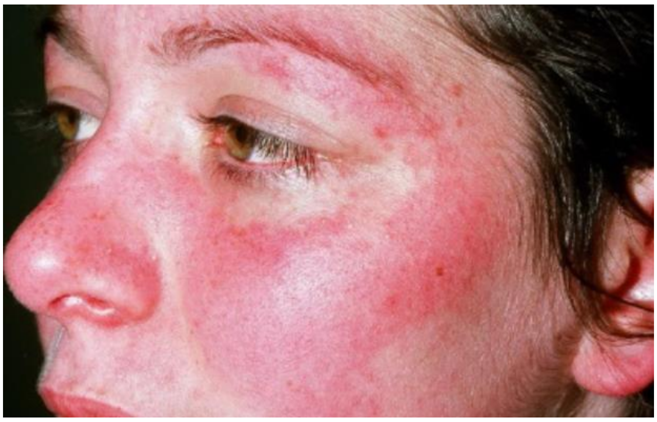
A. Scabies
B. Pityriasis rosea
C. Erythema multiforme
D. Urticaria
E. Guttate psoriasis

A. Scabies

The linear burrows of the scabies mite are clearly seen on this image.

Question 75 of 82

A 34-year-old woman presents with a rash on her face. She has been feeling generally unwell for around three months with lethargy and has a variety of joint pains



What is the most likely diagnosis?

A. Impetigo
B. Perioral dermatitis
C. Sarcoidosis
D. Acne rosacea
E. Systemic lupus erythematosus

E. Systemic lupus erythematosus

The correct answer is **Systemic lupus erythematosus**. This is a chronic autoimmune disease that can affect any system in the body, including the skin, joints, kidneys, heart and lungs. The classic malar or 'butterfly' rash seen in the image, along with systemic symptoms such as fatigue and arthralgia (joint pain), are characteristic of this condition. The rash typically spares the nasolabial folds. It's important to note that not all patients with lupus will present with this rash.

Impetigo is an incorrect answer. Impetigo is a highly contagious skin infection usually caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. It generally presents as honey-coloured crusted lesions on exposed areas of skin and is more common in children. It would not explain this patient's systemic symptoms.

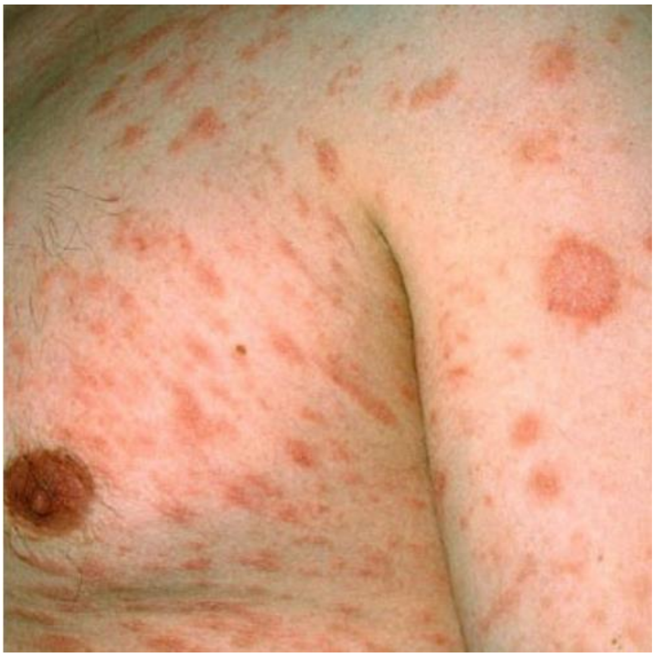
Perioral dermatitis, another incorrect option, typically presents as small red papules around the mouth and sometimes around the eyes or nose. The eruptions may be accompanied by mild itching or burning sensation but do not cause systemic symptoms like lethargy and joint pain.

Sarcoidosis is also an incorrect answer. While sarcoidosis can affect multiple organs and present with systemic symptoms similar to those described, its cutaneous manifestations are diverse but often include erythema nodosum (red tender nodules usually located on the shins) or specific lesions such as plaques, nodules or scars which look different from the presented image.

Finally, **Acne rosacea** is another incorrect choice. While it does present with facial redness and sometimes pustules similar to acne vulgaris, it primarily affects middle-aged adults and tends to be focused in the central face - cheeks, nose, forehead and chin. Rosacea does not cause systemic symptoms like fatigue or joint pains.

Question 76 of 82

A 29-year-old man presents with a rash on his trunk. Around two weeks ago he describes developing a patch of 'eczema' on his torso the size of 50 pence piece. Around a week later a number of smaller, red patches started to appear as well:



He feels systemically well and has no history of note. What is the most likely diagnosis?

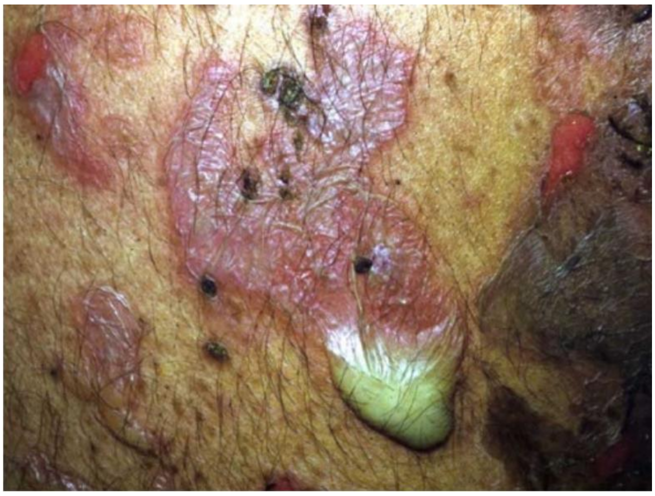
A. Erythema multiforme
B. Lichen planus
C. Pityriasis rosea
D. Guttate psoriasis
E. Tinea corporis

C. Pityriasis rosea

The earlier lesion represents a classical herald patch. Guttate psoriasis is generally has a more homogeneous, 'teardrop' appearance with a more pronounced scale. This image demonstrates the 'fir tree' appearance often seen in patients with pityriasis rosea.

Question 77 of 82

A 74-year-old man develops a painful blistering skin rash on his abdomen. He also complains of a sore throat, pain on swallowing and ulceration of the mouth:



What is the most appropriate treatment?

A. Oral prednisolone
B. Supportive treatment only
C. Intravenous flucloxacillin
D. Oral dapsone
E. Intravenous aciclovir

A. Oral prednisolone

Systemic glucocorticoids are the first-line treatment in pemphigus vulgaris

This patient has developed pemphigus vulgaris which is treated in the first instance by corticosteroids.

Question 78 of 82

A 29-year-old man present to the emergency department with a painful rash and fever. He was recently treated by his GP for a chest infection with oral amoxicillin. He found that his cough was improving but then noticed a painful rash. This was followed by a

fever, joint pain and feeling generally unwell. On examination, he has a maculopapular rash with target lesions, mucosal erosions and blistering lesions including within his oral cavity. His chest is clear on examination.

What timing of exposure is most consistent with Stevens-Johnson syndrome?

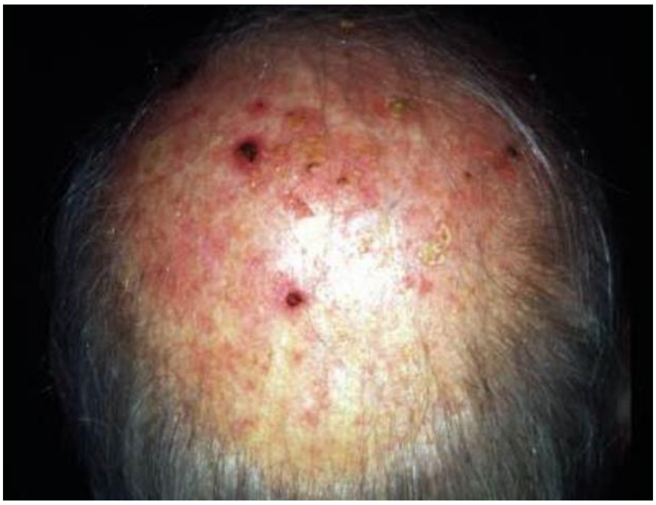
A. Within minutes
B. Within 24 hours
C. Within 3-5 days
D. Within 1-4 weeks
E. Within 4-8 weeks

D. Within 1-4 weeks

The correct answer is within 1-4 weeks. This patient has taken amoxicillin and subsequently developed a severe reaction. The description of a maculopapular rash with blistering lesions, oral involvement, fever and joint pain is all in keeping with Stevens-Johnson syndrome (SJS). SJS can occur within 1-4 weeks days of first drug exposure, and on average occurs at 14 days. In some cases, secondary exposure can lead to an earlier reaction within 48 hours but is more unusual. Another possibility is that it is secondary to Mycoplasma or Streptococcal infection. Drug reaction with eosinophilia and systemic symptoms usually occur within 2-6 weeks, whilst acute generalised exanthematous pustulosis occurs within 3-5 days.

Question 79 of 82

You are asked to look at some skin lesions on a patient who has been admitted with an infective exacerbation of COPD.



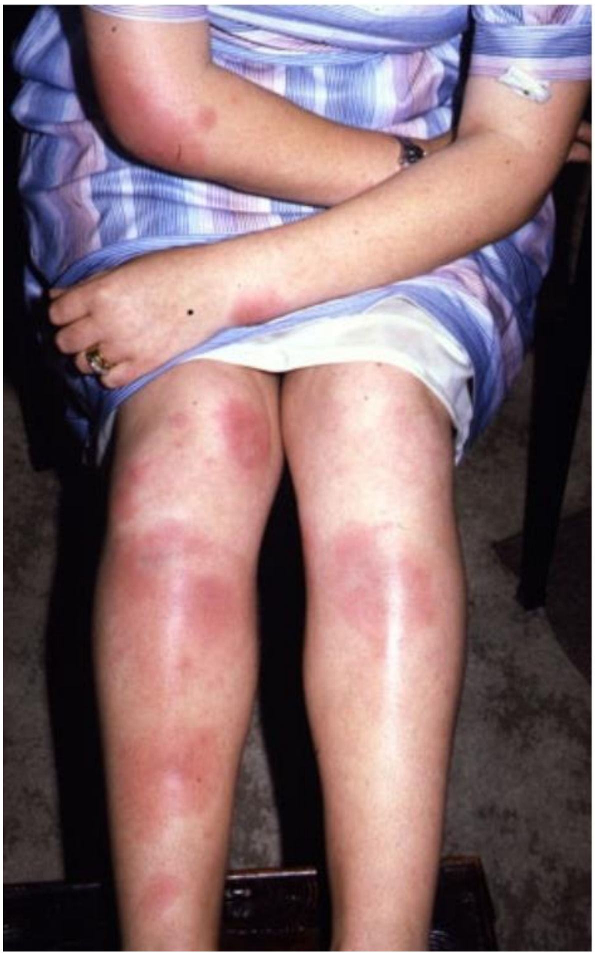
These skin lesions have been present for the past year. What is the most likely diagnosis?

A. Multiple basal cell carcinomas
B. Squamous cell carcinoma
C. Actinic keratoses
D. Seborrhoeic dermatitis
E. Seborrhoeic keratoses

C. Actinic keratoses

Question 80 of 82

A 62-year-old woman presents with painful 'bruises' on her shins and forearms.



She cannot remember knocking herself. What is the most likely diagnosis?

A. Idiopathic thrombocytopenic purpura
B. Erythema ab igne
C. Thrombotic thrombocytopenic purpura
D. Erythema nodosum
E. Cellulitis

D. Erythema nodosum

The most likely diagnosis for this 62-year-old woman presenting with painful 'bruises' on her shins and forearms is **Erythema nodosum**. Erythema nodosum is a type of panniculitis, or inflammation of the subcutaneous fat. It presents as tender, erythematous nodules typically located on the anterior shins but can also appear on the forearms. The condition may occur spontaneously or be associated with systemic diseases such as sarcoidosis, inflammatory bowel disease or streptococcal infection.

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disorder characterised by low platelet count leading to easy bruising and excessive bleeding. However, the bruises in ITP are usually not painful which makes it less likely in this case.

Erythema ab igne is a skin condition caused by prolonged exposure to heat or infrared radiation. It presents as mottled, erythematous patches that can become permanent if exposure continues. Given that the patient does not report any relevant exposures and the lesions are painful rather than asymptomatic, this diagnosis would be less likely.

Thrombotic thrombocytopenic purpura (TTP) is a rare blood disorder that causes blood clots to form in small blood vessels throughout the body. This can lead to serious problems if left untreated such as kidney failure and stroke. The bruises seen in TTP are similar to those seen in ITP - they are usually not painful and often accompanied by other symptoms like fatigue, fever, confusion which have not been reported in this case.

Lastly, **Cellulitis** is an infection of the deeper layers of skin and underlying tissue. It causes redness and swelling on affected areas of skin which are warm to touch due to inflammation caused by bacteria (most commonly Group A Streptococcus or Staphylococcus aureus). Cellulitis typically affects one side of the body, unlike our case where both shins and forearms are involved hence making it less likely.

Question 81 of 82

A 24 year-old gentleman is referred for your opinion from the Emergency Department. He presented with his first tonic-clonic seizure. A CT scan of his head shows a contrast enhancing lesion in the left frontal lobe. On taking a history you elicit that he has been having recurrent nosebleeds and dark stools for the past 12 months.

What is the likely unifying diagnosis?

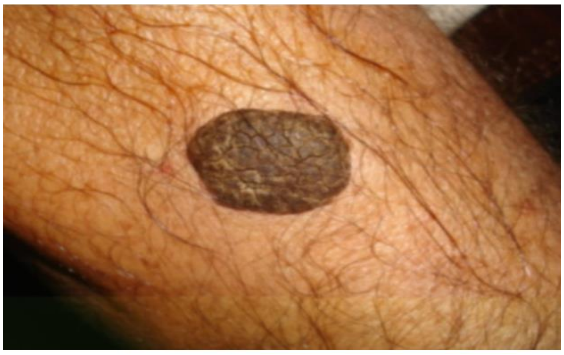
A. Peutz Jeghers syndrome
B. Hereditary haemorrhagic telangiectasia
C. Tuberous sclerosis
D. Von Willebrand disease
E. Neurofibromatosis - type 2

B. Hereditary haemorrhagic telangiectasia

This young gentleman is likely to have a diagnosis of hereditary haemorrhagic telangiectasia (HHT). The contrast enhancing lesion on the CT scan represents an arterio-venous malformation. The history of recurrent nosebleeds and melena is typical of HHT and are secondary to telangiectasia on the nasal and gastrointestinal mucosa.

Question 82 of 82

A 70-year-old man presents to the dermatology clinic with a lesion on his lower shin. He noticed the lesion 3 weeks ago after going on a resort holiday in Turkey and wearing shorts for the first time in several months. He denies pain or itch but does think it is getting bigger in size. His past medical history includes ischaemic heart disease and chronic obstructive pulmonary disease. His lesion is examined, as shown below:



What is the most likely diagnosis?

A. Basal cell carcinoma
B. Malignant melanoma
C. Seborrhoeic keratoses
D. Solar lentigo
E. Squamous cell carcinoma

C. Seborrhoeic keratoses

Seborrhoeic keratoses is correct. This patient has a well-circumscribed pigmented lesion on his shin that appears flat on the skin surface. It also has the appearance of a wart-like texture. This is in keeping with a diagnosis of seborrhoeic keratoses, a benign lesion associated with increasing age, particularly beyond 60 years. Seborrhoeic keratoses often have a 'stuck-on' appearance as seen with this patient. Treatment is not necessary for the lesions. However, curettage or cryotherapy can be offered for complete removal.

Basal cell carcinoma is incorrect. Basal cell carcinoma (BCC) is a locally-invasive cutaneous malignancy that is typically a slow-growing plaque with rolled edges and a smooth surface. They are usually pink or skin-coloured and, therefore, do not represent this patient's lesion.

Malignant melanoma is incorrect. Melanoma is a serious differential diagnosis to consider, particularly for pigmented lesions. However, characteristic features of malignant melanoma include asymmetry, irregular borders, bleeding, change in colour, increase in diameter and evolution. In contrast, this patient's lesion is well-circumscribed with no evidence of hyperpigmentation, bleeding, crusting or irregular borders.

Solar lentigo is incorrect. Solar lentigo is a benign patch of darkened skin secondary to a local proliferation of melanocytes. This process is triggered by UV radiation, giving solar lentigo the alternative name of 'age spots'. Seborrhoeic keratoses may arise from solar lentigo. However, unlike seborrhoeic keratoses, the skin is not thickened in solar lentigo, only darkened.

Squamous cell carcinoma is incorrect. Squamous cell carcinoma (SCC) is an invasive cutaneous malignancy that presents as an enlarging, crusted lesion that may ulcerate and are often tender. SCC typically progresses from actinic keratoses. They are non-melanocytic lesions, making SCC incorrect.

THERAPUTICS

passmedicine PART 2

2024

Question 1 of 138

A peri-arrest call is put out for a 71-year-old woman on the high dependency unit. An arterial line was being inserted and upon administration of some local anaesthetic, a sudden reduction in consciousness was noted. The patient has now started to have a seizure.

Her vital signs are 91% on 15 litres of oxygen, respiratory rate of 7/min, heart rate of 54/min, blood pressure of 72/54mmHg, the patient is unresponsive and has a temperature of 35.9ºC.

As well as emergency management, what would be the most effective treatment to give in this instance?

A. A tropine
B. Flumazenil
C. Fomepizole
D. Lipid emulsion
E. Sugammadex

A. Lipid emulsion

Local anesthetic toxicity can be treated with IV 20% lipid emulsion

This woman is suffering from local anaesthetic toxicity. The most common symptoms initially are confusion, drowsiness, and dizziness, however, this can progress to seizures, respiratory arrest, and coma. Treatment includes life support measures and benzodiazepines to control seizures. The most appropriate reversal agent is intravenous lipid emulsion which is, therefore, the correct answer.

Atropine is effective at treating bradycardia however is not the reversal agent for local anaesthetic toxicity. Whilst this woman is bradycardic, this is very likely to be refractory to treatment solely with lipid emulsion without co-administration of atropine.

Flumazenil is the reversal agent for benzodiazepine overdoses however has no role in local anaesthetic toxicity. In this instance, benzodiazepines are indicated to control the seizures and flumazenil would only act to further lower the seizure threshold.

Fomepizole is the reversal agent for ethylene glycol or methanol which can cause reduced consciousness but has no role in local anaesthetic toxicity which is the diagnosis here.

Sugammadex is the reversal agent for muscle relaxants such as rocuronium. Muscle relaxants are not administered during the insertion of an arterial line and therefore sugammadex is not indicated here.

Question 2 of 138

A 24-year-old man with a history of depression and self-harm is brought to the emergency department by a friend 2 hours after an impulsive overdose of ferrous sulphate. He weighs 65kg and has ingested 65 x 200mg ferrous sulphate tablets. This is equivalent to 4225mg of elemental iron (65mg/kg).

On assessment, he denies any abdominal pain, diarrhoea or vomiting.

Observations are as follows:

- Temperature 36.5
- Respiratory rate 18/min
- Saturations 98% on air
- Heart rate 82bpm
- Blood pressure 136/74 mmHg

Venous blood results show:

Hb	133 g/l	Na +	139 mmol/l	Bilirubin	8 µmol/l
Platelets	287 * 10 /l 9	K +	4.1 mmol/l	ALP	89 u/l
WBC	8.3 * 10 /l 9	Urea	3.4 mmol/l	ALT	34 u/l
Neuts	6.2 * 10 /l 9	Creatinine	72 µmol/l	Albumin	40 g/l
Lymphs	1.9 * 10 /l 9	Serum iron	70 umol/l		
Eosin	0.2 * 10 /l 9	pH	7.40		

Abdominal x-ray demonstrates the presence of iron in the stomach.

What is the appropriate initial medical management

A. Whole bowel irrigation
B. Activated charcoal
C. Emergency endoscopy for removal of iron from the stomach
D. Observe and repeat iron levels 4-6 hours after ingestion
E. Administer desferrioxamine

A. Whole bowel irrigation

Question 3 of 138

A 31-year-old gentleman, with known ulcerative colitis, presents with a three-day history of profuse bloody diarrhoea. He reports opening his bowels up to 12 times each day and describes passing both bloody stool and frank blood.

On examination he is pale. His heart rate is 95 beats per minute, respiratory rate 16 breaths per minute, blood pressure 128/78 mmHg. His chest is clear to auscultation and his abdomen is soft but diffusely tender. The patient is ambulant and despite his diarrhoea appears relatively well.

The patient is diagnosed with a flare of his ulcerative colitis. Intravenous access is obtained and fluids and intravenous steroids given.

Admission bloods show:

Hb	102 g/l
Platelets	556 * 10 /l9
WBC	17.5 * 10 /l9
ESR	78 mm/h

Regarding his venous thromboembolism prophylaxis, what should happen during this admission? ?

A. Compression stockings only

B. No prophylaxis due to active bleeding
C. Intermittent pneumatic compression devices
D. Prophylactic dose low molecular weight heparin and compression stockings
E. Treatment dose low molecular weight heparin and compression stockings

D. Prophylactic dose low molecular weight heparin and compression stockings

The severity of a flare of ulcerative colitis can be categorised used the Truelove and Witt criteria:

SEVERITY	MILD	MODERATE	SEVERE
Bowel movements per day	fewer than 4	4-6	>6 and features of systemic upset
Blood in stools	Small amounts	Between mild and severe	Visible blood
Pyrexia (temp >37.8ºC)	No	No	Yes
Pulse >90 bpm	No	No	Yes
Anaemia	No	No	Yes
ESR (mm/hr)	30 or below	30 or below	Above 30

Based on these criteria, this patient can be defined as suffering an acute severe flare of ulcerative colitis which is a medical emergency. Intensive treatment with intravenous steroids and early surgical intervention has reduced the mortality from acute severe ulcerative colitis to 2.9% however the colectomy rate of 30% in acute flares has not changed for 40 years.

Whilst this patient is complaining of passing blood per rectum an acute flare of ulcerative colitis is an extremely prothrombotic state and as a result, the British Society of Gastroenterology recommends that all patients should receive subcutaneous heparin to reduce the risk of thromboembolism. Intermittent pneumatic compression devices are a form of venous thromboembolism prevention that has evidence in acute stroke so is not the correct answer here. Whilst the patient is in a prothrombotic state, there is no indication for treatment dose low molecular weight heparin and this would increase the patient's risk of excessive blood loss.

Question 4 of 138

A 67 year old man is admitted to the Emergency Department following a deliberate overdose of an unknown drug. On assessment he is unwell and vomiting although he is maintaining an airway. Oxygen saturations are 100% on 15L/min supplemental oxygen and his respiratory rate is 32/min. His chest is clear and heart sounds are rapid. An ECG shows sinus tachycardia with a rate of 135bpm, a broad QRS complex and a QTc 520msec. His skin is flushed and hot. He complains of ringing in his ears and visual blurring as well as abdominal pain. Tympanic temperature is 37.5°C.

Blood results show:

Haemoglobin	101g/L	Sodium	131mmol/L	pH	7.11
White cells	7.8x10^9/L	Potassium	2.9mmol/L	pCO2	2.4kPa
Platelets	97x10^9/L	Urea	9.3mmol/L	pO2	78.4kPa
INR	1.3	Creatinine	198µmol/L	HCO3-	6.3mmol/L
APTT	33secs	Glucose	2.8mmol	BE	-19.7
Chloride	94mmol/L	Lactate	2.4mmol/L		

During assessment he has a generalised tonic-clonic seizure.

Which of the following drugs is he most likely to have overdosed on

A. Ibuprofen
B. Isocarboxazid
C. Paracetamol
D. Quinine
E. Venlafaxine

D. Quinine

Quinine toxicity (cinchonism) presents with myriad **ECG changes**, hypotension, metabolic acidosis, **hypoglycaemia** and classically tinnitus, flushing and visual disturbances. Flash pulmonary oedema may occur

Paracetamol toxicity presents with early hepatotoxicity and coagulopathy, and later renal failure and encephalopathy which are features lacking in this clinical scenario.

Ibuprofen, a non-steroidal anti-inflammatory, is relatively safe in overdose although massive ingestion may cause gastrointestinal ulceration and haemorrhage as well as electrolyte imbalances, coagulopathy and prominent cerebellar signs. This is not commented upon in the clinical vignette.

Venlafaxine is a selective serotonin and noradrenaline reuptake inhibitor and presents with symptoms of serotonin and sympathetic overdrive in poisoning, including agitation, sweating, hyperpyrexia, clonus, tachycardia and hypertension. ECG abnormalities similar to the above may occur, as may hypoglycaemia but venlafaxine is not the most likely agent.

Isocarboxazid is a monoamine oxidase inhibitor and in overdose may also cause symptoms of the serotonin syndrome although sympathomimetic features tend to predominate, including hyperglycaemia.

Question 5 of 138

A 28-year-old female with a history of cerebral palsy is admitted for an elective intrathecal pump refill. The procedure unfortunately was unsuccessful and the pump could not be re-sited. Later on in the evening the patient complains of severe pain in her lower limbs and feels generally unwell.

Blood results are as follows:

Hb	145 g/l	Na^+	138 mmol/l
Platelets	525 * 10 /l 9	K^+	5.6 mmol/l
WBC	14.1 * 10 /l 9	Urea	12.8 mmol/l
Neuts	8.4 * 10 /l 9	Creatinine	156 µmol/l
Creatine kinase	8445 Units/litre (normal range 24-170)	CRP	44 mg/l

What drug is the patient withdrawing from?

A. Lidocaine
B. Baclofen
C. Pethidine
D. Clonidine
E. Ketorolac

B. Baclofen

Intrathecal baclofen withdrawal syndrome is associated with severe spasticity, rhabdomyolysis, acute renal failure and multisystem organ failure

Intrathecal baclofen can be used to treat spasticity. It can be administered continuously via a pump. It is believed to work by agonising GABA receptors.

Discontinuation of baclofen can be associated with a withdrawal syndrome which resembles benzodiazepine withdrawal and alcohol withdrawal. Intrathecal baclofen withdrawal syndrome is associated with severe spasticity, rhabdomyolysis, acute renal failure and multisystem organ failure.

Question 6 of 138

A 76-year-old man presented with shortness of breath to the emergency department. On the basis of a recent knee replacement operation and unremarkable chest x-ray a CT pulmonary angiogram was performed and demonstrated a segmental pulmonary embolus with evidence of mild right heart strain. The patient was haemodynamically stable and required only minimal supplemental oxygen therapy.

The patient had known chronic kidney disease stage IV secondary to type 2 diabetes and hypertension. Treatment was therefore initiated with an intravenous unfractionated heparin infusion.

The patient's condition was stable over the following week with warfarin loading cautiously started at day 6 of admission. Routine blood tests at this point indicated a new abnormality in full blood count leading to further investigations as detailed below.

Haemoglobin	14.5 g / dL
White blood cells	8.6 x 10>3 / microlitre
Neutrophils	4.5 x 10>3 / microlitre
Lymphocytes	2.1 x 10>3 / microlitre
Platelets	67 x 10>3 / microlitre
Mean cell volume	85 fL
Mean cell haemoglobin	30.1 pg
B12	252 pmol / L
Folate	20 nmol / L

Heparin induced thrombocytopenia antibodies: positive (high titre)

Following cessation of IV heparin infusion,

what is the appropriate management of the patient's thrombocytopenia?

A. Bivalirudin
B. Enoxaparin
C. Warfarin
D. Tirofiban
E. Platelet transfusion

A. Bivalirudin

This patient has a confirmed diagnosis of heparin induced thrombocytopenia (HIT) based on the suggestive clinical picture and positive HIT antibody screen. Decision tools such as the Warkentin probability scale can be useful by providing a pre-test probability score of HIT based on the clinical picture. In this case, the timing of thrombocytopenia with onset between 5-10 days after initial exposure to heparin is highly suggestive.

In suspected or confirmed cases of HIT, heparin anticoagulants must be withheld immediately. Treatment with a non-heparin anticoagulant such as bivalirudin should be started to reduce the risk of HIT-related thrombosis. Vitamin K antagonists such as warfarin such be withheld or reversed as they do not prevent HITassociated thrombosis and increase the risk of venous gangrene. Platelet transfusion would not be indicated in this patient.

Question 7 of 138

A 24-year-old man is brought to the emergency department having developed acute confusion and fever. The family tell you he was well on going to bed last night then become poorly over several hours this morning.

He has a background of depression for which he takes sertraline. His mother tells you he has recently been trying some over-the-counter remedies for his depression and has also been complaining of lower back pain, for which he has started new painkillers. A set of observations are available.

Respiratory rate 30/min
Oxygen saturation 97% on air
Heart rate 120/min
Blood pressure 184/106mmHg
Temperature 39.1ºC

On examination, you find him to be agitated and disorientated. Neurological assessment reveals generalised rigidity and brisk reflexes. His pupils are dilated and you note marked myoclonus at both ankles. An ECG shows sinus tachycardia with a normal QRS duration.

What treatment is indicated?

A. Cyproheptadine
B. Dantrolene
C. Glucagon
D. N-acetylcysteine
E. Sodium bicarbonate

A. Cyproheptadine

Treatment of severe serotonin syndrome- cyproheptadine (5-HT2 receptor antagonist)

The correct answer is **cyproheptadine**. This is a 5-HT2 receptor antagonist used in the treatment of serotonin syndrome. Key features include rigidity, tachycardia, hyperpyrexia and hypertension. In this case, the rapid onset, dilated pupils and brisk reflexes support this as the diagnosis. The over-the-counter remedy and new painkiller may represent St. John's wort or tramadol, both of which may interact with SSRIs such as sertraline to induce this syndrome.

Dantrolene is incorrect. This is the treatment for neuroleptic malignant syndrome. This syndrome is associated with antipsychotics rather than anti-depressants. It also generally is of slower onset than serotonin syndrome and presents with normal pupils and diminished reflexes.

Glucagon is incorrect. This is a treatment used in the management of beta-blocker overdose. There is no suggestion this patient has ingested these in the case described. The presentation is also not in keeping with beta-blocker toxicity, particularly tachycardia.

N-acetylcysteine is incorrect. This is the antidote for paracetamol overdose. Although this may be the painkiller he is taking for his back pain, it would not account for the clinical features described. Paracetamol overdose generally causes hepatotoxicity.

Sodium bicarbonate is incorrect. This can be used in the management of tricyclic antidepressant overdose. The case does not describe ingestion of these, and significant toxicity is associated with a widening of the QRS complex leading to ventricular arrhythmias. In this case, we are told the QRS is normal, which would go against significant TCA toxicity.

Question 8 of 138

A 17 year old girl is brought to the Emergency Department following a prolonged seizure lasting seven minutes. She is known to suffer from epilepsy and has been stable on lamotrigine for eight years, having on average only one generalised tonic clonic seizure every eight months. Her mother describes an increase in her seizure frequency over the last four weeks; she has has three generalised tonic-clonic seizures during this period, each lasting around three minutes. There have been no changes to stress levels, sleep pattern or diet. She confirms she has however started a new medication for dysmenorrhoea.

Which is the most likely to explain this increase in frequency?

A. Medroxyprogesterone (Depo-Provera)
B. Mefenamic acid
C. Ibuprofen
D. Aspirin
E. Naproxen

B. Mefenamic acid

Taking a full medication history is an essential aspect of any history; it can be particularly important in epilepsy, not only to gauge medication compliance and anti-epileptic therapy, but to determine any precipitating factors.

Analgesics that are known to induce seizures or worsen seizure control include fentanyl, mefenamic acid, and tramadol (among others). Other drugs that are known to induce seizures include amitriptyline, aminophylline, isotretinoin and haloperidol.

It is important to be aware of the interaction between contraception and antiepileptic medication; contraceptive failure, teratogenicity and reduced seizure control are potential effects.

P450 enzyme inducers will decrease the drug level and therefore increase the failure rate of oestrogen and progesterone containing contraceptives.

- Carbamazepine
- Oxcarbazepine
- Phenytoin
- Phenobarbitone
- Primidone
- Topiramate

Lamotrigine is not a P450 inducer. Studies have shown a slight decrease in levonorgestrel levels, although the clinical significance is undetermined. Levels of lamotrigine are reduced by oral contraceptives containing ethinylestradiol, increased seizure frequency may therefore occur. There is no evidence that progestogen-only methods affect lamotrigine levels.

Question 9 of 138

A 34-year-old man is seen in the emergency department at 5 am on Saturday morning in a state of extreme agitation. He is alert from the end of the bed, tremulous and diaphoretic. His respiratory rate is 26 breaths per minute, oxygen saturation 97% on air, heart rate 132 beats per minute, blood pressure 185/103mmHg and temperature 38.2ºC. There is bilateral air entry on auscultation of the chest with vesicular breath sounds. His peripheries are clammy, hot to touch and his pulse is fast and bounding. His heart sounds are normal with no added murmurs. His JVP is not raised. He is talking to you but is confused. Pupils are equal and reactive to light but markedly dilated. There is no lateralising neurology.

The nurse cannulates the patient and takes blood. The initial investigation results are as follows:

ECG	sinus tachycardia, 1mm T wave inversions in V2-V6
Urine dipstick	+ protein +++ haemoglobin

Venous blood gas:

pH	7.32	7.31-7.41
pO 2	5.35 kPa	4.0-5.3 kPa
pCO 2	4.73 kPa	5.5-6.8 kPa
Lac	3.2 mmol/L	<2.0 mmol/L
Glucose	6.4 mmol/L	4.0-7.8 mmol/L
HCO3	24 mmol/L	23-29 mmol/L
BE	-3	-2 - +2

What would be the next most appropriate management step?

A. Aspirin, clopidogrel, fondaparinux and sublingual glycerine trinitrate
B. CT aortogram
C. IV benzodiazepines
D. IV labetalol
E. IV 8.4% sodium bicarbonate

C. IV benzodiazepines

Treatment of cocaine toxicity is largely supportive with judicious usage of benzodiazepines

This man displays signs of cocaine toxicity with dilated pupils, hypertension, tachycardia, anxiety, likely myoglobinuria secondary to rhabdomyolysis and myocardial strain. The management would involve IV benzodiazepines. Nitroglycerine can also be useful in the face of coronary vasospasm.

It is important to bear in mind that β-blockers are contraindicated in cocaine toxicity due to the risks of the unopposed α-agonist activity. For this reason, IV labetalol would not be the next most appropriate management step.

Aspirin, clopidogrel, fondaparinux and sublingual glycerine trinitrate would be the first line if you suspected a non-ST elevated myocardial infarction. In this case, the main concern is cocaine toxicity which is causing signs of rate-dependent ischemia on the ECG. First line management would be benzodiazepines which would help to resolve this issue.

A CT aortogram would be useful if you suspected aortic dissection. There is no strong evidence that this is occurring and cocaine toxicity is the more likely diagnosis in this case.

IV 8.4% sodium bicarbonate is useful for overdoses of tricyclic antidepressant but it is not the next most appropriate management step in the case of cocaine toxicity.

Question 10 of 138

A 55-year-old man presents to the Emergency Department after taking an overdose. He can not tell you which of his regular tablets he has taken an overdose of. His past medical history includes Crohn's disease, gastroesophageal reflux disease, hypertension, gout, depression and paroxysmal atrial fibrillation.

He is complaining of chest pain and shortness of breath. Observations - respiratory rate 26/min, saturations 94% on air, heart rate 50/min, blood pressure 75/40 mmHg, temperature 37.2ºC.

His ECG shows atrial fibrillation with a broad QRS. Which drug is the most likely culprit?

A. Flecainide
B. Amitriptyline
C. Allopurinol
D. Azathioprine
E. Diltiazem

A. Flecainide

Flecainide is the most likely culprit here due to the chest pain, signs of heart failure and prolonged QRS. Diltiazem would be also be possible, but in overdose would likely show a more marked bradycardia with heart block.

Flecainide is a Vaughan Williams Class Ic anti-arrhythmic drug, associated with PR, QRS, and QTc prolongation on the electrocardiogram and development of life-threatening cardiac toxicity in overdose.

The cornerstone of treatment is fluid resuscitation and the administration of magnesium and sodium bicarbonate. Intravenous fat emulsion has also been trialed with some success.

Note - flecainide should NOT be used in patients who have a structurally abnormal heart due to the risk of causing arrhythmias, including torsades de pointes.

Question 11 of 138

A 27 year old well-nourished male electroplater is admitted to hospital with abdominal pain and neurological symptoms. He tells you that he has had worsening symptoms for the past three months with severe central abdominal pain, diarrhoea, vomiting and painful burning sensation in both feet. He also describes increasing clumsiness with loss of manual dexterity and tripping over his feet frequently. He describes dimming of his vision over the past two weeks with a sepia tinge. On examination, there is mild voluntary guarding of the abdomen but no discrete masses and no organomegaly. The cardiorespiratory examination is normal. Examination of the neurological system reveals distal weakness with MRC power grade 4/5 in all limbs but normal proximal power. There is a mild tremor present with his arms outstretched and trunk ataxia. Sensory examination discloses painful paraesthesia in the hands and feet with hyperalgesia. There is a loss of proprioception. The cranial nerves are notable in that a left sixth nerve palsy is present with accompanying diplopia. Visual acuity is reduced to 6/30 bilaterally and eye movements are painful. He has a bilateral ptosis. He is noted to have minimal body hair, including hairless arms and legs, lateral third of the eyebrow and temporal and crown baldness which he tells you occurred in the past month. He also has scaling of the palms and soles, tender glossitis and transverse white lines on all his nails. He is cyclothymic during assessment.

What is the most appropriate management for this patient?

A. High dose IV hydrocortisone 200mg three times daily
B. High dose IV vitamin B complex (Pabrinex I+II) and folinic acid
C. Intravenous immunoglobulins
D. Oral Prussian Blue 10g twice daily
E. Procaine penicillin (G) 2 million unit daily IM with oral probenicid

D. Oral Prussian Blue 10g twice daily

Thallium poisoning is a rare cause of painful polyneuropathy, mood change and alopecia. Treatment is chelation therapy with oral Prussian Blue

The above clinical descriptor is classical for thallium poisoning. The triad of fluctuating mood, with or without confusion, painful distal paraesthesia and alopecia is virtually pathognomonic of toxicity with this heavy metal.

Thallium is a highly toxic metal; in its univalent Tl+ ion it is readily soluble in water and easily enters the body across the skin or gastrointestinal tract using potassium influx channels. Thallium fumes may also be generated on heating this metal and these may be inhaled when using it during many electroplating manufacturing processes. In the UK, the Health and Safety Executive stipulates that worker occupational exposure limits to thallium in any form must not exceed 0.1mg/m3 in an 8 hour period without adequate ventilation due to the health risks.

Thallium avidly binds to sulphur ligands within cellular proteins, disrupting many intracellular metabolic processes. In massive exposure, death from neuromuscular respiratory failure is rapid, but in more prolonged exposure insidious symptoms of neuropathy, abdominal pain, gastrointestinal bleeding, optic neuritis, confusion and weakness occur. Skin changes such as palm and sole scaling, stomatitis, glossitis, keratitis, eczema and classical alopecia and Mee's lines on the nails typically occur within two weeks of continual exposure. Treatment is with Prussian Blue which is administered orally at a dose of 250-300mg/kg/day (approximately 10g twice daily for an adult) and this complexes with thallium and is excreted in the faeces.

Thallium poisoning is often diagnosed late or not at all due to a low index of suspicion; indeed it is often misdiagnosed as Guillain-Barre syndrome due to the glove and stocking distribution of sensory symptoms and patients may receive intravenous steroids or immunoglobulins unnecessarily. In Guillain-Barre syndrome (GBS), classically there is ascending paralysis that is not seen in thallium poisoning and typically sensory symptoms in GBS are of numbness not hyperalgesia.

Thallium poisoning has also been mistaken for neurosyphilis and severe vitamin B deficiency. While neurosyphilis shares symptoms of confusion, fluctuating mood and palmar lesions as well as neuropathy, abdominal symptoms are usually not present and the diagnostic alopecia is absent in syphilis. Similarly, conditions such as Pellagra (niacin deficiency) and beriberi (thiamine deficiency) may share similar features with thallium poisoning such as alopecia, skin changes and mood disturbances, a painful neuropathy is less common; indeed sensory loss is more common in the extremities. Also in these conditions, the prime pathological aetiology is dietary deficiency and the history gives no suggestion this is an issue in this case.

Question 12 of 138

A 72-year-old male was admitted with 72 hours of progressive ascending motor weakness associated with palpitation and back pain. A diagnosis of Guillain-Barre syndrome was made and he was started on intravenous immunoglobulin (IVIg) with intensive monitoring on the neurology ward. You are asked to review the bloods of the patient on the fourth of five days of IVIg treatment. You note his sodium to have changes as follows: Na 145 → 141 → 134 → 130 → 126. The patient reports 'feeling better after the drip', denies any cough, shortness of breath, diarrhoea, nausea or vomiting. On examination, he appears comfortable in bed, JVP 2/3 cm above the angle of Louis, has warm peripheries and capillary refill time of 2 seconds. His chest is clear on auscultation, cardiovascular examination unremarkable and neurological examination unchanged from admission.

What is your management plan?

A. No action
B. Intravenous fluid
C. Fluid restrict to 1.5 litres
D. Contact endocrinology team regarding possible syndrome of inappropriate anti-diuretichormone (SIADH)
E. Contact intensive care unit regarding escalation and intubation

A. No action

The patient has received four days of intravenous immunoglobulin (IVIg), which is a protein and hence likely to distort the measurement of sodium, producing a pseudohyponatraemia. This is also observed in patients with high serum concentrations of triglycerides, cholesterol and in those with high serum protein such as myeloma patients. This patient is clinically euvolaemic. No action is required.

Question 13 of 138

A 63-year-old man is commenced on anti-tuberculosis therapy, after presenting to the hospital with a history of several months of weight loss, shortness of breath and a productive cough which was sometimes accompanied by haemoptysis.

A chest x-ray had revealed apical consolidation and sputum was positive for acid-fast bacilli, following which a diagnosis of tuberculosis was then made. His only past medical history includes a diagnosis of asthma for which he takes PRN salbutamol and Seretide (25 micrograms of salmeterol and 125 micrograms of fluticasone propionate) inhaler twice daily.

A week after being diagnosed, he is admitted to the acute medical unit with shortness of breath and bilateral expiratory wheeze. His observations reveal a temperature of 37.1ºC, respiratory rate of 27 breaths per minute and oxygen saturations of 94% on room air. Oxygen is commenced via a face mask. A chest x-ray reveals the same apical consolidation as before, with no new features.

What is the most appropriate next step in her treatment?

A. Continue the tuberculosis medication at current dose and increase the steroid dose
B. Continue the tuberculosis medication at current dose and decrease the steroid dose
C. Reduce the tuberculosis medication and increase the steroid dose
D. Stop the tuberculosis medication and increase the steroid dose
E. Continue the tuberculosis medication at current dose and keep the steroid dose the same

A. Continue the tuberculosis medication at current dose and increase the steroid dose

Rifampicin increases the metabolism of corticosteroids, thus patients who are on long-term steroids (as in this case) should receive a higher dose of corticosteroids when starting tuberculosis therapy.

Question 14 of 138

A 27-year-old man presents to his GP with generalised itchiness. This has been ongoing for some weeks and he has tried a number of creams over the counter. The GP provided a steroid cream and chlorphenamine tablets which helped initially but he is now finding he cannot sleep due to the itching. He has become tired and has been late to work as a fitness instructor several times. He denies alcohol use and is an ex smoker. His GP decides to perform some blood tests.

On examination, this well built gentleman looks well with scleral icterus present. There are numerous scratch marks across his torso and he has mild gynaecomastia. His abdomen is soft with no palpable masses. There are no spider naevi. His ankles are soft with no oedema. He has no rashes.

He mother has ulcerative colitis with liver complications and he has no past medical history.

Hb	180 g/l	Na +	145 mmol/l	Bilirubin 45 µmol/l
Platelets	459 * 10 /l 9	K +	3.0 mmol/l	ALP 189u/l
WBC	9.8 * 10 /l 9	Urea	4.5 mmol/l	ALT 61 u/l
Neuts	7.2 * 10 /l 9	Creatinine	95 µmol/l	γGT 213 u/l
Lymphs	1.2 * 10 /l 9	Albumin	45 g/l	
Anti smooth muscle antibody	negative	Anti liver kidney antibody	negative	

What is the likeliest cause of his deranged bloods?

A. Primary biliary cirrhosis
B. Alcoholic fatty liver disease
C. Primary sclerosing cholangitis
D. Anabolic steroid
E. Wilson's Disease

D. Anabolic steroid

Anabolic steroids are a cause of cholestasis

This gentleman presents with a symptomatic LFT rise. The ALP is raised out of proportion to the ALT making this a cholestatic picture which rules out AFLD and Wilson's disease. He has a family history for autoimmune disease but his antibodies are negative making PBC less likely. He is a well built gentleman and works in the fitness industry. Anabolic steroid use is highly prevalent especially with easy access through online sales. This gives an isolated cholestasis but can also give a polycythaemia through erythropoeisis and causes hypernatraemia and hypokalaemia. This should be discussed with the gentleman.

Question 15 of 138

A 29-year-old man is brought to the emergency department after the sudden onset of severe leftsided chest pain.

His observations are taken as follows: temperature 37.2ºC, blood pressure 165/92 mmHg, pulse 129/min and regular, and respiratory rate 20/min. On examination, he is anxious, diaphoretic and agitated. His nasal mucosa is atrophic, and both pupils are dilated. On auscultation, heart sounds are regular with no murmurs or rubs, and the lungs are clear.

An initial ECG shows ST-segment elevation in leads V4-V6. A chest x-ray is normal. His laboratory studies show:

Reference range		
Haemoglobin	165 g/L	Men: 135-180 g/L Women: 115-160 g/L
White blood cells	8.5 * 10 /l 9	4.0-11.0 * 10 /L9
Platelets	310 * 10 /l 9	150-400 * 10 /L9
Sodium	139 mmol/L	135-145 mmol/L

Potassium	4.5 mmol/L	3.5-5.0 mmol/L
Urea	3.5 mmol/L	2.0-7 mmol/L
Creatinine	94 umol/L	55-120 umol/L
Troponin T	32 ng/L	<14 ng/L

Which of the following treatment options must be avoided in this patient?

A. Aspirin
B. Diazepam
C. Diltiazem
D. Labetalol
E. Nitroglycerin

D. Labetalol

Cocaine toxicity - avoid beta-blockers

This patient is presenting with acute cocaine toxicity complicated by myocardial ischaemia. Hints pointing towards cocaine toxicity are excessive sympathetic stimulation, including tachycardia, dilated pupils and sweating. Cocaine toxicity can cause coronary artery vasospasm, giving rise to myocardial ischaemia. Troponin T levels are raised in myocardial ischaemia. The treatment of myocardial ischaemia in patients with and without cocaine intoxication is similar other than one important distinction: **patients with cocaine intoxication are not given beta-blockers**. The rationale behind these guidelines is that beta-blockage can lead to unopposed alpha-adrenergic stimulation and worsening coronary vasoconstriction.

Aspirin is routinely used to treat patients with myocardial infarction, especially those with cocaine intoxication. Cocaine can induce thrombus formation by activating platelets, stimulating their aggregation, and increasing thromboxane production. Patients with aortic dissection, another common complication of cocaine intoxication, should not be given aspirin. This patient's chest xray is normal, and his presentation does not point towards aortic dissection, making aspirin a recommended drug in this case. Aortic dissection presents with severe chest pain radiating to the back or between the shoulder blades. The chest x-rays in such cases often show a widened mediastinum.

Patients with cocaine intoxication often present with psychomotor agitation. In such patients, like this one, IV diazepam is given until the agitation is controlled.

Calcium-channel blockers (diltiazem and verapamil) are used as adjunctive therapy in patients who continue to have ischaemic symptoms despite using nitroglycerin. It is not contraindicated in patients with acute cocaine intoxication.

Sublingual nitroglycerin is one of the first drugs administered to patients presenting with ischaemic chest pain. Both nitrates and calcium channel blockers are beneficial for cocaineinduced coronary artery vasoconstriction.

Question 16 of 138

A 28-year-old woman was admitted to the Emergency Department drowsy and unwell after a suspected suicide attempt at home. The patient was under the care of the community psychiatry and had been receiving treatment for schizoaffective disorder. There was no other known past medical history. The paramedics bringing the patient to hospital also had brought the medications they found in the patient's home including quetiapine, levomepromazine, zopiclone and oxazepam. The paramedics reported that they had not seen evidence of empty medication packets or blister packs at the patient's home.

Initial assessment of the patient was unremarkable except for reduced consciousness level. Basic observations at presentation are listed below.

Blood pressure: 150/79 mmHg Heart rate: 89 bpm Respiratory rate: 20 / min O2 saturations (15 L O2):100 % Glasgow coma score: M5 V3 E2 Blood glucose: 7.0 mmol / L Temperature: 36.8ºC

Results from an arterial blood sample (15 L O2) were as follows.

pH	7.19
PaCO2	3.3 kPa
PaO2	21.2 kPa
Bicarbonate	8.9 mmol / L (reference 20.0-26.0)

Sodium	142 mmol / L
Potassium	3.6 mmol / L
Calcium	2.13 mmol / L (reference 2.20-2.60)
Chloride	110 mmol / L (reference 99-108)
Urea	5.2 mmol / L
Creatinine	110 micromol / L
Lactate	26 mmol / L
Plasma osmolality	380 mmol / Kg (reference 280-295)
Haemoglobin	12.0 g / dL

Based on the above blood results, what is the most likely cause of the patient's reduced consciousness level?

A. Ethanol intoxication
B. Benzodiazepine overdose
C. Ethylene glycol intoxication
D. Quetiapine overdose
E. Chronic renal failure

C. Ethylene glycol intoxication

The patient is unwell with a severe lactic acidosis. However, there is no clinical evidence for conditions that may cause this state (such as shock, hypoxia, sepsis or lactate-inducing drugs). Calculation of the anion gap and osmolality gap provide further clues to the likely cause.

Anion gap = Sodium - (Chloride + Bicarbonate) = 23.1 mmol / L (reference 5-11)

Osmolality gap = Measured osmolality - ((2*Sodium) + Urea + glucose)) = 83.8 mmol / Kg (reference < 6)

A severe lactic acidosis may cause a small osmolality gap (< 10 mmol / Kg) but is not consistent with the high value in this case). Possible causes of a high osmolality gap include pseudohyponatraemia (in extreme hyperproteinaemia or hyperlipidaemia), chronic renal failure or excess of toxic alcohols or glycols.

However, in the case of ethanol intoxication or pseudohyponatraemia the osmolality gap is not associated with a metabolic acidosis. Given that the blood results do not suggest evidence of chronic renal failure, the most likely cause is ethylene glycol intoxication. Testing for serum levels of methanol and ethylene glycol would confirm the diagnosis. Appropriate treatment is with ethanol and haemodialysis.

There is no evidence from the collateral history that the patient had taken an overdose of her prescription medications and this would not explain the metabolic abnormalities.

Question 17 of 138

A 17-year-old girl is brought to the Emergency Department by ambulance after her drink was 'spiked' at a party. Her friends recall her complaining that she felt like she was having an 'out of body experience' and that everything she touched seemed artificial. Over the next hour, she became increasingly distressed, slurring her words and appearing off-balance when walking.

Her past medical history is unremarkable. Her friends state that she does not usually partake in recreational drug use and had only consumed 2 or 3 alcoholic drinks during the course of the evening.

Examination reveals a slim young female with a temperature of 37.3, a pulse of 113bpm and a blood pressure of 137/76mmHg. Her pupils measure 5mm in diameter and she is GCS 14/15 due to persistent confusion. Her chest is clear and her heart sounds are unremarkable. Her abdomen is soft and non-tender. Neurological examination reveals bi-directional nystagmus and truncal ataxia with no focal weakness. Her deep tendon reflexes are brisk and symmetrical.

Which drug is she most likely to have been exposed to?

A. Ecstasy
B. Methoxetamine
C. Cocaine
D. Gamma-hydroxybutyric acid (GHB)
E. Nexus (2C-B)

B. Methoxetamine

Both ecstasy and cocaine could cause the tachycardia, hypertension, mydriasis and marginally elevated temperature described in the above scenario. The 'dead giveaway' however, is the presence of dissociative symptoms in combination with an acute cerebellar syndrome, pointing strongly towards methoxetamine intoxication.

Methoxetamine is an analogue of ketamine; a dissociative anaesthetic that acts as a NMDA receptor antagonist. Its effects are typical of the adverse effects of ketamine and include tachycardia, hypertension, mydriasis, confusion and agitation. Nystagmus, dysarthria, and ataxia can be severe and persist for several days.

GHB is a relatively short-acting CNS depressant that causes euphoria followed by coma. Patients can often be roused by external stimuli before returning to a comatose state. Rapid, spontaneous recovery can occur and patients have been known to extubate themselves.

Nexus (2C-B) is a synthetic phenylethylamine with psychoactive and stimulant effects. It is typically snorted or ingested with the former typically causing intense nasal pain. Its effects on the CNS include euphoria, synaesthesia, hallucinations and increased visual and tactile sensation, and probably occur due to antagonism of the 5HT2 receptor. Nexus (2C-B) is also an alpha-1 receptor agonist and its use can lead to ischaemic complications.

Question 18 of 138

A 35-year-old woman is referred to oncology. She has recently been diagnosed with metastatic breast cancer, which is HER2 positive. She has no other past medical history. She does not smoke or drink alcohol. She is an artist and lives with her husband and two young children.

She is commenced on trastuzumab.

The concurrent administration of which medication or medications should be avoided?

A. Carboplatin and paclitaxel
B. Docetaxel and cyclophosphamide
C. Doxorubicin and cyclophosphamide
D. Pertuzumab
E. Pertuzumab and hyaluronidase-zzxf

C. Doxorubicin and cyclophosphamide

The combination of trastuzumab + anthracyclines (both often used for breast cancer) is particularly cardiotoxic

Doxorubicin and cyclophosphamide is the correct answer. This combination is particularly cardiotoxic and concurrent administration of trastuzumab and anthracyclines (doxorubicin) is not recommended.

Carboplatin and paclitaxel are not correct. This is a possible combination of chemotherapeutic agents that could be used in conjunction with trastuzumab to treated metastatic HER2 positive breast cancer.

Docetaxel and cyclophosphamide is not the right answer. This is a possible combination of chemotherapeutic agents that could be used in conjunction with trastuzumab to treated metastatic HER2 positive breast cancer.

Pertuzumab is incorrect. Research shows that adding pertuzumab to trastuzumab and chemotherapy as part of first-line therapy for HER2-positive metastatic breast cancer improves mortality.

Pertuzumab and hyaluronidase-zzxf is incorrect. This can be combined with trastuzumab to be administered as a single medication combination and is used in the treatment of metastatic HER2 positive breast cancer.

Question 19 of 138

A 19-year-old woman is referred to the acute medical team after presenting to the emergency department. The patient reports taking an overdose of paracetamol that evening, following an argument with her mother. She immediately regretted taking the overdose and asked her mother to take her to the hospital. She is now very upset and anxious that she has caused herself serious harm and is requesting treatment.

The patient took just under two packets of 500 mg paracetamol tablets (an estimated 28 tablets), 40 minutes prior to presentation to hospital. She denied any history of mental or physical health problems, and had never taken an overdose before. She took no regular medications and did not drink alcohol.

Examination revealed an alert but anxious young woman with observations within normal physiological parameters, and no abnormal physical signs.

Haemoglobin	128 g / dL
Mean cell volume	95.0 fl
White cell count	8.4 x 10>3 / microlitre
Platelets	198 x 10>3 / microlitre
Urea	4.3 mmol / L
Creatinine	67 micromol / L
Sodium	137 mmol / L
Potassium	4.3 mmol / L
Albumin	45 g / L (reference 35-50)
Alkaline phosphatase	56 U / L (reference 35-100)
ALT	34 U / L (reference 3-36)
Bilirubin	15 micromol / L (reference < 26)
International normalised ratio	1.1 (reference 0.8-1.2)

What is the most appropriate management of the patient's paracetamol overdose?

A. Treatment with activated charcoal if 4-hour paracetamol level > 100 mg / L
B. Immediate treatment with acetylcysteine
C. Haemodialysis
D. Immediate treatment with methionine

E. Immediate treatment with activated charcoal

E. Immediate treatment with activated charcoal

The patient has taken a large (> 10 g) paracetamol overdose and then presented to the hospital very promptly (< 2 hours). For such patients, activated charcoal should be considered as a first-line therapy, if the risk of aspiration is low. In practice, this means that the patient is either fully compliant with treatment (as in this example) or is intubated.

No randomised controlled trials have examined the role of activated charcoal in paracetamol overdose. However, a cohort study of patients who ingested > 10 g paracetamol, found that treatment with charcoal within two hours was associated with reduced need for acetylcysteine. If this link is assumed to be causal, then number needed to treat to avoid further treatment was 7. In addition, two randomised controlled trials have shown that activated charcoal is very safe.

The use of activated charcoal also increases elimination of anti-epileptic and contraceptive medications, and precautions should be taken against the short-term risk of treatment failure.

Treatment decisions regarding paracetamol poisoning antidote (acetylcysteine or methionine) should be guided by the 4-hour paracetamol level and reference to paracetamol poisoning nomogram. There is no benefit to treatment prior to the 4-hour paracetamol level result; hepatotoxicity following paracetamol toxicity does not occur until glutathione stores are depleted, around 8 hours after the overdose.

Haemodialysis removes only a small proportion of ingested paracetamol, as well as removing acetylcysteine. Therefore, it is not a therapeutic option in paracetamol overdose.

Question 20 of 138

A 78-year-old man with a history of atrial fibrillation, diabetes, hypertension and peripheral neuropathy was referred to the anticoagulation clinic by his General Practitioner due to difficulty controlling the international normalised ratio (INR). He is currently on 12 mg of warfarin and the dose had to be repeatedly increased as his INR has been in the subtherapeutic range in the last month.

Which one of the following medication may be responsible for the above?

A. Omeprazole
B. Carbamazepine
C. Cimetidine
D. Valproate
E. Ciprofloxacin

B. Carbamazepine

Carbamazepine is a P450 enzyme inductor

Carbamazepine is a hepatic enzyme inducer and may reduce the effectiveness of warfarin, whereas the others are enzyme inhibitors.

Others to remember are:

P450 enzyme inducers	P450 enzyme inhibitors
Phenytoin	Amiodarone
Rifampicin	Ketoconazole
Alcohol	Erythromycin
Isoniazid	
Sulphonamides	
Allopurinol	

Question 21 of 138

A 62-year-old man presents to the emergency department after drinking a small amount of methanol in an attempt to end his life. His observations are as follows: heart rate 110 beats per minute, blood pressure 130/85 mmHg, respiratory rate 22 breaths per minute, temperature 37.5ºC, and SpO2 95% on air. A fundoscopic examination is normal.

Blood results are as follows:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	165 * 10^9/L	(150 - 400)
WBC	14.8 * 10^9/L	(4.0 - 11.0)
Na^+	135 mmol/L	(135 - 145)
K^+	4.2 mmol/L	(3.5 - 5.0)
Urea	2.8 mmol/L	(2.0 - 7.0)
Creatinine	68 µmol/L	(55 - 120)
CRP	22 mg/L	(< 5)
Glucose	4.2 mmol/L	(3.9 - 5.6)
Serum osmolarity	305 mOsm/kg	(275 - 295)

You start the patient on fomepizole. What additional treatment is required?

A. Activated charcoal
B. Ethanol
C. Folic acid
D. Folinic acid
E. Haemodialysis

D. Folinic acid

Folinic acid can be used in methanol poisoning to reduce ophthalmological complications

The patient has clinical and biochemical features of methanol toxicity.

The osmolar gap = osmolality (measured) - osmolarity (calculated). A normal osmolar gap should be < 10.

The calculated osmolarity in this case = (2 x [Na+]) + [glucose] + [urea]) = 277 mOsm/kg. Therefore the osmolar gap = 305 - 277 = 28 mOsm/kg.

The patient thus has a high osmolar gap which indicates the presence of an abnormal solute present in significant amounts.

Causes of a high osmolar gap include:

- Mannitol
- Methanol
- Ethylene glycol

Folinic acid is correct. The clinical and biochemical features support a diagnosis of methanol poisoning. For patients with methanol intoxication, early administration of fomepizole will minimise the further metabolism of methanol and the development of clinical and metabolic complications. The addition of folinic acid can help reduce the accumulation of toxic byproducts in the eyes thereby reducing the associated ophthalmological complications.

Activated charcoal is incorrect. Activated charcoal is of no use since it does not adsorb significant quantities of methanol.

Ethanol is incorrect. Ethanol results in competitive inhibition of methanol thereby slowing down formic acid formation. Fomepizole is the preferred antidote since, unlike ethanol, it does not require regular monitoring of blood concentrations or cause inebriation.

Folic acid is incorrect. It is folinic acid rather than folic acid which has the best evidence base to reduce the ophthalmological complications of methanol.

Haemodialysis is incorrect. Haemodialysis has a role in severe or refractory cases. Indicators of severe disease include a methanol concentration greater than 500 mg/L, visual disturbance, features of CNS toxicity, severe metabolic acidosis and renal failure.

Question 22 of 138

A 57-year-old man attends neurology clinic. He has recently been diagnosed with Parkinson's disease and has agreed to start treatment with cabergoline as monotherapy. He has had a full examination, lung function tests, routine blood tests, chest X-ray and an echocardiogram.

Apart from a clinical review, what investigation is most important to arrange regularly to monitor for complications?

A. Chest X-ray
B. FBC
C. U&E
D. Echocardiogram
E. LFT

D. Echocardiogram

The correct answer is echocardiogram. Cabergoline is a dopaminergic drug which can be used to treat Parkinson's disease. Dopaminergic drugs are associated with fibrotic reactions including pulmonary, retroperitoneal and pericardial fibrosis, but cabergoline also assocaited with development of new valvulopathy. The BNF recommends establishing a baseline set of investigations and then to monitor clinically for dyspnoea, persistent cough, chest pain, cardiac failure and abdominal pain or tenderness.

Question 23 of 138

A 52-year-old man is brought into the emergency department resuscitation room. He was found collapsed by his wife 40 minutes ago. He was last seen 3 hours prior. His wife is present, who informs you his past medical history consists of depression, osteoarthritis, sciatica and ischaemic heart disease.

His Glasgow coma scale was 13/15. Nystagmus was noted.

Observations: respiratory rate 28 breath/minute, oxygen saturations 100% on 15 litres of oxygen, heart rate 112 beats/minute, blood pressure 142/92mmHg. Electrocardiogram (ECG) is sinus tachycardia, but otherwise normal.

An arterial blood gas is done and bloods are sent to the lab.

Hb	143 g/L	Male: (135-180)Female: (115 - 160)
Platelets	383 * 10 /L $_9$	(150 - 400)
WBC	13.2 * 10 /L $_9$	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	5 mmol/L	(3.5 - 5.0)
Urea	9 mmol/L	(2.0 - 7.0)
Creatinine	135 µmol/L	(55 - 120)
CRP	14 mg/L	(< 5)
Glucose	6 mmol/L	(4-7)
Osmolality	322mOsm/kg	(275 - 295)
pH	7.31	(7.35-7.45)
pO2	26 kPa	(10-14)
pCO2	2.9 kPa	(4.5-6)
HCO3 -	12 mmol/L	(22-28)
Cl -	95 mmol/L	(95-105)

What is the most likely cause of this man's presentation?

A. Amitriptyline
B. Citalopram
C. Codeine
D. Ethylene glycol
E. Mirtazapine

D. Ethylene glycol

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

This question involves toxicology and utilising the anion gap and osmolar gap helps reach the diagnosis. The presentation of reduced GCS is non-specific and can occur in many toxidromes. From his observations, we can see that he has a high respiratory rate, despite normal saturations.

Assessing his arterial gas, he has a partially compensated metabolic acidosis. His high respiratory rate is helping to blow off CO2 to compensate. The anion gap can be calculated as 33 or 38 (depending on whether you include potassium in your calculation). This is high.

When osmolality is stated in a question regarding toxicology it is often worth calculating the osmolar gap - the difference between measured and calculated osmolality. Calculated osmolality is 2Na + glucose + urea. The normal range of the osmolar gap is less than 10. In this case, it's 27.

Common causes of a high osmolar gap in toxicology are ethylene glycol, ethanol and methanol. Out of these three, only ethylene glycol is an option and so this is the most likely answer.

Paracetamol and selective serotonin reuptake inhibitors may cause high anion gap metabolic acidosis indirectly by causing acute kidney injury, but are not typically associated with a high osmolar gap.

Amitriptyline is a tricyclic. Within 1-2 hours of onset of toxicity they tend to cause hypotension and tachycardia, classically broad-complex. This progresses to seizures and reduced level of consciousness. This patient is not hypotensive and the ECG is not broad-complex so this is less likely.

Codeine is an opioid and so you expect to find respiratory depression if this was the case in this patient.

+

Question 24 of 138

You are in the general medical clinic. A 37-year-old male has been referred by his GP with dyspnoea. His symptoms started about 5 months ago with dyspnea mostly on exertion which is progressively getting worse. He also has a dry cough for last 2 months. There is no orthopnoea or paroxysmal nocturnal dyspnoea. There is also no history of chest pain. His past history includes Hodgkin's lymphoma which was successfully treated 2 years ago with ABVD regimen. He is currently not taking any medications. He works in a printing press and does not smoke. On examination, there is no raised JVP or ankle oedema. Auscultation revealed normal heart sounds and bilateral fine crackles. Results of his investigations are as follows:

Hb	125 g/l	Na +	139 mmol/l	Bilirubin	12 µmol/l
Platelets	188 * 10 /l $_9$	K +	4.1 mmol/l	ALP	95 u/l

WBC	6.7 * 10 /l 9	Urea	4.3 mmol/l	ALT	15 u/l
Neuts	3.5 * 10 /l 9	Creatinine	86 µmol/l	γGT	45 u/l
Lymphs	2.2 * 10 /l 9	ESR	25 mm/hr	Albumin	34 g/l
Eosin	0.3 * 10 /l9				

Chest x-ray normal

What is the next best investigation for evaluation of this patient?

A. Bronchoalveolar lavage (BAL)
B. Mantoux test
C. Echocardiogram
D. Chest ultrasound
E. Pulmonary function tests

E. Pulmonary function tests

Bleomycin may cause pulmonary fibrosis

History is suggestive of interstitial lung disease most likely secondary to bleomycin and pulmonary function tests will aid in diagnosis by showing a restrictive pattern. Bleomycin is part of ABVD

regimen and known to cause pulmonary fibrosis. That's why baseline pulmonary function testing is important in patients receiving bleomycin.

BAL is an invasive procedure with non-specific findings in cases of drug-induced interstitial lung disease. Non-invasive investigations like pulmonary function tests and high-resolution CT (HRCT) are carried out first before proceeding for invasive tests.

Mantoux test can help exclude tuberculosis but tuberculosis is not the most likely diagnosis in the given scenario.

An echocardiogram can be used to exclude dyspnoea due to heart failure, however, there is no history of orthopnoea or paroxysmal nocturnal dyspnoea, and no findings of raised JVP, abnormal heart sounds or ankle oedema.

Chest ultrasound is not helpful unless a pleural effusion was suspected.

Question 25 of 138

A 48-year-old farmer is found collapsed in his workshop having left a suicide note and consumed unknown weedkillers and insecticides from his store. On arrival in the Emergency department, his Glasgow coma scale is 10, pupils are pinpoint and poorly reactive. His blood pressure is 100/70 mmHg, his pulse is 88 beats per minute and regular. He moans incomprehensibly when you palpate his abdomen. You are concerned about the possibility of a paraquat overdose.

How can you screen for it?

A. Serum NADPH testing
B. Serum free fatty acid testing
C. Urine copper sulphate testing
D. Urine ketone testing
E. Urine dithionate testing

E. Urine dithionate testing

Qualitative confirmation of paraquat in the urine is easily performed in any laboratory. The main role of this test is to confirm or exclude exposure to paraquat. The presence of paraquat is confirmed by a colour change noted after the addition of a dithionite solution. The test is usually positive within six hours of a large ingestion and remains positive for several days. It's important not to wait for the results of the test before administering oral Fuller's earth.

The other options have no value in the evaluation of paraquat poisoning. Serum free fatty acids may rise where there is mitochondrial dysfunction, as may urinary ketones. Serum lactate is used in evaluation of metabolic dysfunction associated with cyanide poisoning.

Question 26 of 138

A 35-year-old man was assessed in endocrinology clinic after being referred by his GP for advice on management of the consequences of the patient's use of anabolic steroids. The patient reported that he had been using anabolic steroids intermittently for the previous 10 years to augment his weight-training regime. Having recently become aware of the potential adverse health consequences , the patient now wished to know how he could safely stop his anabolic steroid use.

The patient described his pattern of anabolic steroid use: typically, he had been taking a 'cycle' of one or more oral synthetic testosterone derivatives for between 6-12 weeks, prior to a 3-4 week break in his use of steroids. The patient stated this strategy was an attempt to minimise his risk of side effects. The patient had not received any medical supervision of his anabolic steroid use, relying instead on discussions with friends at his gym and information from online forums. The patient declined to disclose the source from which he had obtained his supply of medications.

The patient stated that he believed his anabolic steroid use had contributed to his male pattern baldness and also had caused intermittent breakouts of acne on his chest and face. The patient was not aware of any other symptoms related to his steroid use, although stated that he was concerned about possible lasting cardiac side effects. The patient had no other significant medical history and took no other regular medications. He did not consume cigarettes, alcohol or recreational drugs.

General examination of the patient revealed a muscular and lean adult male in apparent good health. A cardiovascular system examination noted a forceful but not displaced apex beat. Mild gynaecomastia was present but gastrointestinal examination was otherwise unremarkable. Using an orchidometer the patient's testicular volume was estimated as 16 ml. Although anxious about the possible health consequences of his anabolic steroid use, the patient did not seem to be significantly depressed or anxious.

Haemoglobin	173 g / dL
Sodium	148 mmol / L
Potassium	3.6 mmol / L
Alkaline phosphatase	135 U / L (reference 35-100)
ALT	32 U / L (reference 3-36)
Bilirubin	20 micromol / L (reference < 26)
Prolactin	469 mU / L (reference 80 - 400)
Luteinising hormone	0.9 IU / L (reference 1.8 - 8.6)

Follicle-stimulating hormone	1.2 mU / ml (reference 1.5 - 12.4)
Fasting LDL cholesterol	4.1 mmol / L (reference < 3.0)
Fasting HDL cholesterol	1.0 mmol / L (reference > 1.2)
HbA1C	45 mmol / mol (reference < 42)

What is the appropriate advice to the patient regarding the safe cessation of anabolic steroid use?

A. Convert patient to prescribed testosterone replacement and taper over 1 year
B. Taper anabolic steroid use over period of 6 months
C. Stop immediately, tapered withdrawal not required
D. Taper anabolic steroid use over period of 6 weeks
E. Convert patient to prescribed testosterone replacement and continue lifelong

C. Stop immediately, tapered withdrawal not required

The patient has typical side effects and examination findings associated with long-standing anabolic steroid use. These include male pattern baldness, acne, gynaecomastia and testicular atrophy (typical adult male testicular volume around 25 mL). His blood tests also demonstrate typical abnormalities including erythropoiesis, hypernatraemia, hypokalaemia, cholestatic liver function tests, deranged lipid profile, evidence of elevated serum glucose and typical hormone profile abnormalities.

Question 27 of 138

A 50 year-old man presents to the medical assessment unit with a two day history of nausea and vomiting. His notes are currently not available to you, and the patient is unable to recall his medical problems. He is currently an inpatient at the local psychiatry facility.

On examination, he appears drowsy with an ataxic gait. Neurological examination reveals normal tone with generalised reduced power. He also has a coarse tremor when his hands are outstretched.

Cardiorespiratory examination reveals is unremarkable.

ECG- sinus arrhythmia at 90 beats per minute. T wave inversion in leads V1-V3.

Observations

- Blood pressure- 150/90 mmHg
- Heart rate- 90 beats per minut
- Respiratory rate- 16 breaths per minute
- Oxygen saturations- 99% on room air
- Temperature- 37.3°C

What is the most likely cause of his symptoms?

A. Lithium toxicity
B. Alcohol withdrawal
C. Serotonin syndrome
D. Neuroleptic malignant syndrome
E. Tricyclic antidepressant overdose

A. Lithium toxicity

Lithium salts are used in the prophylaxis and treatment of bipolar disorder, refractory depression and aggressive or self-harming behaviour.

Lithium has a narrow therapeutic range (0.5-1 mmol/l). The likelihood of toxicity increases with increasing serum lithium levels. Toxic effects are seen with a concentration of >2 mmol/l.

Very early features may be non-specific, such as apathy and restlessness

Early signs of toxicity (1-2 mmol/l)

- anorexia and vomiting
- ataxia and dysarthria
- nystagmus
- blurred vision
- coarse tremor drowsiness

Late signs of toxicity (>2mmol/l)

- coma
- seizures
- acute renal failure
- death

Serotonin syndrome is a drug reaction to serotonergic agents, and ranges from mild to severe. It is characterised by a triad of autonomic hyperactivity (hyperthermia, tachycardia), neuromuscular abnormality (tremor) and mental state changes (confusion, coma).

Neuroleptic malignant syndrome is a rare reaction to neuroleptic drugs, often following initiation or increase in dose. It is characterised by recent neuroleptic use, hyperthermia, rigidity and autonomic dysfunction.

Question 28 of 138

A 28-year-old man is brought into the emergency department by paramedics. He was found collapsed by his wife just outside the house. With the paramedics he was rousable and they initially suspected he was drunk.

On transfer, he has become more drowsy but is still talking on physical stimuli. Initial venous blood gas shows a metabolic acidosis with a high anion gap. Lab blood results show:

Hb	148 g/L	Male: (135-180)Female: (115 - 160)
Platelets	345 * 10 /L 9	(150 - 400)
WBC	12.5 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	5.2 mmol/L	(3.5 - 5.0)
Bicarbonate	18 mmol/L	(22 - 29)
Urea	12 mmol/L	(2.0 - 7.0)
Creatinine	148 µmol/L	(55 - 120)
Glucose	6.2 mmol/L	(4-10)
Osmolality	307 mOsm/kg	(275-295)
Paracetamol levels	<5 mg/L	(<5)
Salicylate levels	<5 mg/dL	(<5)

What is the most appropriate treatment?

A. Chlorpromazine
B. Cyproheptadine
C. Ethanol
D. Fomepizole
E. Haemodialysis

D. Fomepizole

Ethylene glycol toxicity management - fomepizole. Also ethanol / haemodialysis

Reduced consciousness is a non-specific symptom of poisoning. Looking at his blood tests show kidney injury, a mild inflammatory response and a high osmolality. The blood tests allow us to calculate whether there is an osmolar gap.

Calculated osmolarity = 2Na + glucose + urea

Calculated osmolarity = 2(135) + 6.2 + 12 = 288.2

Lab osmolality = 307

Osmolar gap = Osmolality (measured) - Osmolarity (calculated)
Osmolar gap = 307 - 288.2 = 18.8 (normal is <10)

There are several causes of an osmolar gap, including ethanol, isopropyl alcohol, methanol, ethylene glycol, and mannitol. **Fomepizole** is the treatment option used in the management of methanol or ethylene glycol poisoning which is likely to be the cause in this patient.

Chlorpromazine may be used in the management of serotonin syndrome. Although serotonin syndrome can cause metabolic acidosis, it would not explain the osmolar gap.

Cyproheptadine may be used in the management of serotonin syndrome. Although serotonin syndrome can cause metabolic acidosis, it would not explain the osmolar gap.

Ethanol is incorrect, as although it can be used in methanol and ethylene glycol poisoning, fomepizole is the superior antidote so is a better treatment if available. Ethanol has many issues as a treatment, including being difficult to dose and maintain appropriate levels.

Haemodialysis has a role in refractory cases of ethylene glycol toxicity. However, in this case, 1stline management should be tried first, and therefore this answer is incorrect.

Question 29 of 138

A 75-year-old man underwent a right hemicolectomy as radical treatment for a caecal adenocarcinoma. During the immediate post-operative period the patient was noted to be significantly confused and investigations to assess for a septic source were requested. Blood tests indicated new neutrophilia and thrombocytopenia. Noting that the patient had been started on enoxaparin for venous thrombosis prophylaxis on the first day after the operation, heparin induced thrombocytopenia antibodies were requested by the surgical junior team.

A specialist medical review was requested on day 6 post-operatively to assess the patient in the light of the results of these investigations. The patient was found to be back to his cognitive baseline and was starting to mobilise on the ward with the help of physiotherapy. Clinical examination was unremarkable except for the healing abdominal surgical incision.

Aside from his recent cancer diagnosis, the patient's past-medical history included only hypercholesterolaemia treated with simvastatin. He had no known allergies or drug sensitivities.

Blood result	Pre-operatively	Day 1 post-op	Day 4 post-op	Day 6 post-op
Platelets (x 10>3 / microlitre)	175	95	125	141
Neutrophils (x 10>3 / microlitre)	5.3	14.8	12.8	8.8
C-reactive protein (mg / L)	6	142	94	25
International normalised ratio	1.0	1.2	1.1	1.1

Chest x-ray: clear lung fields aside from minor bibasal atelectasis

Urine culture: no growth

CT abdomen: minimal abdominal free fluid, no evidence of focal collection, large bowel anastomoses intact

Heparin-induced thrombocytopenia antibodies: positive (moderate titre)

What is the likely cause for the patient's thrombocytopenia?

A. Heparin induced thrombocytopenia
B. Post-operative sepsis
C. Post-operative thrombocytopenia
D. Thrombotic thrombocytopenic purpura
E. Disseminated intravascular coagulation

C. Post-operative thrombocytopenia

Heparin induced thrombocytopenia (HIT) antibodies have a high false positive rate and their interpretation needs to take into account careful consideration of the entire clinical picture. Decision tools to assess the likelihood of HIT such as the Warkentin probability scale are useful in this setting. This provides a pretest probability score to assist with interpretation of HIT antibody results based on the extent of the thrombocytopenia, the timing of onset relative to heparin administration, thrombotic events and the presence or absence of other causes of thrombocytopenia.

In this case, there are few clinical features consistent with HIT and a low pretest probability score would be calculated. The combination of this and moderate titre positive HIT antibodies is considered to exclude a HIT diagnosis.

In this patients case a post-operative thrombocytopenia is the most likely cause in the absence of evidence for other possible answers. The patients elevated inflammatory markers are secondary to surgery with no septic source identified on investigation. TTP can cause thrombocytopenia associated with delirium, although the patients clinical and haematological recovery make this an unlikely cause. DIC is excluded by the normal prothrombin time and improving clinical picture.

Question 30 of 138

A 49-year-old woman has attended the clinic with a 3-month history of heat intolerance, weight loss, and intermittent diarrhoea.

She has a past medical history of paroxysmal ventricular tachycardia and type 2 diabetes mellitus. Her regular medications include amiodarone, metformin, and linagliptin.

On clinical examination, she is mildly tremulous with prominent skin capillaries. She is tachycardia but has no audible murmurs. A neck examination does not reveal a goitre.

Thyroid function tests are requested.

Free T4	42.1	11.0 - 23.0
TSH	0.05	0.35 - 5.00

Given the likely diagnosis, what is the best management option?

A. Carbimazole
B. Levothyroxine
C. Potassium perchlorate
D. Prednisolone
E. Propylthiouracil

D. Prednisolone

In amiodarone induced thyrotoxicosis type 2 the management is with corticosteroids rather than carbimazole

The above case describes a patient with signs and symptoms commonly associated with hyperthyroidism. In combination with ongoing treatment with amiodarone, the diagnosis of amiodarone-induced thyrotoxicosis (AIT) can be made. AIT can be sub-divided into type 1 and type 2. This should not be confused with amiodarone-induced hypothyroidism which is thought to be due to the high iodine content of amiodarone.

Type 1 AIT is caused by excessive iodine from amiodarone causing increased thyroid hormone synthesis, whereas AIT type 2 is related to destructive thyroiditis. The two variations can be clinically distinguished by the presence (AIT type 1) or absence (AIT type 2) of a goitre. Given that the patient in the above scenario has no clinical findings of a goitre, AIT type 2 can be diagnosed. This is treated with corticosteroids, such as prednisolone.

Carbimazole is a well-recognised anti-thyroid medications commonly used in hyperthyroidism. It acts by reducing T3 and T4 production via thyroid peroxidase. It is an option in the management of AIT type 1.

Levothyroxine is used for thyroid hormone replacement in hypothyroidism and can be used in amiodarone-induced hypothyroidism.

Potassium perchlorate is an oxidising agent used as an anti-thyroid agent in thyrotoxicosis. It acts by competitively inhibiting iodine uptake in follicular thyroid cells. Along with carbimazole, it is a management option in type 1 AIT.

Although a treatment option in hyperthyroidism, propylthiouracil is not used in the management of amiodarone-induced thyrotoxicosis.

Question 31 of 138

A 35-year-old woman presents to the emergency department with agitation and sweating. She was recently started on paroxetine for depression. She takes St John's Wort over the counter. There is no history of substance abuse.

On examination, various muscle groups have sudden, brief involuntary twitching. She is diaphoretic, agitated and confused. There is hyperreflexia. She has a heart rate of 124 beats per minute and a temperature of 40ºC.

An ECG demonstrates sinus tachycardia.

Given the likely diagnosis, what is the appropriate treatment?

A. Bisoprolol
B. Co-amoxiclav
C. Cyproheptadine
D. Dantrolene
E. Procyclidine

C. Cyproheptadine

Treatment of severe serotonin syndrome- cyproheptadine (5-HT2 receptor antagonist)

Cyproheptadine is correct. The patient has serotonin syndrome as a consequence of the interaction between St. John's Wort and paroxetine. Her presentation is clinically severe and she should be treated with cyproheptadine, which is a 5-HT2 receptor antagonist. Milder cases can be treated with benzodiazepines alone.

Bisoprolol is incorrect. Sinus tachycardia does not tend to need treatment with cardiovascular medications and the treatment should be against the underlying cause.

Co-amoxiclav is incorrect. While the patient has a fever, the clinical history of the recent combination of an SSRI and St. John's Wort along with myoclonus and hyperreflexia suggest serotonin syndrome rather than infection.

Dantrolene is incorrect. This is the treatment for malignant hyperthermia. This is also characterized by high fever and muscle spasms but occurs post exposure to inhalational anaesthetics or depolarising muscle relaxants.

Procyclidine is incorrect. This is an anti-cholinergic drug used in the treatment of drug-induced Parkinsonism.

Question 32 of 138

A 47-year-old man has been referred to the endocrinology clinic. He has a history of hypertension and bipolar disorder. He can recall his antihypertensives, lisinopril, and amlodipine, but cannot remember which medication he is on for his bipolar disorder.

Recently he has developed polydipsia and polyuria. His GP performed some blood tests and found elevated blood glucose. His HbA1c is sown below.

HbA1C	62 mmol/mol	42 - 48

What medication is the most likely cause?

A. Aripiprazole
B. Lithium
C. Olanzapine
D. Risperidone
E. Sertraline

C. Olanzapine

Long-term use of olanzapine is a significant risk factor for the development of type 2 diabetes mellitus

Although the pathophysiology is not known, it is recognised that **olanzapine** carries a significant risk for the development of type 2 diabetes mellitus, along with other antipsychotic agents. Olanzapine has an antagonistic effect on muscarinic acetylcholine receptor 3 which has been found to be crucial in glucose-induced insulin resistance. Olanzapine also leads to hyperglycaemia through its antagonistic effects on dopamine 2 receptors (increased appetite), H1 histamine receptors (insulin resistance) and 5-HT2A serotonin receptors (insulin resistance).

As with all antipsychotic medications, **aripiprazole** can cause hyperglycaemia, however, it carries a small risk, compared to olanzapine which carries significant risk.

Long-term use of **lithium** can increase blood glucose levels. However, it carries a risk of the development of diabetes insipidus rather than diabetes mellitus.

Risperidone carries an intermediate risk of weight gain and the development of diabetes. The risk of diabetes development is higher with olanzapine.

According to the BNF, **sertraline** should be used with caution in people with known diabetes. This is due to its increased effect on insulin secretion thus increasing the risk of hypoglycaemia. Sertraline has not been shown to increase the risk of type 2 diabetes.

Question 33 of 138

A 20-year-old man is brought to the Emergency Department by the Police with agitation and aggression. He is accompanied by a friend, who says they had been out celebrating his brother's birthday and that the patient may have 'snorted something'.

He recalls the patient complaining of intense nasal pain for some time after he allegedly took the substance, but it soon settled and he seemed in good spirits; talking enthusiastically about seeing vivid lights and waves emanating from the club's speakers. As the night went on, however, he became increasing disturbed; shouting at other clubgoers and complaining about hearing threatening voices.

On examination, his temperature is 39.2ºC. His pulse is 117bpm and his blood pressure is 181/98mmHg. He is difficult to examine due to intermittent aggression, and he has lashed out on several occasions.

In order to ensure his own safety, a decision to sedate the patient is made. The patient is successfully restrained and cannulated but suffers a tonic-clonic seizure shortly afterward. He is given 4mg IV lorazepam, but then suffers a cardiac arrest from which he cannot be resuscitated.

Which drug is most likely to be responsible?

A. Lysergic acid diethylamide (LSD)
B. Nexus (2CB)
C. Spice
D. Gamma-hydroxybutyric acid (GHB)
E. Methoxetamine

B. Nexus (2CB)

Nexus is a designer drug belonging to the 2C family; a group of ring-substituted phenethylamines similar in structure to 3,4-methylenedioxy-N-methylamphetamine (MDMA). 2C refers to the presence of two carbon atoms between the amine group and the benzene ring in the chemical structure.

Common features of 2C intoxication include agitation, aggression, and hallucinations, often complicated by the presence of serotonergic or sympathomimetic toxidromes. It is possible to increase the hallucinogenic effects of these drugs by placing substituents on the aromatic ring at positions 2, 4, or 5. Synthesis of 2C drugs by amateur chemists can, therefore, lead to the inadvertent formation of dangerously potent agents.

2Cs are ingested orally or by insufflation, with the latter being extremely painful. At low doses, 2Cs have stimulating effects and cause increased visual, auditory and tactile sensations. Hallucinations occur at moderate doses, whilst high doses can cause frightening hallucinations, hypertension, tachycardia, hyperthermia, seizures and excited delirium.

Patients with excited delirium often exhibit aggression, hyperactivity, hyperthermia and, as in this case, unexpected cardiac arrest. It is thought to relate to excessive dopamine release in the mesolimbic pathways and has been linked to a number of 2C-related deaths.

LSD is also a hallucinogen, but it would not cause the hypertension or hyperthermia evident in the vignette. Fatal overdose is rare.

GHB is a CNS depressant that causes euphoria followed by coma. It has a short duration of action and toxicity is often maximal at presentation.

Methoxetamine is a ketamine derivative that causes dissociative symptoms, tachycardia, hypertension, confusion, and occasionally an acute cerebellar syndrome. It does not typically cause hallucinations.

Spice is a synthetic cannabinoid. Like marijuana, spice is usually smoked or ingested orally. Intoxication results in elevated mood, relaxation, and altered perception. Spice, however, is more likely than marijuana to cause hypertension, tachycardia, seizures and acute psychosis.

Question 34 of 138

A 74-year-old man presents increasing ankle swelling but is otherwise well. The swelling is uncomfortable and impacting on his quality of life. He takes amlodipine 10mg once daily (OD) and losartan 75mg OD. His blood pressure is 128/73 mmHg in clinic. His examination reveals pitting oedema in the ankles but nil else. He had a recent chest radiograph which was normal and an echocardiogram that showed good systolic function.

What action would you take?

A. Add furosemide 20mg once daily
B. Add spironolactone 25mg once daily
C. Fluid restrict to 1.5 litres a day
D. Reduce amlodipine to 5mg once daily
E. Prescribe compression stockings

D. Reduce amlodipine to 5mg once daily

This is likely a medication side effect given his normal echocardiogram. Amlodipine is heavily associated with ankle swelling. Therefore its dose should be reduced and if the blood pressure rises a further agent can be added.

There is no indication for diuretic therapy at this stage since there is no heart failure and the blood pressure is controlled.

Question 35 of 138

A 19-year-old female is admitted to the ward with reduced conscious level. Her mother found her at home lying on her bedroom floor. She has a past medical history of anxiety, depression, and hypothyroidism. On examination her heart rate is 110 beats per minute, blood pressure 124/80 mmHg, and respiratory rate is 36 breaths per minute.

Blood results are as follows:

Hb	122 g/l	Na +	134 mmol/l
Platelets	488 * 10 /l 9	K +	5.6 mmol/l
WBC	14.2 * 10 /l 9	Urea	10.8 mmol/l
Neuts	11.8 * 10 /l 9	Creatinine	158 µmol/l
Lymphs	1.8 * 10 /l 9	CRP	42 mg/l
Chloride	105 mmol/l		

An arterial blood gas is as follows:

PaO2	10.1 kPa
PCO2	2.2 kPa
pH	7.28
HCO3	12 mmol/l

What is the most likely diagnosis?

A. Addisonian crisis
B. Intracerebral hemorrhage
C. Morphine overdose
D. Encephalitis
E. Salicylate overdose

E. Salicylate overdose

Salicylate overdose can cause a mixed primary respiratory alkalosis and metabolic acidosis

The patient clearly has a metabolic acidosis as demonstrated by the low pH and low bicarbonate. With a primary metabolic acidosis we would expect the body to compensate by generating a respiratory alkalosis. Indeed this patient has hyperventilation and a low PCO2 indicating respiratory alkalosis. However it is important to remember that there is a limit for respiratory compensation. Even though respiratory compensation occurs relatively quickly, it can take up to twelve hours to reach maximal capacity.

The maximal respiratory compensation for metabolic disturbance can be calculated with:

pCO2 (maximal response in kPa) = (0.2 * HCO3) + 1

If the patient's pCO2 lies within 0.5 kPa of this calculated value, then the respiratory response is appropriate. If the pCO2 is higher then either the compensation is in a very early stage or the patient has a superimposed respiratory acidosis. In this case we would expect a maximal compensation of 3.4 kPa. The pCO2 value is actually less than this indicating we also have a superadded primary metabolic alkalosis.

When dealing with a metabolic acidosis it is also important to work out the anion gap which is very useful for identifying the cause. In this case the anion gap = (Na + K) - (Cl +HCO3) = 22.6. This is a high anion gap metabolic acidosis (HAGMA). Causes of HAGMA include ketoacidosis, uraemia, lactic acidosis and toxins (e.g. salicylates, ethylene glycol and methanol).

The combination of HAGMA with a superadded primary respiratory alkalosis makes salicylate overdose the most likely diagnosis. Salicylates toxic effects on the brainstem result in hyperventilation and respiratory alkalosis.

Encephalitis can also affect the brainstem resulting in abnormal respiratory patterns and respiratory acid base balance disorders. However we would not expect there to be a severe HAGMA as evident in this case.

Morphine overdose typically causes respiratory depression resulting in a respiratory acidosis.

An Addisonian crisis typically causes a normal anion gap metabolic acidosis (NAGMA) and would not be associated with a primary respiratory alkalosis.

Question 36 of 138

You receive a request for a second opinion from a GP who has performed a general physical check on one of their new patients. He is a 54-year-old man who is from Thailand. He had been complaining of low mood, fatigue and sensitivity to the cold. His body mass index is 31 kg/m^2. The following is a list of investigations performed by the GP.

Na^+	141 mmol/l
K^+	4.8 mmol/l
Urea	9.8 mmol/l
Creatinine	142 µmol/l
CRP	4 mg/l

Bilirubin	14 µmol/l
ALP	86 u/l
ALT	27 u/l
Calcium	2.89 mmol/l
Albumin	39 g/l
TSH	24.0 mU/l
Free T4	0.8 pmol/l
Free T3	0.4 pmol/l

ECG: Heart rate 68, sinus rhythm, QRS width 128ms, flattened T waves V1 to V6

The patient has told the GP that he takes one medication regularly but is unable to give the name.

Which medication is most likely to cause the following abnormalities?

A. Bendroflumethiazide
B. Amiodarone
C. Lithium
D. Carbimazole
E. Propylthiouracil

C. Lithium

The answer is Lithium. Long-term treatments with Lithium causes hypothyroidism in up to a third of patients with middle-aged females being the most likely demographic to get this complication. In addition, Lithium therapy is known to cause hypercalcaemia and hyperparathyroidism. Longterm lithium therapy is well known to cause renal impairment and weight gain on Lithium is common too. Cardiac side effects are rare on lithium but the most common ECG changes are flattened T waves and a widened QRS complex, in particular, a modified Brugada pattern may be seen.

Options D and E can cause hypothyroidism but are not known to cause any of the other abnormalities seen. Option A can cause weight gain and hypercalcaemia but is not known to cause any of the other abnormalities seen. Option B can cause hypothyroidism and similar ECG changes as seen here but is not known to cause any of the other abnormalities.

Question 37 of 138

A 23-year-old female student presents to the emergency department with a headache which has developed since starting her third year at university studying economics. She has also been noticing nausea and breathlessness. She had spent the summer travelling to Argentina and teaching English, after which she returned to the UK and moved into shared student accommodation in preparation for her next term. She had been well during her travels except for four days of diarrhoea shortly after she arrived. She has a past medical history of chlamydia which was treated by a local GUM clinic. She does not smoke and has minimal alcohol intake. On examination, she appears tired but otherwise well. Auscultation of her chest is normal. A urinary pregnancy test is positive.

Blood tests:

Hb	127 g/l
Platelets	336 * 10 /l9
WBC	9.4 * 10 /l9
Na^+	137 mmol/l
K^+	4.2 mmol/l
Urea	3.7 mmol/l
Creatinine	63 µmol/l

Arterial blood gas:

pH	7.41 g/l
pCO_2	3.6 mmHg
pO_2	9.4 mmHg
Na^+	137 mmol/l
FCOHb	22%

She is started on 15L of oxygen via a non-rebreather mask. How should she be further managed?

A. Wean off oxygen guided by standard pulse oximetry saturation levels
B. Add IV mannitol
C. Maintain high-flow oxygen until asymptomatic or carbon monoxide levels are <10%
D. Refer urgently for hyperbaric oxygen treatment
E. Arrange urgently for non-invasive ventilation

D. Refer urgently for hyperbaric oxygen treatment

This is a case of carbon monoxide poisoning in a pregnant patient and therefore needs urgent consideration of hyperbaric oxygen treatment. The danger of carbon monoxide poisoning to the foetus is significant as carbon monoxide has greater affinity to foetal heamaglobin and the placenta is unable to substantially compensate for reduced oxygen delivery. Whilst mild to moderate poisoning has not been shown to cause any adverse outcomes, severe maternal poisoning has been shown to cause neurobehavioural deficits when treated with normobaric oxygen alone.

Standard pulse oximetry would be unable to assess oxygenation levels in carbon monoxide poisoning. Whilst if this patient was not pregnant, there would be no indication for hyperbaric oxygen treatment and maintaining high flow oxygen until asymptomatic or carbon monoxide levels would be less than 10% would then be appropriate. Non-invasive ventilation has no role in carbon monoxide poisoning, and mannitol is only indicated in cerebral oedema.

Question 38 of 138

A 52-year-old male was brought to the emergency department by his wife after being found confused and unsteady whilst walking. He had been well that morning but his wife had found him confused about 2 hours prior to presenting in the emergency department. He had a background of alcohol excess and bipolar disorder, for which he was on lithium. His wife reported the patient had recently been low in mood, triggered by his recent job loss.

On examination, the patient was confused with a flushed complexion, slurred speech, horizontal nystagmus, and a marked ataxic gait. Observations were as follows:

oxygen saturations 97% on room air

heart rate 65 bpm

blood pressure 129/84mmHg temperature 37.2ºC

Blood results were as follows:

Creatinine	110 µmol/L	(55 - 120 µmol/L)
Urea	7 mmol/L	(2.0 - 7.0 mmol/L)
Na +	140 mmol/L	(135 - 145 mmol/L)
K +	4 mmol/L	(3.5 - 5.0 mmol/L)
Cl -	100 mmol/L	(96 - 106 mmol/L)
Bicarbonate	17 mmol/L	(22 - 29 mmol/L)
pH	7.24	(7.35 - 7.45)
Anion gap	27 mmol/L	(<16 mmol/L)
Glucose	5.0 mmol/L	(4.0 - 11.1 mmol/L)
Lactate	2.5 mmol/L	(<2.3 mmol/L)
Ethanol	7.2 mmol/L	(<0.1 mmol/L)
Osmolality	359 mOsm/kg	(285 - 295 mOsm/kg)
Osmolar gap	59 mOsm/kg	(<10 mOsm/kg)
Salicylate	negative	
Paracetamol	negative	
Lithium	pending	

What is the most likely cause of the patient's presentation?

A. Lithium overdose
B. Ethanol toxicity
C. Ethylene glycol toxicity
D. Wernicke's encephalopathy
E. Cyanide toxicity

C. Ethylene glycol toxicity

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

This question is looking at the calculation of both the anion gap and osmolar gap.

This patient presents with features of intoxication. He is acidotic and has a raised anion gap as follows: (Na+K) - (HCO3+Cl) = 144 - 117 = 27mmol/L.

A normal anion gap is <16 mmol/L.

He also has a raised osmolar gap. This is calculated using the following equation: Osmolar gap = measured osmolality - calculated osmolality.

- Measured osmolality = 359 mOsm/kg.
- Calculated osmolality = 2Na + glucose + urea = 288 + 7 + 5 = 300 mOsm/kg.
- Osmolar gap = 359 - 300 = 59 mOsm/kg.

A normal osmolar gap = <10 mOsm/kg.

We can add the ethanol concentration provided into our calculation of osmolality, to make it even more representative of the true osmolality. Despite this, we would still only have a calculated value of 307.2 mOsm/kg. This indicates that there is an unmeasured osmole present in the blood, causing a high osmolality, which is not explained by the presence of ethanol.

It is evident that this patient has consumed alcohol given the mildly raised serum ethanol concentration. Whilst ethanol toxicity can cause this presentation, the level is not high enough to account for such a severe presentation (according to Toxbase, symptoms of moderate toxicity such as ataxia and confusion typically occur when ethanol levels are 21.7 - 43.4 mmol/L). Furthermore, the high osmolar gap indicates the presence of another unmeasured osmole in the blood.

There are many causes of a high anion gap metabolic acidosis (please see the mnemonic CATMUDPILES below for a helpful way to remember these!). One such cause is a high concentration of serum lactate. This patient has a mildly raised lactate which could be caused by cyanide poisoning (cyanide toxicity is typically associated with signs such as 'cherry red' skin and confusion). However, whilst lactate can cause a high anion gap, it does not cause a high osmolar gap. Furthermore, cyanide poisoning severe enough to cause this presentation would typically be associated with a much higher lactate concentration (a lactate level of >7mmol/L is typically associated with cyanide poisoning). Lactate levels are often falsely elevated in ethylene glycol poisoning.

Lithium overdose is not associated with a raised osmolar gap and typically presents with nausea, tremor, and muscle weakness (early signs).

Wernicke's encephalopathy can present with confusion, ataxia, nystagmus, and ophthalmoplegia, particularly in those with a history of alcohol excess. However, this is due to a deficiency in thiamine and does not explain the metabolic abnormalities present.

Interestingly, the treatment for ethylene glycol poising is fomepizole or ethanol. There have been cases where the co-ingestion of ethylene glycol and ethanol has provided some protective benefit, but ethanol levels much higher than 7mmol/L are normally required.

Some causes of a raised anion gap metabolic acidosis can be remembered by the mnemonic CATMUDPILES (from lifeinthefastlane.com): -

- Cyanide, carbon monoxide –
- Alcoholic ketoacidosis –
- Toluene
- Methanol, metformin –
- Uraemia
- Diabetic ketoacidosis
- Phenformin, pyroglutamic acid, paraldehyde, propylene glycol, paracetamol –
- Iron, isoniazid
- Lactate (numerous causes) –
- Ethanol, ethylene glycol –
- Salicylates

Some causes of a high osmolar gap are also provided below (from lifeinthefastlane.com): -

- Mannitol –
- Methanol
- Ethylene glycol –

- Sorbitol
- Polyethylene glycol (IV lorazepam)
- Propylene glycol (IV lorazepam, diazepam, and phenytoin) –
- Glycine (TURP syndrome) –
- Maltose (IV IG - Intragram)

Question 39 of 138

A 57-year-old male is admitted to hospital with an acute kidney injury (AKI). His past medical history includes polycystic kidney disease for which he received a renal transplant 4 years ago, and type 2 diabetes mellitus. His drug history includes tacrolimus, mycophenolate mofetil, amlodipine and simvastatin. Tacrolimus toxicity is suspected to have caused his AKI.

He informs you that he has only recently been discharged, where he was started on rifampicin and erythromycin for Legionnaires' disease. He was also started on pioglitazone after a diabetic team review.

Which of his other medications is the most likely culprit of the tacrolimus toxicity?

A. Pioglitazone
B. Erythromycin
C. Simvastatin
D. Rifampicin
E. Mycophenolate mofetil

B. Erythromycin

Despite his complicated medical and drug history, this is a relatively simple question about drug interactions.

Erythromycin is a potent inhibitor of the cytochrome P450 system, which means it can have a rapid effect on levels of other drugs metabolised by this system, e.g. tacrolimus, warfarin.

Clarithromycin, fluconazole and clotrimazole are also inhibitors.

Rifampicin is an enzyme inducer, which would cause decreased tacrolimus concentrations, potentially leading to symptoms of organ rejection.

Question 40 of 138

A 23-year-old woman is reviewed following admission for paracetamol overdose. She ingested 25 grams of paracetamol and was started on N-acetylcysteine as her paracetamol level was 812 micromol/L eight hours following ingestion. She feels well, denying any abdominal pain or other symptoms.

At what point should N-acetylcysteine be stopped?

A. When INR <1.3 and ALT less than 2x upper limit
B. When abdominal pain resolved
C. When pH is >7.35
D. When paracetamol levels become undetectable
E. After 48 hours

A. When INR <1.3 and ALT less than 2x upper limit

The correct answer is when INR <1.3 and ALT less than 2x upper limit. Note that the primary measure of synthetic liver function is clotting which is why it is so closely monitored in paracetamol overdose and helps indicate when the liver is improving. pH is a useful measure for criteria for a liver transplant but is not helpful in most cases as it generally remains normal despite severe liver dysfunction. Abdominal pain is often present but not always and is therefore not a very sensitive marker. Paracetamol levels do not reflect the extent of liver damage and they can be very difficult to interpret in staggered overdoses. Depending on the extent of liver damage, treatment may need to be longer than 48hrs and in some cases shorter.

Question 41 of 138

A 62-year-old man is currently being treated with linezolid for MRSA bacteraemia.

Which of the following medications may need to be discontinued whilst this is being administered?

A. Metformin
B. Citalopram
C. Alendronic acid
D. Candesartan
E. Atorvastatin

B. Citalopram

Linezolid was originally discovered as a psychotropic agent with antidepressant effects through mild reversible nonselective inhibition of monoamine oxidase (MAO), before it was found to have antibiotic efficacy against drug-resistant gram-positive cocci. In combination with serotonin agonists there is a risk of serotonin syndrome. Therefore, when using linezolid it must be considered to discontinue SSRIs.

There are no known listed interactions between alendronic acid, candesartan and atorvastatin.

Linezolid may potentially enhance the hypoglycaemic effect of metformin. Therefore careful capillary glucose monitoring should occur in a patient on both medications, but this is not necessarily a reason to discontinue the drug.

Question 42 of 138

A 72-year-old lady is admitted with a tonic-clonic seizure. She was initially treated with two doses of 10mg diazepam however she failed to respond. She was then prescribed a loading dose of intravenous phenytoin and then prescribed maintenance dose phenytoin. Past medical history included a previous stroke, gallstones and hypertension. Drug history included clopidogrel, amlodipine, simvastatin. She recovered well and was discharged 6 days later.

Three weeks after her hospital admission she visits her GP accompanied by her husband complaining of feeling generally unwell and a rash. On examination she has a wide spread morbilliform eruption on most of her body and some mild right upper quadrant pain. The GP could palpate cervical and inguinal lymph nodes. Observations heart rate 110 regular, blood pressure 120/80, saturations 97% on air and temperature 38.2. The GP sends the patient to hospital for further tests. Bloods show:

Hb	110 g/l
WCC	14 * 10 /l9
Neutrophils	7.2 * 10 /l9
Eosinophils	2.3 * 10 /l9
Platelets	81 * 10 /l9
Na +	141 mmol/l

K +	4.3 mmol/l
Creatinine	101 µmol/l
Urea	6.8 mmol/l
Bilirubin	22 µmol/l
Alk phos	80 u/l
ALT	150 u/l
Albumin	32 g/l
INR	1.1

What is the most likely diagnosis?

A. Lymphoma
B. DRESS syndrome
C. Cholecystitis
D. EBV
E. Meningococcal septicaemia

B. DRESS syndrome

This patient has DRESS syndrome (drug reaction with eosinophilia and systemic symptoms) after starting phenytoin.

Question 43 of 138

You are asked to review a 75-year-old lady on the surgical ward. She has malignant carcinoma of the colon and had a large bowel resection seven days ago. Despite being on dalteparin since admission, she had developed a right-sided deep venous thrombosis (DVT). She tells you she had a similar problem ten years ago and had to take 'blood-thinning injections' for several months.

On examination, she looks well with no signs of respiratory distress. Her oxygen saturations are 99% on room air and on auscultation she has vesicular breath sounds throughout both lung fields.

Her pre-operative blood tests are as following:

Hb	119 g/l	Na +	135 mmol/l	Bilirubin	12 mol/l
Platelets	457 * 10 /l 9	K +	4.5 mmol/l	ALP	111 u/l
WBC	6.8 * 10 /l 9	Urea	4.9 mmol/l	ALT	45 u/l
Neuts	4.0 * 10 /l 9	Creatinine	81 µmol/l	γGT	30 u/l
Lymphs	0.9 * 10 /l 9	Albumin	34 g/l		
Eosin	0.0 * 10 /l9				

Her blood results today are as follows:

Hb	105 g/l	Na +	133 mmol/l	Prothrombin time	10.7 s
Platelets	77* 10 /l 9	K +	4.1 mmol/l	APTT	27.5s
WBC	7.6 * 10 /l 9	Urea	5.7 mmol/l	APTT ratio	45 u/l
Neuts	4.9 * 10 /l 9	Creatinine	98 µmol/l	D-Dimer	>1000 ng/ml
Lymphs	1.1 * 10 /l 9	Albumin	31 g/l		
Eosin	0.1 * 10 /l9				

Which of the following represents the optimal management for this patient while she remains an inpatient?

A. Warfarin
B. Bivalirudin
C. IV heparin infusion
D. Plasma exchange
E. Rivaroxaban

B. Bivalirudin

This lady has heparin-induced thrombocytopenia (HIT). She needs anticoagulation but should ideally be switched to a non-heparin drug for now. Bivalirudin is a direct thrombin inhibitor and is not associated with HIT.

Plasma exchange would be the treatment of choice for thrombotic thrombocytopenic purpura, which is not the case here.

Warfarin causes a rapid fall in protein C levels, risking complications such as skin necrosis, so is not used acutely.

Question 44 of 138

A 35-year-old man presents to the emergency department complaining of chest pain. He has no significant past medical history and does not take any regularly prescribed medications. He has been awake for twenty-four hours having ingested a large quantity of cocaine.

His observations are as follows: heart rate 111 beats per minute, respiratory rate 21/minute, blood pressure 180/100 mmHg, oxygen saturation 97% on room air and temperature 37ºC.

On examination, he is diaphoretic and anxious. Chest auscultation is normal. The heart sounds are normal with no added sounds or murmurs. The jugular venous pulse is not raised and there is no peripheral oedema. Abdominal and neurological examinations are normal.

ECG demonstrates sinus tachycardia with T wave inversion in leads V5-V6, I and AVL.

What medication should be avoided in this circumstance?

A. Aspirin
B. Benzodiazepines
C. Bisoprolol
D. Glyceryl trinitrate
E. Sodium nitroprusside

C. Bisoprolol

Cocaine toxicity - avoid beta-blockers

Bisoprolol is the correct answer. Beta-blockers should be avoided in cocaine-induced chest pain. The rationale is that beta-antagonism may result in unopposed alpha-mediated coronary vasospasm.

Aspirin is incorrect. This patient has an acute coronary syndrome and in addition to cocaine specific treatment, he will need antiplatelet treatment and coronary angiography.

Benzodiazepines are incorrect. This class of medication is used early in the treatment of cocaineinduced chest pain.

Glyceryl trinitrate is incorrect. This class of medication is used in the management of cocaineinduced chest pain.

Sodium nitroprusside is incorrect. The use of this may be indicated in those patients suffering from cocaine toxicity and persistent hypertension.

Question 45 of 138

A 68-year-old man is admitted with a two day exacerbation of COPD. He arrives unwell and is started on steroids, nebulisers, aminophylline, ciprofloxacin and non invasive ventilation. He improves well and is weaned off the ventilation by his second day but starts to complain of palpitations and chest pain on the third day. He is usually well taking fostair twice a day. He used to smoke and drinks 25 units of alcohol a week.

You review him and find he has a pulse of 134 beats per minute that is irregular. He is clammy and his blood pressure is 96/76mmHg. He has a chest that is wheezy throughout and is saturating at 91% with 2 litres of nasal cannulae oxygen. He is visibly trembling and feels nauseous. A cardiac monitor is attached showing an irregular narrow complex tachycardia.

Na +	145 mmol/l
K +	3.2 mmol/l
Urea	4.5 mmol/l
Creatinine	76 µmol/l
Theophylline level	28 mcg/ml (normal range 10-20)
ECG	irregular narrow complex tachycardia with no visible p-waves
Chest x-ray	hyperexpanded film, no consolidation seen

What is the likely cause of his drug toxicity?

A. Ciprofloxacin
B. Hypokalaemia
C. Anxiety
D. Hidden pneumothorax
E. Alcohol withdrawal

A. Ciprofloxacin

Quinolones -> inhibit liver enzymes -> risk of theophylline toxicity in COPD/asthma exacerbation

This gentleman has developed new fast atrial fibrillation despite his initial improvement. The hypokalaemia probably contributes but it is clear he is toxic with aminophylline. Aminophylline concentrations are highly sensitive depending on the speed of liver metabolism. Ciprofloxacin is a liver enzyme inhibitor and when started alongside aminophylline, patients can be slow to metabolise and rapidly develop theophylline toxicity unless the dose is reduced. Alcohol withdrawal and anxiety are two differentials if no abnormalities showed on the investigations. A hidden pneumothorax is unlikely to be the cause here.

Question 46 of 138

A 69-year-old woman attends the emergency department with a 2-day history of lower back pain after falling down the stairs. She has been taking 1g of paracetamol every 1-2 hours to control the pain but says this has not helped her symptoms. Over the last 8 hours, she now has developed right upper quadrant pain and nausea. Her last dose of paracetamol was 45 minutes ago.

Laboratory investigations:

Hb	123 g/L	(115 - 160)
Na +	137 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	77 µmol/L	(55 - 120)
Bilirubin	16 µmol/L	(3 - 17)
ALP	99 u/L	(30 - 100)
ALT	42 u/L	(3 - 40)
Paracetamol levels	35 mg/L	(10-30)

What is the most initial step in the management of this patient?

A. Activated charcoal
B. Initiate N-acetylcysteine
C. No treatment indicated
D. Referral to liaison psychiatry
E. Repeat paracetamol levels at 4 hours from last ingestion

B. Initiate N-acetylcysteine

This patient has taken a staggered overdose of paracetamol, having taken 1g every 1-2 hours for back pain. Regardless of the paracetamol level and where it corresponds on the treatment graph, patients should be immediately treated with **N-acetylcysteine** to prevent liver toxicity.

Activated charcoal is incorrect. This can be administered within the 1st hour of paracetamol ingestion, to reduce absorption. However, in the event of taking a staggered overdose, NICE guidelines recommend commencing N-acetylcysteine regardless of the paracetamol levels and time following ingestion.

No treatment indicated is incorrect. Not treating a staggered paracetamol overdose is dangerous and could lead to long-term hepatic complications or death from acute liver failure.

Referral to liaison psychiatry is incorrect. Whilst patients who have presented with a drug overdose should be considered for referral to liaison psychiatry, this patient has no other presenting signs to suggest an intentional overdose. Nevertheless, the most important initial step is to administer treatment with N-acetylcysteine prior to referring to liaison psychiatry.

Repeat paracetamol levels at 4 hours from last ingestion is incorrect. In most cases of paracetamol overdose, guidelines state that paracetamol levels should be taken 4 hours from the last ingestion. If the paracetamol levels are then over the treatment line, then treatment with Nacetylcysteine can be commenced. However, the exception to the rule includes a large overdose (>150mg/kg) or a staggered overdose of paracetamol.

Question 47 of 138

A 28-year-old lady is brought in by her mother having taken an overdose of an unknown medication. She has recently broken up with her boyfriend and has been fired from her job for turning up late to work persistently. She was found in her room by her mother with a small bottle of vodka which was empty and some burnt medication packaging. She has no history of mental health disease, although did self-harm (arm cutting) twice whilst a teenager. She has no medical history other than being treated for malaria during a recent trip to west Africa. The patient is tearful, regrets the overdose and is currently complaining of nausea, epigastric discomfort, slightly blurred vision and a ringing in her ears.

On examination, her heart rate is 115 beats/min, her blood pressure 98/48 mmHg and she appears flushed. Her respiratory rate is 18 breaths per minute and her oxygen saturations 98% breathing room air. Her Glasgow coma score is 15/15 and her pupils are equal and reactive. Her blood results are as follows.

Na +	135 mmol/l
K +	4.3 mmol/l
Urea	5.1 mmol/l
Creatinine	86 µmol/l
Bilirubin	18 µmol/l
ALP	65 u/l
ALT	56 u/l

What is the most likely toxin?

A. Quinine overdose
B. Ibuprofen overdose

C. Alcohol intoxication
D. Paracetamol overdose
E. Malarone overdose

A. Quinine overdose

Cinchonism is the syndrome described (blurred vision, tinnitus, nausea...) and can be secondary to quinine or quinidine ingestion as an overdose, but also less commonly with normal dosing. Although uncommon in the western world use of quinine as a drug in overdose is not uncommon in malaria endemic areas such as south-east Asia. The tinnitus may be associated with transient loss of high frequency hearing loss. The blurred vision can progress to complete blindness, which in some cases can be permanent. None of the other toxins would explain this toxidrome.

Question 48 of 138

A 65-year-old woman attends the emergency department complaining of three weeks of gradual visual loss. She has a past medical history of rheumatoid arthritis, type 2 diabetes, and pulmonary tuberculosis. Her medications include methotrexate, hydroxychloroquine, metformin, rifampicin, ethambutol hydrochloride, pyrazinamide, isoniazid and pyridoxine.

On examination, visual acuity is 20/50 in both eyes. There are central scotomas bilaterally on visual field testing. The macula and fovea are normal.

Blood tests:

ESR 88 mm/hr	(<20)
Hba1c	54 mmol/mol (<48)

What is the likely cause of her presentation?

A. Ethambutol treatment
B. Giant cell arteritis
C. Hydroxychloroquine treatment
D. Multiple sclerosis
E. Vitreous haemorrhage

A. Ethambutol treatment

Optic neuritis is common in patients taking ethambutol

Ethambutol treatment is correct. The patient presents with insidious onset painless loss of central vision. This is typical of optic neuropathy associated with ethambutol treatment. Eventually, the optic nerve may become visually abnormal but it may be normal early in the course of the disease. The raised ESR is likely due to either tuberculosis or rheumatoid.

Giant cell arteritis is incorrect. This can cause visual loss and a raised ESR. However, visual loss in giant cell arteritis (GCA) is typically unilateral and sudden rather than bilateral and progressive.

Hydroxychloroquine treatment is incorrect. This can cause painless bilateral loss of vision. However, we would expect macular oedema, which is absent here. Hydroxychloroquine (HCQ) retinopathy typically occurs when patients are treated with HCQ for extended periods of time i.e. > 5 years.

Multiple sclerosis is incorrect. This can cause optic neuritis. However, this is more likely to be painful and unilateral rather than painless and bilateral.

Vitreous haemorrhage is incorrect. This can occur as a complication of diabetes. However, it would typically be unilateral and cause sudden painless loss of vision. Additionally, blood may be visible on fundoscopic examination.

Question 49 of 138

A 45-year-old woman presents to the emergency department with bilateral hand tremor, unsteady gait, and blurry vision. Her past medical history is significant for bipolar disorder, which has been under control for the last year on lithium. Recently, her general practitioner started her on amlodipine for essential hypertension. Additionally, she started taking paracetamol and oral ibuprofen daily over the last week for knee pain related to a recent fall.

On examination, a coarse tremor is noted in both hands. There is also nystagmus, dysdiadochokinesia, and past pointing.

What is the best next step in managing this patient?

A. Increase lithium dose
B. Start haemodialysis
C. Stop amlodipine
D. Stop ibuprofen
E. Stop paracetamol

D. Stop ibuprofen

Lithium toxicity can be precipitated by NSAIDs

The patient presents with classic symptoms of lithium toxicity related to recent use of ibuprofen. **Increasing the dose of lithium** would cause further deterioration of her symptoms. Lithium should be held, and lithium levels should be measured to guide further management.

Management of lithium toxicity is mainly supportive. It is essential to discontinue lithium and the drug that precipitated lithium toxicity (e.g., ibuprofen, bendroflumethiazide) and consider administration of intravenous fluids based on the patient's fluid balance status. **Haemodialysis** may be required in the context of severe symptoms, kidney dysfunction, and significantly raised lithium levels, but it is not indicated as a first-line treatment for this patient.

Amlodipine does not interact with lithium and, as such, it can be continued for the management of essential hypertension.

This patient presents with classic features of lithium toxicity. This has been precipitated by ibuprofen ingestion. Non-steroidal anti-inflammatory drugs and thiazide-type diuretics can increase lithium levels and, as such, should be avoided in patients on lithium. In this case, **ibuprofen should be discontinued** in the first instance.

Paracetamol does not interact with lithium, and as such, it can be continued for the management of essential hypertension.

Question 50 of 138

A 24-year-old man presents to the accident and emergency department with his girlfriend after collapsing in a nightclub at 0400hrs. It is now 0600hrs On examination he is V on the AVPU scale with dry mucous membranes, he has flushed skin and feels very warm to the touch. There is mildly increased muscle tone, myoclonic jerks and hyperreflexia globally but worse in the lower limbs. Pupils are dilated but respond to light equally and bilaterally. He is disorientated and agitated during the examination, thrashing about in the bed and occasionally lashing out at people

Heart rate 126/min, blood pressure 90/60 mmHg, respiratory rate 18/min, temperature = 40.3°C, sats 97% on 10l of oxygen.

Na +	136 mmol/l

K +	3.9 mmol/l
Urea	2.3 mmol/l
Creatinine	77 µmol/l
Glucose	4.6 mmol/l
Creatinine kinase	12,000 U/l

Bilirubin	25 µmol/l
ALP	185 u/l
ALT	125 u/l
γGT	144 u/l
Albumin	40 g/l

CT Head: No abnormality detected. Lumbar puncture reveals:

Opening pressure	15 cmCSF
Appearance	Clear
Glucose	3.5 mmol/l
Protein	0.3 g/l

White cells	4 / mm^3

He has a past medical history of schizoaffective disorder. His girlfriend shows you his regular medications, the prescription has been unchanged for 1 year. Olanzapine 15mg and Sertraline 150mg. His girlfriend tells you that he took an unknown white powder whilst in the club

What is the most appropriate treatment plan?

A. IV Ceftriaxone
B. Stop Olanzapine and give dantrolene
C. Stop sertraline and give IV lorazepam and consider cyproheptadine
D. Give IV naloxone
E. Stop olanzapine and sertraline and supportive therapy

C. Stop sertraline and give IV lorazepam and consider cyproheptadine

The diagnosis is MDMA intoxication which has led to serotonin syndrome and rhabdomyolysis. The treatment for serotonin syndrome is stopping any serotonergic agents, using benzodiazepines for agitation and consideration of the use of serotonin antagonists such as cyproheptadine if there is severe autonomic disturbance. MDMA intoxication can lead to serotonin syndrome, especially if used in conjunction with any drug which increased serotonin transport across the synapses eg SSRIs such as sertraline.

Serotonin syndrome presents with agitation, reduced consciousness, flushing of the skin, hyperthermia, hyperreflexia, myoclonus (worse in the lower limbs), tachycardia, hypertension or labile BP. Most cases of serotonin syndrome present within 6 hours of any change in medication or dose i.e in this case after the MDMA.

Neuroleptic malignant syndrome would present in a similar way and would be treated by option B.However NMS usually evolves over 1-3 days with extreme muscle rigidity being a characteristic feature. NMS is less likely when on a lower potency antipsychotic such as Olanzapine and less likely when the dose has been stable for a long period of time.

Heroin overdose would not present with these features. Dilated pupils essentially rule this out and heroin is not usually a white powder which makes option D less likely.

Although meningitis can present with fever and reduced consciousness the normal LP rules out this diagnosis and therefore option A is an inappropriate treatment

Option E is inappropriate as this gentleman is severely unwell with autonomic instability, severe hyperthermia and significant rhabdomyolysis with renal impairment. Active management other than supportive treatment would be recommended for this individual if the diagnosis were NMS or serotonin syndrome

Question 51 of 138

A 65-year-old woman attends the clinic with shortness of breath. This has progressively worsened over the past 3 months. She also complains of swollen ankles. She has a past medical history of breast cancer which was treated with docetaxel, cyclophosphamide, trastuzumab, and radiotherapy. She also has rheumatoid arthritis for which she takes methotrexate.

On examination, you note bilateral pitting oedema to the mid calves and coarse crepitations to the mid zones of the lungs. Observations are as follows: heart rate 92 beats per minute, respiratory rate 18 breaths per minute, blood pressure 125/75 mmHg, SpO2 94% on air, and temperature 37.2ºC.

An echo is performed:

Echo	Biventricular failure; left ventricle ejection fraction 28%; no evidence of pericardial thickening

What is the most likely implicated therapeutic?

A. Cyclophosphamide
B. Docetaxel
C. Methotrexate
D. Radiotherapy
E. Trastuzumab

E. Trastuzumab

Trastuzumab (Herceptin) - cardiac toxicity is common

Trastuzumab is correct. Trastuzumab (Herceptin) is a monoclonal antibody directed against the HER2/neu receptor. Cardiotoxicity is a well-recognised complication and is more common when anthracyclines have also been used.

Cyclophosphamide is incorrect. Although higher doses of this drug may produce significant cardiac toxicity (including fatal hemorrhagic myocarditis), the incidence is much less so compared to trastuzumab.

Docetaxel is incorrect. Cardiac failure is a rare side effect of this agent.

Methotrexate is incorrect. Several clinical trials have shown that methotrexate is associated with improved endothelial function, slower atherosclerosis progression, decreased risk of major cardiovascular adverse events, and benefits on overall survival.

Radiotherapy is incorrect. Constrictive pericarditis is a late complication of radiation therapy. Patients typically present with signs and symptoms of heart failure, similar to other causes of constrictive pericarditis. The absence of pericardial thickening on echo makes this a less likely diagnosis.

Question 52 of 138

A 65-year-old female presents to her GP with a four days history of non-itchy rashes on her face, neck and bilateral upper limbs. Her chest and abdomen are not affected. She does regular gardening. Her past medical history includes myocardial infarction and asthma. Further history reveals that last week she was seen in the cardiology outpatient clinic for arrhythmias and was started on a new medication.

Which of the following drug is most likely casuing the patient's symptom?

- A. Digoxin
- B. Dabigatran
- C. Verapamil
- D. Amiodarone
- E. Flecainide

D. Amiodarone

The distribution of the rash suggests phototoxicity. Among the list of the medications, only amiodarone and flecainide are assocaited with phototoxicity. However, flecainide is contraindicated in patients with history of myocardial infarction.

Question 53 of 138

A 22-year-old male is 'blue-lighted' to the Emergency Department having been found collapsed at a party. On arrival, his GCS is 3/15 and he is immediately intubated and ventilated by the Emergency Physicians.

On examination he is afebrile. He is mildly bradycardic at 53bpm and his blood pressure is 109/69mmHg. His pupils measure 2mm bilaterally. IV access is obtained and 400 micrograms of naloxone are administered without effect. The on-call radiologist is contacted and a CT head scan is arranged.

One hour later the patient extubates himself without warning. He is referred to medicine as his GCS is still 13/15. His CT demonstrates no acute intracranial pathology. By the time you arrive in the Emergency Department his GCS has improved to 15/15 and he is demanding to go home.

Which drug is most likely to be implicated?

- A. Diazepam
- B. Methoxetamine
- C. Gamma-hydroxybutyric acid (GHB)
- D. Heroin
- E. Methamphetamine

C. Gamma-hydroxybutyric acid (GHB)

GHB or 'Grievous Bodily Harm' is a colourless, odourless, bitter-tasting substance that acts as a CNS depressant. It is abused for its ability to induce euphoria, amnesia, and hypnosis. It is popular amongst party-goers and achieved notoriety for its use as a date-rape drug.

GHB toxicity occurs secondary to its effects as a CNS depressant. Patients typically present with coma, respiratory depression, mild bradycardia, and vomiting. The key feature of GHB toxicity is its short recovery time. Patients typically recover in 6 hours and toxicity is often maximal on presentation. Recovery often occurs spontaneously in the Emergency Department and patients have been known to self-extubate.

Heroin and diazepam could both produce a similar toxidrome. Recovery is generally more gradual, and one would expect naloxone to reverse a heroin overdose.

Methamphetamine is a stimulant. Clinical features include agitation, tachycardia, hypertension, mydriasis, and hyperthermia.

Methoxetamine is an analogue of the dissociative anaesthetics ketamine and phencyclidine (PCP). In addition to dissociative phenomena, it also causes tachycardia, hypertension, confusion, and mydriasis. Patients may also present with an acute cerebellar syndrome.

Question 54 of 138

A 35-year-old man is brought to the emergency department. He was a bystander at a house fire, who called the fire and ambulance services. The female resident of the property had escaped the fire but was found collapsed in the front garden. The bystander started cardio-pulmonary resuscitation including mouth-to-mouth breathing until the ambulance crew arrived.

Whilst the emergency services were dealing with the fire and unconscious resident, the 35-yearold man starts to feel 'light-headed'. The ambulance crew bring him to the emergency department as a precaution.

He is quickly reviewed by the emergency team, who refer this gentleman because of ongoing symptoms and feel he needs a longer period of observation in the medical assessment unit. They handover there was no clinical features to suggest inhalation injury from the fire.

Upon your review, the patient has deteriorated. He is confused and unable to provide any history. You are able to perform a limited examination which reveals a temperature of 37.5ºC, heart rate 38 beats/min, blood pressure 80/60 mmHg, respiratory rate 10/min and oxygen saturation of 98% on room air. Examination of the chest reveals equal vesicular breath sounds, no added sounds and dual heart sounds with no murmurs. Neurological assessment reveals confusion, a reduced level of consciousness and dilated pupils bilaterally.

You take an urgent arterial blood gas and prescribe a bolus of crystalloid fluid. A 12 lead ECG shows sinus bradycardia. Whilst awaiting the results of the arterial blood gas, the patient develops generalised convulsions.

You and the emergency team work together to stabilise the patient - he is intubated, placed on mechanical ventilation and vasopressors are commenced to support his blood pressure. During this time, you are presented with the results of the arterial blood gas:

pH	7.11
PaO2	100mmHg
SaO2	96% on room air
PaCo2	28mmHg
Bicarbonate	7 mmol/L
Chloride	105 mmol/L
Lactate	8 mmol/L
Carboxyhaemoglobin	0.7%
Na+	138 mmol/l
K+	4.5 mmol/l

The full blood count and biochemistry results are still awaited.

Which of the following is the most appropriate management for this patient?

- A. Urgent computed tomography (CT) imaging of the brain
- B. Atropine boluses, followed by atropine infusion
- C. Pralidoxime
- D. Benztropine
- E. Sodium thiosulfate

E. Sodium thiosulfate

Whist carbon monoxide poisoning is most associated with exposure to house/industrial fires, cyanide toxicity from burning of synthetic materials should also be considered

This man has cyanide poisoning. Performing mouth to mouth resuscitation has led to the oral transmission of cyanide molecules from the resident. The absorption of cyanide is slower via the oral route as compared to inhalation, which explains why this patient had a relatively 'delayed' presentation of cyanide poisoning. Also, exposure to small amounts of cyanide can lead to a longer duration of symptoms before cardiopulmonary arrest. The antidote for cyanide poisoning is intravenous sodium thiosulfate (+/- hydroxocobalamin).

Fire is the most common source of cyanide exposure in industrialised countries. Mouth-to-mouth resuscitation is contraindicated in cyanide poisoning because of risk to the provider of CPR.

The other differential diagnosis, in this case, is carbon monoxide inhalation. However, seizures are common in cyanide poisoning but are rare in carbon monoxide poisoning. Cyanide poisoning also causes mydriasis. whereas carbon monoxide does not affect the pupils. Administration of 100% oxygen is indicated for both carbon monoxide and cyanide poisoning.

In normal human physiology, detoxification of cyanide occurs via rhodanese, an enzyme found in many tissues but particularly in the liver and muscle. Rhodanese converts cyanide to thiocyanate, a water-soluble molecule excreted in the urine.

In poisoning, rhodanese is saturated and unable to remove the surplus cyanide molecules. Sodium thiosulfate serves as a sulfur donor in the reaction catalyzed by rhodanese. Hence administration of sodium thiosulfate increases cyanide to thiocyanate conversion. Hydroxocobalamin (vitamin B12) has also been approved for the treatment of cyanide poisoning.

Although rare, you should think of cyanide poisoning in any patient with unexplained severe lactic acidosis, coma, bradycardia, and normal oxygenation.

Option 1 - treating the poisoning should take priority over investigating the reduced level of consciousness/seizures with brain imaging

Option 2 - this is part of the treatment algorithm for organophosphate poisoning

Option 3 - this is also part of the treatment algorithm for organophosphate poisoning

Option 4 - this is part of the treatment algorithm for dystonic reactions that may be secondary to anti-psychotic overdose

Option 5 - the correct answer

Question 55 of 138

A 33-year-old woman with bipolar affective disorder attends as she is struggling to conceive. She also complains of severe fatigue, palpitations, and a worsening acneiform facial rash.

On review, you note that she has been taking olanzapine for over ten years.

Which of the following is she at increased risk due to long-term use of this medication?

A. Acne
B. Agranulocytosis
C. Polycystic ovarian syndrome
D. Prolonged QTc
E. Type 2 diabetes mellitus

E. Type 2 diabetes mellitus

Long-term use of olanzapine is a significant risk factor for the development of type 2 diabetes mellitus

Type 2 diabetes mellitus is correct. Long-term olanzapine use is a significant risk factor for developing type 2 diabetes.

Acne is incorrect. There is no evidence to show a link between the development of acne and olanzapine use.

Polycystic ovarian syndrome is incorrect. There is no evidence to suggest an increased risk of polycystic ovarian syndrome as a result of olanzapine use. Traditional neuroleptics can lead to raised levels of prolactin which causes relative infertility. Olanzapine has only minimal effect on prolactin levels.

Agranulocytosis is incorrect. Some antipsychotic medications including clozapine, tetracyclic antidepressants, and phenothiazines have been shown to cause agranulocytosis, but this is not the case with olanzapine. There are a small handful of case reports showing blood dyscrasias with olanzapine and so monitoring full blood counts is still recommended.

Prolonged QTc is not seen with olanzapine use but can be seen with other neuroleptic medications such as chlorpromazine, fluoxetine, haloperidol, and amitriptyline.

Question 56 of 138

A 45 woman is admitted with fever, night sweats and weight loss. She has a past medical history of type 1 diabetes. At a recent retinal screen there were microaneurysms and dot and blot haemorrhages noted on the periphery of both her discs. She has never noted any visual problems.

A sputum sample is positive for acid fast bacilli and she is subsequently started on Rifampicin, Isoniazid, Pyrazinamide, ethambutol and pyridoxine.

On the same admission she is diagnosed with HIV. Her CD4 count is 140 cells/µL. She is started cotrimoxazole and a few weeks later starts antiretroviral therapy with Efavirenz, emtricitabine and tenofovir.

She makes a good recovery and is discharged from hospital. A few months later she complains of increasingly blurry vision. Fundoscopy shows pale optic discs, microaneurysms and blot haemorrhages.

What is the most likely cause for her visual symptoms?

A. CMV retinitis
B. Ethambutol
C. Efavirenz
D. Diabetic retinopathy
E. Pyrizinamide

B.Ethambutol

Ethambutol is the correct answer here and is well known to cause optic neuritis. Diabetic retinopathy is unlikely to cause such an acute deterioration considering her recent retinal screen. CMV retinitis is unlikely to cause this picture and efavirenz and pyrazinamide do not have ocular side effects.

Question 57 of 138

A 46-year-old male was transferred to the Intensive Care Unit (ICU) as an emergency admission. He had been scheduled to undergo an elective open cholecystectomy under general anaesthetic. He had been intubated and ventilated successfully, but a few minutes into the operation he had become tachycardic, with his heart rate rising from a resting rate of 72 bpm to a rate of 142bpm. His oxygen saturations dropped down to 92% on 15 litres of oxygen per minute, and his blood pressure rose from his baseline of 114/78 mmHg up to 162/98 mmHg. In addition, his end tidal CO2 concentration rose, despite several checks to ensure that the tracheal tube was correctly sited. His past medical history was unremarkable except for an appendicectomy under general anaesthetic aged 26 yrs old.

The operation was abandoned. Upon his arrival to ICU, he was intubated and ventilated, maintaining an oxygen saturation of 96% on 15 litres per minute of oxygen. He appeared flushed and had significant muscle rigidity. His blood pressure had risen to 174/102 mmHg, and his heart rate was 136bpm. His temperature was 38.2 C. Examination of the cardiovascular revealed vasodilated peripheries with a bounding pulse and normal heart sounds. Auscultation of the lungs revealed good air entry in all zones and a correctly cited tracheal tube. Examination of the abdomen was unremarkable. Examination of the neurological system confirmed the presence of equal and reactive pupils, with generalised muscle hypertonicity and masseter muscle spasm. A central venous catheter and arterial line were inserted. The central venous pressure was 9 cm.

An arterial blood gas sample on 15 litres of oxygen was taken:

pH	7.26
HCO3	18 mmol/l
Pa02	17 kPa
PaC02	7.6 kPa
Na+	139 mmol/l
K+	7.1 mmol/l

What is the next best immediate management step?

A. Commence IV labetalol infusion
B. Commence IV meropenem
C. Commence high dose IV hydrocortisone
D. Commence IV dantrolene
E. Arrange immediate therapeutic hypothermia

D. Commence IV dantrolene

This patient has developed malignant hyperthermia as a result of his anaesthetic. In addition to stopping the responsible anaesthetic agent, the best immediate management step involves commencing IV dantrolene. Early commencement of dantrolene has greatly reduced mortality associated with malignant hyperthermia and should be administered as soon as the diagnosis is suspected. Note that hyperthermia is a relatively late feature of malignant hyperthermia, and earlier features include hypoxia, hypercarbia, masseter muscle spasm and hypertonicity.

Question 58 of 138

A 58-year-old man presents with several months of feeling generally tired, cold and experiencing some weight gain. His past medical history includes atrial fibrillation, for which he has taken amiodarone for several years.

Blood tests are performed, which show the following:

Thyroid-stimulating hormone (TSH)	9.2 mU/L	(0.5-5.5)
Free thyroxine (T4)	6.7 pmol/L	(9.0 - 18)

Given the above, what is most appropriate?

A. Continue amiodarone and start carbimazole
B. Continue amiodarone and start levothyroxine
C. Stop amiodarone and monitor
D. Stop amiodarone and start levothyroxine
E. Stop amiodarone and start prednisolone

B. Continue amiodarone and start levothyroxine

In amiodarone induced hypothyroidism, amiodarone can be continued with levothyroxine

The scenario above demonstrates an example of amiodarone-induced hypothyroidism. This is common, with around 1 in 6 patients taking amiodarone developing some form of thyroid dysfunction. As well as **treating the deficit with levothyroxine, amiodarone can be continued** in these patients, and so this is the correct answer.

Continuing amiodarone and starting carbimazole is inappropriate. Carbimazole would be appropriate for thyrotoxicosis, not hypothyroidism. In thyrotoxicosis, amiodarone should be stopped, unlike hypothyroidism, and so continuing would be incorrect. If type 1 - excess iodineinduced thyroid hormone synthesis and a goitre present, carbimazole is an appropriate option.

Stopping amiodarone and monitoring is not the preferred management option here. Amiodarone is important with regards to controlling this patient's atrial fibrillation. Also, levothyroxine should be administered to treat hypothyroidism.

Stopping amiodarone and starting levothyroxine is not quite right. Although commencing levothyroxine is appropriate, amiodarone should be continued.

Stopping amiodarone and starting prednisolone is incorrect. This would be suitable for type 2 thyrotoxicosis. Type 2 is defined as amiodarone-related destructive thyroiditis with an absent goitre.

Question 59 of 138

A 48-year-old man is referred to the outpatient department by his GP, having experienced tremor, heat intolerance and 2 kg weight loss over the last 6 weeks. His past medical history includes having atrial fibrillation for which he takes warfarin and amiodarone. He is a non-smoker and drinks on average 10 units of alcohol per week.

Blood tests are performed and reveal:

Hb	142 g/l	
Platelets	220 * 10 /l9	
WBC	7.2 * 10 /l9	
Na +	140 mmol/l	
K +	4.2 mmol/l	
Urea	4.5 mmol/l	
Creatinine	45 µmol/l	
Thyroid stimulating hormone (TSH)	0.03 mu/l	
Free thyroxine (T4)	29 pmol/l	
Total T3 (TT3)	252 ng/dL	Normal rar

A colour flow Doppler sonography of the thyroid is performed and shows absent vascularity and gland destruction.

What is the most likely diagnosis?

A. Type 1 amiodarone-induced thyrotoxicosis
B. Type 2 amiodarone-induced thyrotoxicosis
C. Grave's disease
D. Hashimotos thyroiditis
E. De Quervains thyroiditis

B. Type 2 amiodarone-induced thyrotoxicosis

Type 2 amiodarone-induced thyrotoxicosis typically occurs in patients without underlying thyroid disease and is the result of the toxic effect of amiodarone on the thyroid follicular cells, causing a destructive thyroiditis that results in excess release of preformed T4 and T3 into the circulation. The condition has two phases a thyrotoxic phase which can last weeks to months, which is often followed by a hypothyroid phase and an eventual recovery in most patients.

Type 1 amiodarone-induced thyrotoxicosis normally occurs in patients with underlying thyroid pathology like Graves disease. In these patients, there is accelerated thyroid hormone synthesis secondary to the iodide load from the amiodarone therapy.

Question 60 of 138

A 25-year-old woman presents to the Emergency department some 90 mins after taking 50x300mg aspirin tablets. She feels nauseated, has vomited once, complains of severe tinnitus, and is hyperventilating. She has no past medical history of note and takes no regular medications. Examination reveals a blood pressure of 105/70 mmHg, pulse is 87 beats per minute and regular. Chest is clear, respiratory rate is elevated at 35/min. She has been given activated charcoal on admission. 1 litre of normal saline given intravenously over 1hr is in progress.

investigations

Hb	125 g/l
Platelets	189 * 10 /l9
WBC	10.2 * 10 /l9
Na +	145 mmol/l
K +	3.1 mmol/l
Urea	6.1 mmol/l
Creatinine	90 µmol/l
pH	7.54
Serum salicylate	4.2 mmol/l

Which of the following is the most appropriate next step?

A. IV furosemide
B. IV sodium bicarbonate
C. Oral diazepam
D. Referral for haemodialysis
E. Repeated activated charcoal

IV sodium bicarbonate

Administration of sodium bicarbonate is recommended to drive alkalinisation of urine, even where there is respiratory alkalosis in aspirin overdose. It is therefore the correct next step here.The

recommended dose If the salicylate concentration in an adult is above 3.6 mmol/L is 225 mmol sodium bicarbonate, (225 mL of 8.4% over 60 minutes or 1.5 L of 1.26% over two hours).

Forced diuresis with furosemide is not recommended as large fluid shifts may increase the risk of pulmonary oedema associated with aspirin overdose. Oral diazepam is not appropriate and would potentially just shorten the time to development of acidosis. Haemodialysis is considered when salicylate concentration is greater than 5.1 mmol/l.

Question 61 of 138

A 52-year-old gentleman presents after hearing a popping sound followed by acute onset right ankle pain. On examination he is unable to plantar flex his right ankle. He denies any recent strenuous exercise. He has never had any joint problems but does tell you he has recently been treated for a urinary tract infection.

Which one of these antibiotics is likely have contributed to his presentation?

A. Erythromycin
B. Trimethoprim
C. Nitrofurantoin
D. Ciprofloxacin
E. Co-amoxiclav

D. Ciprofloxacin

Ciprofloxacin may lead to tendinopathy

A rare side effect of ciprofloxacin is tendon inflammation +/- tendon rupture as listed in the BNF. With a history suggestive of tendon rupture remember to ask about recent antibiotic usage.

Question 62 of 138

A 37-year-old man attends endocrinology clinic for assessment of the unwanted effects of longterm anabolic steroid use. The patient had been a competitive bodybuilder, who had used anabolic steroids to enhance his training regime, but now stated that he had 'retired' from bodybuilding last week and so stopped using steroids. The patient was concerned about the longterm health consequences of his previous use.

The patient described a 10-year period of anabolic steroid use. Typically he would take a daily oral formulation of a synthetic testosterone supplemented by an intramuscular injection of a longer acting agent every few weeks. The patient would take breaks from anabolic steroid use intermittently throughout the year, to reduce unwanted effects and also to evade anti-doping testing arranged by the organisers of the competitions in which he competed. The patient stated that he had never shared or reused needles when injecting himself with anabolic steroids.

The patient reported a range of unwanted effects he had developed secondary to his anabolic steroid use. These included severe acne affecting the patient's face and chest, intermittent symptoms of gastrointestinal dysfunction, and male pattern baldness. When asked directly, the patient reported that he had suffered from erectile dysfunction and scrotal discomfort towards the end of his use of anabolic steroids. The patient did not report any other concerns, in particular, he denied symptoms associated with heart or liver disease. The patient had no other significant past medical history and disclosed being a former user of recreational drugs, including cocaine.

Examination of the patient's cardiovascular and respiratory symptoms was unremarkable except for moderate pitting oedema to the level of the mid-tibia bilaterally. Examination of the abdomen noted mild bilateral gynaecomastia but no other signs of chronic liver disease. The patient's testicular volume was estimated as 18 ml bilaterally. A brief mental state examination did not reveal any evidence of a significant mood or anxiety disorder.

HbA1C	47 mmol / mol (reference < 42)
Fasting LDL cholesterol	4.5 mmol / L (reference < 3.0)
Fasting HDL cholesterol	1.0 mmol / L (reference > 1.2)
Prolactin	501 mU / L (reference 80 - 400)
Luteinising hormone	1.4 IU / L (reference 1.8 - 8.6)
Follicle-stimulating hormone	1.2 mU / ml (reference 1.5 - 12.4)
Transthoracic echocardiogram	Normal systolic and diastolic function; no left ventricular hypertrophy; normal valvular function

Which of the patient's unwanted effects will be irreversible with cessation of steroid use?

A. Pitting oedema

B. Erectile dysfunction
C. Scrotal pain
D. Male pattern baldness
E. Gastrointestinal dysfunction

D. Male pattern baldness

Anabolic steroid use is associated with a wide variety of unwanted effects. Morbidity and mortality from cardiac diseases are increased, although the precise mechanism of this effect is unknown. In addition, serious liver disease - for example, hepatocellular carcinoma - is also associated with anabolic steroid use. There are a variety of less dangerous but troubling unwanted effects as described below, some of which will be irreversible with cessation of anabolic steroid use. Due to the potential risk to long-term health, anabolic steroid users should be strongly advised to stop their use. No tapering of the dose is required. Active or former users should be monitored lifelong for evidence of complications.

Reversible unwanted effects of anabolic steroids include:

- Increased appetite
- Gastrointestinal dysfunction
- Mood swings
- Anxiety
- Acne
- Oedema
- Libido change
- Scrotal pain
- Erectile dysfunction
- Menstrual irregularities

Irreversible unwanted effects of anabolic steroids include:

- Hirsutism
- Voice pitch changes
- Male pattern baldness
- Skin striae or keloid scarring
- Chest pain
- Clitoral hypertrophy
- Short stature due to premature fusion of growth plates

It is unclear whether other unwanted effects are reversible with cessation of anabolic steroids; for example, gynaecomastia, testicular atrophy and infertility. Some limited studies suggest that normal sperm production and fertility return following cessation of anabolic steroid use, although on a timescale ranging from 4 months to 5 years.

The patient also has a typical pattern of hormonal irregularities associated with anabolic steroid use. A deranged lipid profile and impaired glucose tolerance are also frequently observed. The patient's echocardiogram is reassuringly normal, which suggests that his leg oedema will resolve with cessation of anabolic steroid use.

Question 63 of 138

A 23-year-old male is brought to the ED via ambulance after a seizure. His friends reported an episode of jerking of all four limbs lasting 1-2 minutes associated with urinary incontinence.

He has vomited twice in the ED and is complaining of muscle aches.

On examination the patient is agitated, confused and appears to be hallucinating. Myoclonic jerks are present. The chest is clear to auscultation and oxygen saturations are 98% on room air. Heart sounds are normal, the pulse rate is 130bpm and the blood pressure is 161/84mmHg.

An ECG reveals sinus tachycardia. The pupils measure 8mm and are equal and reactive. The patient's temperature is 36.6ºC.

Blood tests reveal:

Hb	138 g/l
Platelets	362 * 10 /l9
WBC	11.2 * 10 /l9
Na +	135 mmol/l
K +	2.7 mmol/l
Urea	12.6 mmol/l
Creatinine	187 µmol/l
Bilirubin	18 µmol/l
ALP	98 u/l
ALT	53 u/l
γGT	27 u/l
Albumin	32 g/l

What is the most likely cause for this patient's presentation?

A. Toluene solvent toxicity
B. Amyl nitrate toxicity
C. Gamma hydroxybutyric acid toxicity
D. Synthetic cannabinoid toxicity
E. Heroin toxicity

D. Synthetic cannabinoid toxicity

The hallucinations, seizure, myoclonus, mydriasis, hypertension, acute kidney injury and hypokalaemia are consistent with synthetic cannabinoid toxicity.

Features of toluene toxicity can be similar however irritation to the eyes, nose and respiratory tract is often seen from inhalation in toluene abuse.

Amyl nitrate is a vasodilator so toxicity tends to result in hypotension rather than hypertension as in this case. Other features of amyl nitrate toxicity include blurred vision, xanthopsia and haemoptysis.

Features of gamma hydroxybutyric acid (GHB) toxicity include CNS and respiratory depression, hypersalivation, bradycardia and hypotension.

Heroin toxicity typically results in depression of the respiratory and central nervous systems and pin-point pupils (rather than mydriasis in this case).

Question 64 of 138

A 69-year-old man with a history of chronic obstructive pulmonary disease is admitted to the Emergency department with an exacerbation. His GP has started ciprofloxacin some 3 days earlier. Other medication of note includes high dose salmeterol fluticasone, oral theophylline and tiotropium. Over the past 24hrs he has begun to vomit and feels light-headed. Of note is that his blood pressure is 132/88 mmHg with a postural drop of 15 mmHg, and his serum potassium is 3.0 mmol/l.

Which of the following is the most appropriate intervention?

A. Stop salmeterol fluticasone
B. Stop theophylline
C. Stop tiotropium
D. Stop ciprofloxacin
E. Start oral potassium replacement

B. Stop theophylline

Stop theophylline when CYP450 inhibitors are prescribed

Theophylline is metabolised by the CYP1A2 isoenzyme. Ciprofloxacin is a moderate inhibitor of CYP1A2, which can drive accumulation of theophylline. Symptoms of toxicity include nausea, vomiting, hyperventilation and marked hypokalaemia, as is seen here. The most important intervention is withholding of the theophylline.

Metabolism of salmeterol and tiotropium is not affected by co-administration of ciprofloxacin as such there is no reason for discontinuing these medications. Starting oral potassium replacement won't affect the build up of theophylline and won't therefore prevent further symptoms of theophylline toxicity. Clozapine, olanzapine, ropinirole and duloxetine are other examples of drugs metabolised by CYP1A2, accumulation of which may be driven by ciprofloxacin.

Question 65 of 138

A 20-year-old female presents having taken 20 aspirin 500mg tablets in a suicide attempt. She has felt well since and is asymptomatic, and now regrets these actions. She has a background of borderline personality disorder for which she takes olanzapine and has never attempted suicide in the past. She was seen by her GP with a presumed respiratory tract infection one week ago and prescribed amoxicillin. Cardiovascular, respiratory and abdominal examinations are all unremarkable. Her blood gas reveals a ph 7.41, lactate 0.5mmol/L and laboratory bloods are unremarkable other than a salicylate level 4 hours post ingestion of 660mg/L.

Which management step should be taken next?

A. Intravenous (IV) Sodium Chloride 0.9%
B. Reassure and discharge
C. IV Sodium bicarbonate 1.26%
D. N-acetylcysteine infusion
E. Dialysis

C. IV Sodium bicarbonate 1.26%

Although this young lady demonstrates no obvious compromise from her overdose, guidelines suggest that salicylate levels greater than 450mg/L in adults represents moderate poisoning. Sodium bicarbonate used here alkalinises the urine which is more effective than a massive diuresis. Urine pH should be greater than 7.5, ideally 8.0-8.5.

Question 66 of 138

A 77-year-old woman is admitted to the acute medical ward with a 3-day history of right loin pain and dysuria. A diagnosis of pyelonephritis is made and she is treated with intravenous gentamicin and ceftazidime.

Gentamicin levels are taken 8 hours post-dose:

Trough level	3.1 mg/L	(1 - 2)

What is the most appropriate next step in the management of this patient?

A. Continue with dose and prescribe IV 0.9% sodium chloride
B. Delay next dose of gentamicin
C. Reduce dose of gentamicin
D. Stop gentamicin
E. Switch antibiotic to ciprofloxacin

B. Delay next dose of gentamicin

For multiple daily dose regimens of gentamicin, if the pre-dose ('trough') concentration is high, the interval between doses must be increased. If the post-dose ('peak') concentration is high, the dose must be decreased

Patients receiving gentamicin therapy should have both pre-dose (trough) and post-dose (peak) levels checked. The recommended trough levels should be 1-2 mg/L, whilst the peak levels should be between 5-10 mg/L. A raised trough level means that there should be a **delay in the next dose of gentamicin**.

Continuing with the dose and prescribing IV 0.9% sodium chloride is inappropriate as this means that the patient could be receiving a harmful dose that could cause toxicity such as renal or otic impairment.

In contrast to raised trough levels, a raised peak level means that there should be a **reduced dose of gentamicin**.

There is no need to **stop gentamicin** at this stage. Instead, a raised trough level indicates an increased drug dosage interval as per the BNF. If the drug were to no longer be indicated or was evidenced to be causing significant harm or impairment in renal function, then careful discussion regarding its continuation would be needed.

Switch antibiotic to ciprofloxacin is incorrect. Rather than changing antibiotics, a raised trough level indicates that an increased dosing interval before the next administration of gentamicin is needed. It would be inappropriate to change antibiotics as there are risks for antimicrobial resistance.

Question 67 of 138

A 19 year old girl is brought to the Emergency Department by a friend. She is a first year university student and her friends are concerned her behaviour has altered in the past few weeks. On assessment she is confused with an AMTS of 6/10. She has a flat affect. Cardiorespiratory examination is normal although the respiratory rate is 22 at rest. Oxygen saturations are 97% on air. Heart rate is 85bpm regular and blood pressure is 100/55 mmHg.

Examination of her neurological system reveals prominent paraesthesia in both feet with absent vibration sense and proprioception. The ankle and knee reflexes are absent and plantar responses are extensor. There is mild distal weakness in the legs with MRC grading 4/5. Examination of the cranial nerves shows no evidence of nystagmus but visual acuity is reduced to 6/20 bilaterally. She has an ataxic gait.

Her medical history is significant only for coeliac disease and she is taking no regular medications. Routine blood results show:

Haemoglobin	7.6g/L	Sodium	137mmol/L	Magnesium	0.81mmol/L
Cell volume	103.2 fL	Potassium	4.6mmol/L	CRP	4.5mg/L
White cells	5.9x10^9/L	Urea	1.9mmol/L	Thyroid tests	Normal
Neutrophils	4.0x10^9/L	Creatinine	55mol/L	HIV	Negative
Lymphocytes	1.9x10^9/L	Calcium (corr)	2.43mmol/L	Syphilis	Negative
Platelets	300x10^9/L	Phosphate	1.01mmol/L		

The patient's friend tells you she has recently started using recreational party drugs.

Which of the following inhaled recreational drugs most explains the above picture?

A. Crack (cocaine)
B. H (heroin)
C. Hippie crack (nitrous oxide)
D. Poppers (amyl nitrate)
E. Spice (synthetic cannabinoid

C. Hippie crack (nitrous oxide)

Nitrous oxide use can precipitate severe vitamin B12 deficiency with pronounced neurological and haematological signs, particularly in susceptible individuals

The above vignette describes a state of profound vitamin B12 deficiency with clinical signs of subacute combined degeneration of the cord. The constellation of signs of ataxia, loss of deep tendon reflexes with dorsal column signs (loss of proprioception and vibration sense) and paraesthesias with positive Babinski response are known as myelosis funicularis and is highly suggestive of B12 deficiency. In this patient there are also signs of confusion and of reduced visual acuity which increase likelihood of B12 deficiency.

Nitrous oxide, also known as nitrous, hippie crack, laughing gas or whippet, is a relatively recent addition to the arsenal of recreational drugs of abuse. It is sold as cartridges to the catering industry for use in making whipped cream, but can be released and inhaled directly or through balloons or bags. Erroneously regarded as a safe drug it is reported to cause euphoric symptoms in users with a brief onset of actions. It is used clinically as a dental anaesthetic and anxiolytic and hence also promotes feelings of relaxation, detachment and sensory changes. Deaths have been reported due to hypoxia since catering nitrous oxide is not mixed with oxygen as it is when used medically.

Nitrous oxide can cause a rapid depletion in vitamin B12 stores in users, particularly in susceptible individuals such as vegans, anorexics, coeliac patients and those with problems with intestinal absorption. Nitrous oxide reacts with cobalt in the vitamin B12 molecule converting it from an active to an inactive bivalent form, thereby rendering it unusable in vivo. Symptoms of rapid neurological and haematological deterioration can occur including subacute combined degeneration of the cord, depression, dementia, psychosis and blindness, as well as megaloblastic anaemia. Chronic use can lead to pancytopaenia. In the acute phase, symptoms are reversible on cessation of the drug and high dose vitamin B12 supplementation. Chronic users may suffer irreversible neurological damage.

Poppers (amyl nitrate) cause euphoria and sensory dissociation on inhalation but long term effects are rare. A serious complication of their use is the oxidation of ferrous ions within haemoglobin molecules to ferric ions, creating methaemoglobinaemia, reducing the oxygen delivering capacity of the blood. They are not indicted in vitamin deficiencies.

Crack cocaine causes myriad sympathomimetic and serotonergic effects in users but is not directly attributable to anaemia or avitaminosis although this can occur secondarily in the serotonin syndrome. Crack cocaine can also cause choreoathetoid movements in some users. Similarly, heroin causes analgesic and depressant effects at opioid receptors but is not attributable directly to haematological or neurological symptoms although these may be seen in long term users due to self neglect. Spice is a synthetic cannabinoid drug with similar but augmented effects to cannabis. CNS effects of its use include agitation, confusion, psychosis, convulsions, nystagmus and blindness. It is rare for haematological effects to occur although renal failure may be seen.

Question 68 of 138

A 42-year-old woman is admitted for dysuria, fever and rigors that have developed over the past 24 hours. A urine sample is sent to the lab and cultures demonstrate sensitivity to gentamicin. Her renal function is normal and so she is commenced on a typical loading regime.

She is stable on a twice-daily regime of gentamicin for several days. Blood tests are measured one day, pre-and post-evening dose:

Pre-dose	0.6mg/L	(<1)
One hour post-dose	7mg/L	(3-5)

What is the most appropriate action to take?

A. Decrease the dose
B. Decrease the time interval between doses
C. Increase the time interval between doses
D. Recheck levels around the next dose
E. Withhold the next dose

A. Decrease the dose

For multiple daily dose regimens of gentamicin, if the pre-dose ('trough') concentration is high, the interval between doses must be increased. If the post-dose ('peak') concentration is high, the dose must be decreased

The correct answer is to decrease the dose. The post-dose ('peak') concentration is high. As such, the dose is too high and so the **dose should be reduced**.

Decreasing the time interval between doses is incorrect. This would further increase the gentamicin levels, which is inappropriate.

Increasing the time between doses is also incorrect. This would be appropriate if the pre-dose ('trough') level was too high, not the post-dose level.

Rechecking levels is not sufficient. Action needs to be taken given the result - the dose needs reducing.

Withholding the next dose would be an appropriate step if both pre-dose and post-dose levels were too high. The patient should then be rediscussed with microbiology.

Question 69 of 138

You are working in the renal ward when you are asked to urgently see a 70-year-old woman. She has just returned from a tunnelled central venous catheter insertion for a planned start on dialysis and has developed tachycardia and hypotension. You note that the procedure report suggests a difficult insertion poorly tolerated by the patient. On return to the ward, she complained to the nurse of numbness around her mouth and tingling of her tongue.

She has type 2 diabetes mellitus with nephropathy and atrial fibrillation. Medication includes alfacalcidol, bisoprolol, bumetanide, and edoxaban.

Observations are as follows.

- Respiratory rate 30
- Oxygen saturations 94% on air
- Heart rate 180 beats per minute
- BP 100/65 mmHg

- T 37.4ºC

ECG shows a regular broad complex tachycardia at 180 beats per minute. An urgent blood gas shows results as follows.

Na +	136 mmol/L	(135 - 145)
K +	5.0 mmol/L	(3.5 - 5.0)
Glucose	6.1 mmol/L	(3.3 - 5.8)

What is the most appropriate immediate course of action?

A. Administer 10% calcium gluconate and organise urgent haemodialysis
B. Administer IM glucagon
C. Administer IV lipid emulsion
D. Commence IV antibiotics for line infection
E. Urgent DC cardioversion

C. Administer IV lipid emulsion

Local anaesthetic toxicity can present with CNS (e.g. reduced GCS, seizures) and cardiovascular (e.g. tachyarrhythmias, hypotension, bradyarrhythmias) features. Treatment of severe toxicity is with IV lipid emulsion.

The correct answer **administer IV lipid emulsion**. This patient has likely developed local anaesthetic toxicity during the line insertion. Early clues include circumoral numbness, tongue paraesthesia, and dizziness. Patients can then develop CNS toxicity including drowsiness and coma. In this case, the patient has developed cardiovascular toxicity which can include arrhythmias such as ventricular tachycardia. The treatment of choice is IV lipid emulsion, which is thought to bind the local anaesthetic in the serum, therefore facilitating its clearance from the tissues in which it has a toxic effect.

Administer 10% calcium gluconate and organise urgent haemodialysis is incorrect. This would be the treatment for severe hyperkalaemia in a dialysis-dependent patient. While this can lead to ventricular tachycardia, the normal potassium on the blood gas is reassuring.

Administer IM glucagon is incorrect. This is a treatment option for beta-blocker overdose, which typically presents with bradycardia and resultant hypotension. Tachyarrhythmias are not a feature. It can also be used in hypoglycaemia but this would be unlikely to result in the clinical picture described. The glucose on the blood gas is also normal.

Commence IV antibiotics for line infection is incorrect. This would be very early for line infection to have developed and the lack of fever goes against this differential. Sepsis obviously could result in hypotension but would be unlikely to cause VT, which is the primary cause of the haemodynamic instability in this case.

Urgent DC cardioversion is incorrect. This would be the treatment of choice for any tachyarrhythmia with shock, defined by the resuscitation council as a systolic BP <90 mmHg. This patient's blood pressure is above this so other measures should be pursued first, particularly in the context of a toxic cause with a recognised antidote available.

Question 70 of 138

A 48-year-old man is reviewed in the Medical Admissions unit complaining of palpitations. He has a past medical history of hereditary obstructive cardiomyopathy (HOCM), for which he has taken amiodarone for the last year. He has no personal or family history of autoimmune disease.

On examination, he is flushed and diaphoretic. He appears thin, and he has a fine tremor when his hands are outstretched. There is no discernible goitre.

His observations are as follows: heart rate 102/min; blood pressure 126/82 mmHg; respiratory rate 14/min; temperature 37.9ºC; oxygen saturations 97% on air.

Selected blood test results are shown below:

Free T4	28.6 pmol/L	(12 - 22)
Free T3	9.1 pmol/L	(3.1 - 6.8)
TSH	< 0.05 mU/L	(0.27 - 4.2)

Given the likely diagnosis, what is the most appropriate management option?

A. Carbimazole
B. Lithium
C. Lugol's iodine
D. Prednisolone
E. Propylthiouracil

D. Prednisolone

In amiodarone induced thyrotoxicosis type 2 the management is with corticosteroids rather than carbimazole

The correct answer is **prednisolone**. This patient has a likely diagnosis of amiodarone-induced thyrotoxicosis (AIT) type 2. The thyroid function tests are in keeping with thyroid overactivity, whilst the examination findings clearly describe him as clinically thyrotoxic. In the absence of an alternative explanation (e.g. known Graves disease), this is most likely due to the patient taking amiodarone. The diagnosis of AIT type 2 is more likely than AIT type 1, as AIT type 2 is a destructive thyroiditis that tends not to present with goitre formation. The initial management of AIT type 2 is with corticosteroids such as prednisolone.

Carbimazole is incorrect. This would be an appropriate initial management option for this patient if he had a goitre on examination, and hence if the clinical picture were more consistent with AIT type 1. Antithyroid drugs are favoured in AIT type 1, where the pathophysiology involves excess thyroid hormone synthesis stimulated by the iodide load from amiodarone therapy (the Jod-Basedow phenomenon).

Lithium is incorrect. This would be an appropriate management option for either AIT type 1 or type 2 that was refractory to initial therapy (with either antithyroid drugs or corticosteroids respectively).

Lugol's iodine is incorrect. Lugol's iodine is used for its antithyroid properties in the management of severe thyrotoxicosis, and as a preparation for thyroidectomy surgery in patients with Graves disease. It is not routinely used in the management of AIT type 2, where the anti-inflammatory properties of corticosteroids are preferred.

Propylthiouracil is incorrect as corticosteroids, rather than antithyroid drugs are the first-line management option for AIT type 2.

Question 71 of 138

You are called to the emergency department to review a 33-year-old man. He is an Estonian national and works on a farm. His spoken English is poor but he tells you he feels unwell. He is being treated in a side-room because of loose stools.

On examination he is drooling slightly and has watery eyes. His pupils are equal in size but miotic. His blood pressure is 102/58 mmHg and an ECG shows sinus bradycardia.

How should this patient be managed? :

A. Amiodarone
B. Pyridostigmine
C. Glucagon
D. Haemodialysis
E. Atropine

E. Atropine

Organophosphate insecticide – atropine

This man has features of organophosphate poisoning and demonstrates some of the anticholinesterase effects exerted by industrial insecticides. The only suitable treatment listed is atropine. Atropine exerts an anticholinergic effect at the level of the muscarinic receptor, thus opposing the effects of accumulated acetylcholine.

Amiodarone is not typically used to treat bradyarrhythmias. Glucagon can be used in beta-blocker overdose, but beta blockade would not cause the miotic pupils or lacrimation. Pyridostigmine is an anticholinesterase agent used in the treatment of myasthenia gravis; it would do nothing to help in this situation.

Organophosphates are not amenable to haemodialysis (remember the 'BLAST' mnemonic for overdoses that can be dialysed:

Barbiturates Lithium

Alcohols e.g. ethylene glycol

Salicylates Theophyllines)

Question 72 of 138

A 17-year-old woman with a history of epilepsy and deliberate self-harm is brought into the emergency department with a Glasgow coma score of 13 (E3 V4 M6) and respiratory rate of 8/min.

On examination, her pulse is 56/min and regular, blood pressure 110/60 mmHg and her chest is clear. She has no signs of injury but an empty packet of diazepam was found in her handbag. Whilst the patient is breathing room air a nurse in the emergency department has taken an arterial blood gas shown below.

pH	7.39
pO2	10.1 kPa
pCO2	5.6 kPa
BE	0.8 mEq/l

What is the best initial management?

A. Flumazenil 200mcg infused IV over 15 minutes
B. Flumazenil 200mcg bolus IV over 15 seconds
C. Naloxone 400mcg IM injection
D. Urgent intubation with anaesthetic support
E. Supportive care only

E. Supportive care only

The blood gas shows her ventilation appears inadequate but at this stage the best management is supportive, allowing levels of diazepam to reduce over time, something that can be easily assessed clinically with and with the aid of an arterial blood gas sample.

Administering the benzodiazepine antidote flumazenil to an epileptic puts her at high risk of seizures. Naloxone is an antidote to opiate overdose. If however despite simple manoeuvres her ventilation deteriorated or GCS dropped to less than 8, anaesthetic support should be sought.

Question 73 of 138

A 55-year-old woman presents to the emergency department with shortness of breath. She has no significant past medical history and does not have any regular medications. She smokes ten cigarettes daily and lives alone.

Her observations are heart rate 110 beats per minute, blood pressure 120/88 mmHg, respiratory rate 18/minute, oxygen saturations 97% on 4L of oxygen and temperature 37ºC.

Clinical examination is unremarkable.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	180 * 10 /L 9	(150 - 400)
WBC	5.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
D-dimer	2000 ng/mL	(<250)
Trop	8 ng/L	(<15)

A chest x-ray is normal.

A CTPA demonstrates a large saddle embolus. There is no CT or echocardiographic evidence of right heart strain.

She is commenced on a heparin infusion. She successfully manages to wean oxygen by day 5 of treatment and has some repeat blood tests prior to a switch to an oral anticoagulant.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	32 * 10 /L 9	(150 - 400)
WBC	4.6 * 10 /L 9	(4.0 - 11.0)

Given the likely diagnosis, what is the most suitable medication to switch to from the heparin infusion?

A. Abciximab
B. Argatroban
C. Enoxaparin
D. Platelet transfusion
E. Warfarin

B. Argatroban

Heparin-induced thrombocytopenia: anticoagulation can be provided by direct thrombin inhibitor e.g. argatroban

Argatroban is the correct answer. The patient has heparin-induced thrombocytopenia, as evidenced by a > 50% drop in platelets with a nadir platelet count > 20 * 10 /L, occurring between days 5-10 post heparin administration, in the absence of another cause. She does not have any clinical evidence of thrombosis clinically but is at high risk of thrombotic events. Argatroban is a small molecule direct thrombin inhibitor and it is given intravenously. Patients can be transitioned to an oral anticoagulant once the platelet count has recovered.

Abciximab is incorrect. This is a glycoprotein IIb/IIIa receptor antagonist and is used as an antiplatelet medication rather than an anticoagulant.

Enoxaparin is incorrect. This is a rarer cause of induced-thrombocytopenia but is not recommended in the management of this condition.

Platelet transfusion is incorrect. The patient is not bleeding and the platelet count is > 30. Therefore platelets are not indicated. Indeed, they may increase thrombotic risk.

Warfarin is incorrect. The patient can be transitioned from argatroban to warfarin once the platelet count has recovered.

Question 74 of 138

Sonia is a 24-year-old woman presenting to the emergency department after being brought in by her flatmate. Sonia was found collapsed on the ground surrounded by unmarked bottles. She was noted to have been arguing with her boyfriend earlier today and given her history of depression, her friend thought she should have checked to ensure Sonia was safe. She is unsure is the bottles contained medications or other liquids.

Sonia was initially significantly disorientated on presentation and could not accurately recall where she was or why she was in the hospital. She began to experience nausea and vomiting while in the emergency department. After 1 hour in the emergency department, she became incredibly drowsy and became unrousable.

Physical examination was otherwise unremarkable. Skin colour was relatively normal. There was no tenderness on palpation of her abdomen. She is tachypnoeic with a respiratory rate of 30 breaths/minute.

Blood tests are as follow:

Hb	140 g/L	Male: (135-180)Female: (115 - 160)
Platelets	250 * 10 /L 9	(150 - 400)
WBC	7.0 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.0 mmol/L	(2.0 - 7.0)
Creatinine	100 µmol/L	(55 - 120)
CRP	<5 mg/L	(< 5)
Bicarbonate	12 mmol/L	(22 - 29)
Chloride	98mmol/L	(95-105)
Measured osmolarity	350mOsm/kg	(275-295)
Bilirubin	14 µmol/L	(3 - 17)
ALP	60 u/L	(30 - 100)
ALT	30 u/L	(3 - 40)
Î³GT	40 u/L	(8 - 60)
Albumin	34 g/L	(35 - 50)

Arterial blood gases showed:

pH	7.27	7.35-7.45
pO2	13.7 kPa	11-13 kPa
pCO2	3.2 kPa	4.7 - 6.0kPa
HCO3	12	22-26
BE	-4	-2 - +2

An ECG was performed and this showed sinus tachycardia. No abnormalities of the QRS complex was noted.

What is the likely agent that had been taken?

A. Aspirin
B. Ethylene glycol
C. Iron tablets
D. Organophosphate pesticide
E. Paracetamol

B. Ethylene glycol

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

The patient has taken an overdose of an unknown substance. Her only symptoms included nausea, vomiting before progressing to drowsiness and stupor, all relatively non-specific.

Her blood tests do provide additions information as this shows a metabolic acidosis from her arterial blood gas. Further assessment of her blood tests reveals an underlying raised anion gap along with a raised osmolar gap. Osmolar gap is calculated by measured serum osmolarity - calculated serum osmolarity (2x Na + glucose + urea). A gap of >=10 suggests an elevated osmolar gap.

Causes of a raised osmolar gap are alcohol ingestion (including methanol and ethylene glycol), sugars (mannitol and sorbitol), lipids (hypertriglyceridemia) and proteins (hypergammaglobulinemia). Given the combination of her blood tests and symptoms, ethylene glycol remains the likely substance ingested.

Aspirin can cause metabolic acidosis with a raised anion gap. However, it will be associated with more symptoms including tinnitus and fevers. Also, it is not associated with a raised osmolar gap.

Iron overdose will present with other symptoms including haematemesis and abdominal pains. It can present with a raised anion gap metabolic acidosis.

Paracetamol overdose will not result in the blood tests seen. Also, it can present with hepatic dysfunction before progression to hepatic encephalopathy in severe cases.

Organophosphate poisoning is unlikely as the patient does not display any clear cholinergic symptoms including salivation, lacrimation or diarrhoea.

Question 75 of 138

A 32-year-old mechanic is admitted to the emergency department. He is drowsy and confused. He is accompanied by his girlfriend who informs you they had been drinking alcohol the previous night. She became concerned when he appeared increasingly confused throughout the day despite no further alcohol intake. She tells you his mood has been low over the last number of months and has recently expressed suicidal ideation.

On your assessment his Glasgow coma scale is 14/15, pupils are equal and reactive to light. His Blood pressure is 124/81mmHg with a heart rate of 97/minute. Oxygen saturations are 94% on room air and he is tachypnoeic with a respiratory rate of 32/minute. There is bilateral flank tenderness, the clinical exam is otherwise unremarkable.

His urine toxicology screen is clear. Urine dipstick is positive for blood. Arterial blood gas:

PH	7.10
PO2	12.3Kpa
PCO2	2.6Kpa
Bicarbonate	8.0mEq/L
Lactate	2.3mmol/L

Biochemistry:

Na +	145 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Cl +	105 mmol/L	(98-106)
Urea	11mmol/L	(2.0 - 7.0)
Creatinine	113µmol/L	(55 - 120)
Glucose	5.7mmol/L	(3.9-5.8)
Serum Osmolality	358mOsm/Kg	(275-295)
Ethanol	<10mmol/L	
Paracetamol	0mg/dl	

Which of the following is the most likely cause for this man's presentation?

A. Alcoholic ketoacidosis
B. Ethylene glycol toxicity
C. Alcohol intoxication
D. Methanol poisoning
E. Paracetamol overdose

B. Ethylene glycol toxicity

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

This question requires you to identify a metabolic acidosis with a high anion gap and a high osmolar gap. This can be seen due to the presence of several different compounds or their toxic metabolites (glycols, methanol, oxoproline, lactate, ketones, aspirin, etc). In this case, the clinical history allows you to identify the likely cause.

Ethylene glycol and methanol are commonly found in automotive coolant, antifreeze, windshield wiper fluid, solvents, cleaners, and fuels. This patient is a mechanic with easy access to these compounds. Both methanol and ethylene glycol are metabolized by alcohol dehydrogenase (ADH) before having their effects via toxic metabolites. Ethanol competitively inhibits ADH, thereby diminishing the formation of toxic metabolites of the parent compound. Our patient had been drinking alcohol the previous night which may have masked his early symptoms and delayed the formation of toxic metabolites.

The clinical findings can help differentiate between methanol and ethylene glycol toxicity. Advanced methanol toxicity is associated with retinal injury and visual disturbance. Ethylene glycol more commonly presents with oliguria, hematuria, and flank pain. This patient had microscopic haematuria and bilateral flank pain. Definitive diagnosis can be made with direct testing of toxic alcohols or by identifying the consumed substance.

Calculating the anion gap:

Anion gap mmol/L = sodium mmol/L - (chloride mmol/L + bicarbonate mmol/L). Calculated anion gap = 32 (normal range 8->12).

Calculating the osmolar gap:

Osmolal gap = measured serum osm (358) - calculated serum osm (307). Serum osmolality = (2 Ã— Na + (BUN / 2.8) + (glucose / 18) + (ethanol / 3.7). Calculated serum osmolality = 307 mOsm/kg.

Measured serum osmolality = 358mOsm/kg.

Osmolal gap = 51(normal range (-10) - (+10).

Question 76 of 138

A 47-year-old Latvian man is brought to the Emergency Department by two of his friends. He is confused and aggressive and walks with an unsteady gait. History is difficult to obtain from the patient due to slurring of his speech and a slight language barrier. You note that he fails to meet your gaze when you are talking to him. Examination shows a GCS of 13/15 but he is drowsy and irritable. There is a vague smell of alcohol on his breath. He is flushed in the face and his eyes are red and hyperaemic. Pupils are slow to react to direct light but equal in size. The cardiorespiratory examination is unremarkable aside from a respiratory rate of only 8/min but SpO2 is 98% on air. The abdomen is soft and non-tender with no hepatomegaly and no signs of chronic liver disease. Despite the department being well lit, he asks you to turn the lights on.

Biochemistry reveals:

Haemoglobin	149g/L	Sodium	150mmol/L	pH	7.25
White cells	8.9x10 /L 9	Potassium	5.9mmol/L	pC02	3.9kPa
Neutrophils	5.9x10 /L 9	Urea	13.8mmol/L	pO2	12.6kPa (air)
Platelets	229x10 /L 9	Creatinine	156mol/L	HCO3-	12.5mmol/L
Prothrombin time	11 sec	Glucose	24.7mmol/L	BE	-13.2mEq/L
Ethanol	110mg/dL	Chloride	100mmol/L	Lactate	2.0mmol/L
Anion gap	38	Osmolar gap	25 (-10 to +15)		

What is the most appropriate next step in the management of this patient?

A. Begin high dose oral folic acid and vitamin B complex
B. Establish IV access and begin fast fluids with Pabrinex I+II (Vitamin B12)
C. Establish IV access and send blood for methanol levels; give oral ethanol in the form ofneat 40% whisky at a dose of 175ml
D. Establish IV access and send blood for methanol levels; begin IV fomepizole 1000mg in500ml 5% dextrose over 30 minutes
E. Refer to Intensive Care to begin haemofiltration

D. Establish IV access and send blood for methanol levels; begin IV fomepizole 1000mg in500ml 5% dextrose over 30 minutes

Methanol poisoning is preferentially treated with IV fomepizole; this should be commenced immediately the suspicion is raised

The clinical picture in this scenario is typical of an acute alcohol intoxication syndrome with descriptors of ataxia, confusion, aggression and drowsiness. Often there will be a smell of alcohol present when examining the patient and unfortunately, a coherent history is often absent due to poor compliance and often incapacity. However, in the vignette, there are features which might not be expected with a case of ethanol intoxication such as difficulties with vision, often detected by the failure of making any eye contact or of requesting extra lighting in a well-lit room. This suggests damage to the optic nerve and is a feature of methanol poisoning. Methanol toxicity is often very difficult to distinguish from ethanol intoxication but visual symptoms should prompt consideration coupled with a careful history.

Similar to drinkable ethanol, methanol is rapidly metabolised by hepatic enzymes; ethanol dehydrogenase converts methanol to formaldehyde and aldehyde dehydrogenase further metabolises this to formic acid (formate) which is extremely toxic to the central nervous system. Accumulation of formate in the central nervous system leads not only to cellular hypoxia due to interruption of mitochondrial cytochrome activity but also a profound acidosis. Coupled with this methanol itself, similar to ethanol, causes central nervous and respiratory depression further augmenting its toxicity.

Typically bloods will show a metabolic acidosis with a high anion gap - often co-ingestion of ethanol will have occurred and this may account for some of the unmeasured ions but often the plasma ethanol level will not be sufficiently raised to explain it in totality. Calculation of the osmolar gap may also be elevated initially which is not seen so much with ethanol toxicity.

Treatment of methanol toxicity is by blockade of the metabolism of methanol to formate leading to renal clearance of the unmetabolised methanol. Both ethanol and fomepizole are competitive inhibitors of methanol metabolism as they preferentially have an affinity for both ethanol dehydrogenase and aldehyde dehydrogenase and so toxic formate is not produced. Fomepizole, although very expensive, is preferentially used over ethanol as there is a risk of precipitating ethanol toxicity with its associated central nervous and respiratory depression. If ethanol is used as an antidote, regular monitoring of plasma ethanol concentrations are needed to ensure maintenance within the range of 100-200mg/dL. In this case, plasma ethanol levels are within this range anyway and methanol toxicity is still occurring. Both fomepizole and ethanol need to be continued until plasma methanol concentrations fall below <50mg/L.

In addition, intravenous folinic acid should be given as this aids in the speedy metabolism of formic acid and helps in reducing the central nervous toxicity. Unfortunately, oral folic acid is insufficiently rapidly absorbed to be helpful in this situation. Supplementation of B vitamins is important in cases of any alcohol toxicity as this avoids development of Wernicke's encephalopathy and this should take the form of Pabrinex I+II, however, it is not the most pressing concern in a potential methanol toxicity case. Oral vitamin B complex is important in chronic alcoholism but not in an acute situation. Haemofiltration is a potential mechanism for clearing methanol from the circulation, however, this is usually reserved for occasions when fomepizole fails or is not tolerated.

In cases of methanol toxicity, an intensive care opinion may be useful however as central venous access may be required to administer bicarbonate in severe acidosis or in case of respiratory depression requiring intubation and assisted ventilation.

Note that in cases of suspected methanol poisoning, commencing an antidote immediately is important and should be done before methanol levels have been confirmed.

Question 77 of 138

A 30-year-old man was referred to endocrinology clinic for the assessment of the adverse consequences of anabolic steroid use. The patient reported that he had recently decided to stop using anabolic steroids, having been a regular user for the previous 5 years to support his bodybuilding training. The patient cited the potential health risks of long-term anabolic steroid use as the reason behind his decision to cease his use.

The patient had followed a regime of an intramuscular injection of long-acting synthetic testosterone derivative every two weeks. The patient took a 4-week break from anabolic steroids every 12 weeks, in an attempt to limit the adverse side-effects. The patient denied ever having used oral or topical synthetic testosterone preparations and had always used sterile injecting equipment.

The patient stated that he had developed significant gynaecomastia and also suffered significant male pattern baldness since starting to use anabolic steroids. In addition, 2 years previously he had suffered a ruptured right biceps tendon while exercising, requiring a surgical repair and had a prolonged period of rehabilitation. There was no history of symptoms suggestive of cardiac or liver disease. The patient took no regular prescribed medications and reported an alcohol consumption of between 15 to 20 units per week.

General examination of the patient revealed a highly muscular and lean adult male. Moderate gynaecomastia was present, but there were no other signs of chronic liver disease. Examination of the cardiovascular and respiratory systems was unremarkable.

Please see below for the available results of blood tests taken prior to the patient's attendance at the clinic.

HbA1C	47 mmol / mol (reference < 42)
Total cholesterol	6.1 mmol / L (reference < 5.0)
Fasting LDL cholesterol	5.0 mmol / L (reference < 3.0)
Fasting HDL cholesterol	1.1 mmol / L (reference > 1.2)
Prolactin	490 mU / L (reference 80 - 400)
Luteinising hormone	*result pending*
Follicle-stimulating hormone	*result pending*
Testosterone	*result pending*
Epitestosterone	*result pending*

What pattern of results for the pending blood tests is consistent with the patient's anabolic steroid use?

A. Elevated testosterone:epitestosterone ratio; normal luteinising hormone; normal folliclestimulating hormone

B. Suppressed testosterone:epitestosterone ratio; elevated luteinising hormone; suppressedfollicle-stimulating hormone

C. Suppressed testosterone:epitestosterone ratio; suppressed luteinising hormone;suppressed follicle-stimulating hormone

D. Elevated testosterone:epitestosterone ratio; suppressed luteinising hormone; suppressedfollicle-stimulating hormone

E. Normal testosterone:epitestosterone ratio; elevated luteinising hormone; elevated folliclestimulating hormone

D. Elevated testosterone:epitestosterone ratio; suppressed luteinising hormone; suppressedfollicle-stimulating hormone

The patient has developed some of the typical unwanted effects associated with anabolic steroid use; namely gynaecomastia and accelerated male pattern baldness. In addition, tendon rupture is frequently associated with anabolic steroid use due to the disproportionate enhancement of muscle bulk compared to tendon strength. Other common unwanted effects include acne, testicular atrophy (or clitoral hypertrophy in females), impaired glucose tolerance and a deranged blood lipid profile. More worryingly, anabolic steroid use is also associated with serious liver disease and an increased mortality from heart disease.

Epitestosterone is a naturally occurring stereoisomer of testosterone produced by the testes. In healthy males, the testosterone:epitestosterone ratio is typically 1:1. However, exogenous administration of testosterone does not increase levels of epitestosterone, so anabolic steroid use is associated with an increase in the testosterone:epitestosterone ratio (typically to greater than 4:1). In anti-doping testing for competitive sports, an elevated testosterone:epitestosterone ratio is considered possible evidence of anabolic steroid use.

Physiological production of testosterone is promoted by the release of the gonadotropins luteinising hormone and follicle stimulating hormone by the pituitary gland. Both these hormones increase the number of testosterone-producing Leydig cells in the testes, with luteinising hormone also increasing testosterone production by Leydig cells. Elevated testosterone levels reduce gonadotropin production via negative feedback to the hypothalamus (causing reduced gonadotropin releasing hormone production) and the pituitary gland. Therefore, high levels of exogenous testosterone will act to suppress luteinising hormone and follicle stimulating hormone.

Question 78 of 138

A 64-year-old man presents with several months of weight loss, anxiety, and palpitations. His wife mentions that he keeps the house temperature cool as he is generally feeling too hot. He has a background of ventricular tachycardia, for which he has been taking amiodarone for some years.

On examination, he has a slight tremor and appears thin. His heart rate is 105/min. There is no goitre present.

Blood tests are taken:

Thyroid stimulating hormone (TSH)	<0.05 mU/L	(0.5-5.5)

Free thyroxine (T4)	25 pmol/L	(9.0 - 18)

He is subsequently referred for an ultrasound scan of the neck, which shows absent vascularity and probable gland destruction.

What is the most appropriate treatment?

A. Carbimazole
B. Iodine
C. Prednisolone
D. Propranolol
E. Propylthiouracil

C. Prednisolone

In amiodarone induced thyrotoxicosis type 2 the management is with corticosteroids rather than carbimazole

This patient is likely experiencing amiodarone-induced thyrotoxicosis (AIT). This can be divided into two types. Type 1 results from excess iodine-induced thyroid hormone synthesis; a goitre is typically present. Type 2 results from amiodarone-related destructive thyroiditis and, as in this scenario, a goitre is absent. Differentiation of the two types is important as they have different management. The ultrasound scan here also shows probable gland destruction, pointing towards type 2. Management involves the use of corticosteroids and so **prednisolone** is correct.

Carbimazole is typically used for the treatment of hyperthyroidism and would be suitable for the management of type 1 AIT. However, this scenario is more likely to be occurring as a result of type 2 AIT and so prednisolone remains more appropriate.

Iodine may be used as part of the management of hyperthyroidism generally, as well as a thyroid storm. Definitive management for type 2 AIT, however, is corticosteroid use.

Propranolol is a beta-blocker and can be used for short-term symptom relief of hyperthyroidism. It does not play a role in the definitive management of type 2 AIT.

Propylthiouracil is another drug used in the management of hyperthyroidism. Again, with the management of type 2 AIT specifically, corticosteroids are more appropriate.

Question 79 of 138

A 45-year-old man was found unconscious at home by his partner, with empty packs of flecainide, codeine and valerian root tablets besides him. He was only found after his partner got worried when he had locked himself in his room and after 4 hours not heard any sounds from the room. He had been depressed for the past couple of months and relations between him and his partner had been strained. He has a past medical history of back pain, paroxysmal atrial fibrillation, angina and hypertension.

On examination, he was drowsy, unable to give a history, with a heart rate of 50bpm, respiratory rate of 16 breaths per minute, oxygen saturation of 96% on air, and a blood pressure of 110/58mmHg. Pupils were 3mm and equal and reactive to light.

Investigations:

Na+	136 mmol/l
K+	4.6 mmol/l
Urea	10.9 mmol/l
Creatinine	110 µmol/l
Serum bilirubin	30 µmol/l
Serum alkaline phosphatase	135 IU/l
Serum aspartate aminotransferase	50 IU/l
C Reactive protein	2mg/l
Haemoglobin	14.6 g/dl
White cell count	5.6 x 109/L
INR	1.4

ABG (on air):

pH	7.258
pO2	11.7 kPa
pCO2	3.4 kPa
Lactate	1.6 mmol/l
Base Excess	-8.4 mmol/l
Bicarbonate	11.9 mmol/l

ECG showed bradycardia with widened QRS complexes and giant inverted T waves. After fluid resuscitation,

what is the next single most important management step?

A. Activated Charcoal
B. Magnesium Sulphate
C. Sodium Bicarbonate
D. Haemodialysis
E. N-Acetyl Cysteine infusion (NAC)

C. Sodium Bicarbonate

This patient has overdosed on a number of medications, the most toxic being codeine and flecainide. He has evidence of cardiac arrhythmias, bradycardia and metabolic acidosis consistent with flecainide overdose, and also mildly deranged liver functions. There is no evidence of respiratory depression.

Flecainide is a class 1c antiarrhythmic, which blocks sodium channels leaving the action potential unchanged. Cardiac features predominate, causing bradycardia, hypotension, nodal and ventricular tachycardia. ECG abnormalities include marked prolongation of the QRS and Q-T interval and giant inverted T waves. Other features include hypoxia, respiratory depression, metabolic acidosis, and reduced renal function. Nausea, vomiting, coma and convulsions have been reported.

As the time of ingestion is unknown, possibly up to 4 hours ago, he has probably missed the window for gastric decontamination with activated charcoal. The presence of QRS prolongation and acidosis would require rapid correction with sodium bicarbonate infusions, ideally via a central line, to reverse the effects of flecainide.

Haemodialysis are of no value in eliminating flecainide from the system. Magnesium is indicated if there is evidence of a prolonged QT interval. NAC is indicated for paracetamol overdose.

Valerian root tablets are herbal sleeping remedies and do not have lasting side effects if taken in large quantities.

Question 80 of 138

A 59- year- old male presented with palpitations, excessive sweating and weight loss for two months. Two years ago he was diagnosed with atrial fibrillation and commenced on amiodarone.

On examination, his pulse rate is 80 beats per minute, irregularly irregular, and his blood pressure is 135/80. There was no goitre, no eye signs or hand signs.

Investigations reveal:

Serum free T4	60 pmol/l
Serum free T3	15 pmol/l (5-10)
Serum TSH	<0.05 mU/l
Serum antithyroid peroxidase	negative
TSH receptor antibodies	negative

Radioactive iodine uptake scan showed reduced uptake by the thyroid gland.

What is the most appropriate management for this patient?

A. Discontinue amiodarone and give carbimazole
B. Discontinue amiodarone and give potassium perchlorate
C. Discontinue amiodarone and give prednisolone
D. Radioactive iodine
E. Total thyroidectomy

C. Discontinue amiodarone and give prednisolone

The diagnosis is amiodarone induced thyrotoxicosis (AIT) type 2 which is a destructive thyroiditis treated with prednisolone.

AIT type 2 is differentiated from AIT type 1 by the reduced iodine uptake, absence of thyroid autoantibodies and absence of goitre.

AIT type 1 is treated with carbimazole or potassium perchlorate.

If amiodarone could not be stopped as in ventricular tachycardia, then total thyroidectomy should be considered.

Question 81 of 138

An 85-year-old female is admitted under the general medical unit with acute thoracic back pain from a T6 crush fracture following a fall. She has a past history of systolic heart failure, depression and osteoporosis.

Her regular medications included aspirin, frusemide, spironolactone, bisoprolol, sertraline and calcium, vitamin D and weekly alendronate. These are continued throughout her admission.

Two days into her admission, the nurses note that she is agitated and a bit confused.

On examination, she looks flushed and is tachycardic with a heart rate of 120 beats/min and is hypertensive with a blood pressure of 185/70 mmHg, but is afebrile. Both her pupils are mildly dilated, she is mildly tremulous and is noted to have deep tendon hyperreflexia with easily inducible clonus.

Use of which of the following analgaesic medication could explain her current symptoms?

A. Paracetamol
B. Ibuprofen
C. Oxycodone
D. Tramadol
E. Hydromorphone

D. Tramadol

Serotonin syndrome is a disorder characterised by serotonin excess, usually due to the use of 2 or more serotonergic drugs. Manifestations of the syndrome include changes in mental status, neuromuscular changes and autonomic overactivity. Clinically, this can be observed as hypertension, tachycardia, flushing and sweating, hyperflexia, clonus and muscle rigidity. Other potential signs include fever and changes in mental status, including agitation.

Serotonergic drugs that are associated with serotonin syndrome include tramadol, selective serotonin reuptake inhibitors (SSRI), monoamine oxidase inhibitors (MAOI), triptans and St Johns wort.

The management of serotonin syndrome involves discontinuation of all serotonergic drugs and

supportive care. If required, benzodiazepine can be administered to control agitation. In moderate to severe cases, 5-HT antagonists (e.g. cyproheptadine and chlorpromazine) are sometimes administered.

Question 82 of 138

A 63 year old farmer is brought to the Emergency Department after falling into a trough of organophosphate sheep dip. On arrival in the department he is in extremis with profuse vomiting and productive of copious respiratory secretions. His airway is threatened but he is also agitated and difficult to assess. Respiratory rate is 20 breaths per minute and oxygen saturations are 87% on 4L/min oxygen. Wheeze is audible from the end of the bed. The heart rate is 55bpm and the blood pressure is 92/44mmHg. Heart sounds are normal. He is incontinent of urine and faeces and has severe abdominal pain. There is widespread muscle fasciculation and global weakness. Pupils are pinpoint.

Which of the following best describes the toxic action of organophosphate compounds?

A. Adrenergic blockade due to competitive inhibition of α1, α2, β1 and β3 receptors
B. Adrenergic upregulation due to inhibition of monoamine oxidase
C. Cholinergic upregulation due to inhibition of acetylcholinesterase
D. Cholinergic upregulation due to direct activation at muscarinic M1, M2 and M3 receptors
E. Cholinergic upregulation due to direct activation at nicotinic CNS and muscle receptors

C. Cholinergic upregulation due to inhibition of acetylcholinesterase

Organophosphate poisoning occurs due to inhibition of acetylcholinesterase leading to upregulation of nicotinic and muscarinic cholinergic neurotransmission

Organophosphate insecticides are highly effective pesticidal agents. They work by binding to and irreversibly inactivating the enzyme acetylcholinesterase (AChE) which is essential for respiration in insects. Unfortunately, they also inhibit AChE in humans too, which exerts toxic effects when inadvertent exposure occurs occupationally, and this class of agents can also be used as a chemical weapon in the form of nerve gases.

Due to the non-specificity of acetylcholinesterase in cholinergic synapses, inhibition of the enzyme leads to upregulation of neurotransmission at all cholinergic synapses, giving rise to both nicotinic and muscarinic symptoms. Classically, the muscarinic symptoms seen can be remembered by the mnemonic SLUDGE: salivation, lacrimation, urination, defecation, gastrointestinal pain, emesis, and also pupillary constriction, bronchoconstriction and bradycardia. Nicotinic symptoms include headache, anxiety, fasciculations, weakness, ataxia, confusion and respiratory depression.

Sometimes there is variation in the extent of symptoms observed due to the relative upregulation of each neurotransmitter symptom with either predominant nicotinic symptoms or muscarinic ones, for example either bradycardia due to muscarinic overdrive or tachycardia due to nicotinic drive.

Knowledge of the pathophysiological effects of organophosphates is important because it guides treatment. Severe exposure to organophosphates may cause death within minutes due to respiratory failure. Provision of supplemental oxygen is important. The first life-saving intervention which may be provided is intravenous atropine which is a competitive antagonist at muscarinic receptors, predominantly subtypes M1, M2 and M3. This increases heart rate and improves respiratory function by relaxing bronchial smooth muscle and drying secretions. Atropine administration may need to be repeated multiple times at doses up to 2mg every five minutes until heart rate is above 80. Definitive treatment may be provided by administration of pralidoxime or obidoxime which are oxime drugs which bind to an allosteric moiety of AChE and causes a conformational change in the enzyme allowing it to be released from the organophosphate. Organophosphates irreversibly bind to AChE when in their physiological state but conformational change by oximes allows this to be undone. This is time dependent however and a process known as aging occurs whereby the longer the enzyme is inhibited the less likely the oxime is to be able to reanimate it. In warfare, soldiers are often supplied with auto-injectors containing atropine, pralidoxime and midazolam as an immediate response to exposure to nerve agents.

While exposure to organophosphates often produces hypotension and bradycardia with bronchoconstriction, they have no effect on adrenergic neurotransmission.

It is also important to note that organophosphate exposure is from environmental sources and as such decontamination is vital to prevent exposure to healthcare providers and appropriate personal protective equipment must be worn by rescuers.

Question 83 of 138

A 49-year-old woman with a diagnosis of Hashimoto's thyroiditis is seen in clinic with recurrence of lethargy, constipation, cold intolerance and pedal oedema. These symptoms had previously resolved on starting treatment with levothyroxine.

Her co-morbidities include type 2 diabetes mellitus and hypertension. She was also diagnosed with mycobacterium tuberculosis of the lung five months ago. Her current medications are levothyroxine, amlodipine, ramipril, metformin, gliclazide, rifampicin, isoniazid and pyridoxine.

Her temperature is 36.5°C, pulse 55 beats per minute, blood pressure 165/102 mmHg and respiratory rate 15 breaths per minute.

Thyroid function tests showed:

Free thyroxine (T4)	5 pmol/L (10-25)
Free triiodothyronine (T3)	3 pmol/L (5-10)
Thyroid-stimulating hormone	7.2 mU/L (0.4-5.0)

What is the likely cause of her symptoms?

A. Vitamin B6 deficiency
B. Rifampicin
C. Isoniazid
D. Non-compliance with medications
E. Amlodipine

B. Rifampicin

Rifampicin is a P450 enzyme inductor

In patients with treated hypothyroidism, thyroxine requirements are increased by cytochrome P450 inducing drugs such as rifampicin. Isoniazid does not have this effect.

Non-compliance with levothyroxine may also give a similar picture, but there is no firm evidence

Question 84 of 138

A 52-year-old farmer was brought into the Emergency Department by his wife. Over the last few hours, he developed severe diarrhoea, passing 10 loose stools in the last four hours. He was also passing urine more frequently and on a couple of occasions was incontinent of urine. He also complained of feeling unwell with a headache and nausea and as well as a cough with white phlegm, and at times felt very short of breath particularly upon coughing. He denied the presence of chest pain. He had a past medical history of COPD, atrial fibrillation, depression and hypertension and his drug history comprised of Seretide 2puffs BD, salbutamol PRN, digoxin 250mcg OD, warfarin 2mg OD, sertraline 150mg OD, diazepam 2mg BD PRN and amlodipine 5mg OD.

Examination revealed the presence of an unwell and unkempt gentleman. His heart rate was 46 bpm and regular, his blood pressure was 88/48mmHG, his respiratory rate was 18, oxygen saturations 96% on air and temperature 35.7ºC. His BM was 3.8 mmol/l. Examination of his cardiovascular system revealed the presence of warm well perfused peripheries with normal heart sounds and a JVP of 3cm. Examination of his respiratory system revealed the presence of copious upper airways secretions but the absence of respiratory distress. Examination of his gastrointestinal system revealed the presence of excess salivation but was otherwise unremarkable. Examination of his neurological system revealed the presence of bilateral pupil constriction but otherwise no abnormalities and a GCS of 15.

He was promptly transferred to the resuscitation area and cannulated with 2 large bore cannulae. Stat intravenous saline 3 litres were promptly infused and an urgent medical consult was requested. Initial investigations revealed the following:

Hb	140 g/l
Platelets	198 * 10 /l9
WBC	6.6 * 10 /l9
CRP	4 mg/l

Coagulation screen: INR 2.2, APTT and fibrinogen within normal limits Portable chest x-ray: poor quality rotated film. Normal appearance of heart and lung fields.

ECG: sinus bradycardia heart rate 45bpm, normal sinus rhythm, normal QRS and QTc intervals, no acute ST/T changes

Arterial blood gases on air:

pH	7.33
Pa02	12.6 KPa
PaCO2	5.8 kPa
HCO3	18 mmol/l
BE	-4

Of the following options which is the most appropriate curative management step?

A. Commence digoxin fragment binding antibody (Digibind)
B. Commence broad spectrum intravenous antibiotics and instigate sepsis protocol
C. Commence intravenous noradrenaline
D. Commence intravenous flumazenil
E. Commence intravenous atropine

E.Commence intravenous atropine

Organophosphate insecticide – atropine

This gentleman has presented with organophosphate toxicity, as manifest by excess salivation, defecation, urinary frequency and copious respiratory secretions. His blood pressure was low and he was bradycardic. He had a history of depression and was prescribed a large dose of sertraline, and statistically was therefore at greater risk of deliberate self-harm (though it may also have been accidentally ingested). Of the following options, atropine is the only antidote to organophosphate and is, therefore, the most appropriate answer (note the question asked for the option most likely to lead to a cure, rather than the next best step, excluding option 3).

Of the remaining options, his symptoms do not correlate well with digoxin toxicity and his ECG has no changes other than bradycardia making this a less likely option. Even if he had ingested diazepam in excess there is no indication to commence flumazenil, and there is little evidence to suggest that he Is suffering from sepsis.

Question 85 of 138

A 70-year-old man is admitted to hospital with shortness of breath and a productive cough. Following initial investigation a community-acquired pneumonia is diagnosed and treatment with IV fluids and IV antibiotics initiated promptly. Subcutaneous enoxaparin for venous thromboprophylaxis was initiated on the day of admission. Due to persistent hypotension and oliguria secondary due to presumed septic shock, the patient was admitted to the General Intensive Care Unit for inotropic support around 12 hours after initial presentation.

The patients past medical history featured a previous ST elevation myocardial infarction, treated with primary percutaneous coronary interventions one year previously. Regular medications included Aspirin, Clopidogrel, Ramipril, Bisoprolol and Atorvastatin. The patient had no known drug allergies and lived independently in a house with his wife.

With the above management, the patients condition stabilised and he was discharged to a respiratory ward on day 3 of the admission. Routine blood tests taken on day 7 of admission demonstrated a marked fall in platelet count compared to admission bloods. Full examination of the patient at this time did not demonstrate any evidence of venous thrombosis with no skin changes. Following advice from haematology further investigations were requested as detailed below.

Blood results	Day 0 (admission)	Day 3	Day 7
Platelets (x 10>3 / microlitre)	189	156	87
International normalised ratio	1.1	1.3	1.2

Heparin induced thrombocytopenia antibodies: positive (moderate titre)

What further investigation is required (if any) to confirm a diagnosis of heparin induced thrombocytopenia?

A. Serotonin release assay
B. Repeat heparin induced thrombocytopenia antibodies
C. Venous doppler ultrasound of lower limbs
D. Fibrinogen break-down products
E. No further investigation required

A. Serotonin release assay

The diagnosis of heparin induced thrombocytopenia is based on the correlation of the clinical presentation and laboratory results. It is helpful to calculate a pre-test probability score using a tool such as the Warkentin probability scale to assist with interpretation of HIT antibody results. In this case the patient has an intermediate clinical probability of HIT based on the fall in platelet count > 50 % of baseline between day 5-10 of initiating heparin therapy. However, the presence of an alternative cause of thrombocytopenia (severe sepsis) reduces the probability of HIT.

The combination of moderate clinical probability and moderate HIT antibody titre indicate the need for additional testing. Functional assays such as the serotonin release assay have a high sensitivity and specificity for HIT (> 95 %) and so will confirm or exclude a diagnosis of HIT.

Given the clinical picture, it would be prudent in this case to hold further heparin anticoagulants and introduce a non-heparin anticoagulant such as Bivalirudin to reduce the risk of HIT related thrombosis while further testing is being conducted.

Question 86 of 138

A 62-year-old man is seen in the Emergency Department with a rash which has developed over the last 24 hours. He has had increasing malaise throughout the day. His past medical history includes hypertension and gout. He was started on allopurinol 3 weeks ago due to increasing frequency of his gout attacks. He also takes ramipril and amlodipine.

On examination he has an erythematous maculopapular rash over his whole body, worst on his trunk. He is tachycardic at 105 beats per minute with a blood pressure of 110/55 mmHg and a temperature of 38.1 ºC. He has some residual pain in his right great toe but no other focal signs or symptoms.

His blood tests are as follows:

Hb	130 g/l	Na +	141 mmol/l
Platelets	550 * 10 /l 9	K +	4.7 mmol/l
WBC	12.5 * 10 /l 9	Urea	6 mmol/l
Neuts	6 * 10 /l 9	Creatinine	95 µmol/l
Lymphs	5 * 10 /l 9	CRP	65 mg/l
Eosin	1.5 * 10 /l9		

What is the most likely diagnosis?

A. Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome
B. Stephens-Johnson syndrome
C. Anaphylactoid reaction
D. Toxic epidermal necrolysis
E. Reactive arthritis

A. Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome

The presence of maculopapular rash, fever and raised lymphocytes and eosinophils points to a likely diagnosis of DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome. This is a rare complication following treatment with chemotherapy agents, allopurinol or antiepileptics.

Stevens-Johnson syndrome and toxic epidermal necrolysis are part of a spectrum of skin reaction and can also occur with allopurinol. However typically patients present with a target-like rash and progressive blistering and eventual skin detachment. Eyes and other mucosal surfaces are often involved. Anaphylactoid reactions are immediately occurring and present with angioedema, bronchospasm and hypotension. Reactive arthritis presents with a triad of arthritis, urethritis and eye involvement.

Question 87 of 138

A 38-year-old man presents to the emergency department following the ingestion of a staggered paracetamol overdose, after an argument with his partner. He appears well and N-acetylcysteine is administered.

Twenty-four hours later, he deteriorates clinically and appears confused. Further blood tests are taken, the results are pending, and the medical team is discussing the option of a liver transplant.

What single feature would justify this?

A. Arterial pH <7.3
B. Creatinine >300 µmol/l
C. Grade III or IV encephalopathy
D. Prothrombin time >100 seconds
E. Staggered overdose requiring N-acetylcysteine

A….Arterial pH <7.3

Liver transplantation criteria in paracetamol overdose: pH < 7.3 more than 24 hours after ingestion

The correct answer is an **arterial pH <7.3**. The King's College Hospital criteria define two categories of patients with poor prognosis following paracetamol overdose. One cohort is those in whom arterial pH is less than 7.3, over 24 hours after ingestion. The other cohort is patients who have all three of the following: creatinine >300 µmol/l, prothrombin time >100 seconds and grade III/IV encephalopathy. Therefore, of the options above, the only option which, alone, would warrant consideration of transplantation is arterial pH <7.3.

Creatinine >300 µmol/l alone is therefore incorrect. This forms part of three elements, as described above, which must all be present.

For the same reason, **grade III or IV encephalopathy** alone is also therefore incorrect. It must be present alongside elevated creatinine and prothrombin time.

Prolonged prothrombin time is also incorrect for the reasons described above.

Whether the overdose was **staggered and/or required N-acetylcysteine** infusion does not form part of the criteria.

Question 88 of 138

A 19 year old man is brought into the Accident & Emergency department by his parents who are very concerned about his well being, and a medical opinion is sought. He arrived home from an evening with friends and was behaving bizzarely. When you talk to him, he tells you that he is feeling on top of the world and that he is an angel sent from god. He also describes seeing music as colours coming out of the radio earlier in the evening. He describes colours being more vivid and vibrant but denies any hallucinations. He has been unable to sleep for the past 24 hours

On examination, he is confused and disorientated but alert, skin colour is normal, central capillary refill time less than 2 seconds with moist mucous membranes. Normal eye movements, no peripheral focal neurology HR 115 sinus tachycardia (ECG normal) Blood tests (essentially normal) RR 16. Pupils dilated but responsive to light equally BP 174/98. When you are testing his eye movements he describes seeing trailing colours and when he closes his eyes he can see afterimages that persist for a few seconds. He repeatedly asks you for glasses of water during the consultation and drinks them quite rapidly.

His mother says that he has no past history of medical problems and that his mental state has been normal until today and that he was well before he left the house 6 hours ago this evening. There is a family history of depression and he has recently left university due to not achieving the required grades

Towards the end of the consultation, he suddenly becomes very agitated and fearful, pointing at a wall believing that he is being chased by a monster, his family are unable to comfort him or lessen his agitation.

What is the the most appropriate treatment to give at this time?

A. Haloperidol 5mg IM
B. Lorazepam 1mg IM
C. Lorazepam 1mg PO
D. Olanzapine 10mg PO
E. Lorazepam IV 1mg and cyproheptadine.

C. Lorazepam 1mg PO

This man is suffering from LSD intoxication. He is describing the symptom of synaesthesia where sensations are perceived in a different modality, in this case seeing music He is also describing palinopsia which is where an after image persists for a few seconds after looking away from the original stimulus. This can happen in a clear sensorium if on focuses on an image for long enough but then the colours will be inverted. In palinopsia there is no inversion of colours. Palinopsia and synaesthesia can occur in temporal lobe epilepsy and other organic conditions, but is quite typical of hallucinogenic usage, particularly LSD. LSD intoxication can also cause expansive mood and grandiosity as seen here and this may rise to delusional intensity. Illusions (distortions of normal perception) and hallucinations in any modality are relatively common as is agitation and anxiety.

The answer is C. In the fist instance reassurance should be used and the patient should be placed in a calm environment with familiar people around. If this fails then benzodiazepenes should be administered. They should be tried orally first as the rate of action PO is similar to IM and injection may cause unecceasry distress in an agitated patient. The question tells you that he has drank water during the consultation, so it is reasonable to try PO first, if this fails then IM would be the next line.

Options A and D could be used as second line therapy if benzodizaepenes fail and also can be used in the treatment of mania. Mania is not the diagnosis here as there is a short history of onset, palinopsia and synaesethesia are much less common and you should not see dilated pupils.

Option E would be a treatment for severe seritonergic syndrome. LSD intoxication can cause serotinergic syndrome, especially if taken in conjunction with other drugs such as MDMA, SSRIs or TCAS. However, there is no evidence of this in our individual.

Question 89 of 138

A 66-year-old woman is reviewed in the rheumatology clinic for ongoing rheumatoid arthritis, which has been difficult to control. Several joints are currently flaring up and her current agent is not effective in controlling her symptoms.

After some consideration, she is switched to another agent. Blood tests are measured before she starts:

eGFR	>90 ml/min/1.73 m^2	(>90)
Creatinine	56 µmol/L	(55 - 120)

Several weeks after commencing the new drug, her blood tests are measured again:

eGFR	27 ml/min/1.73 m^2	(>90)
Creatinine	198 µmol/L	(55 - 120)

What is she most likely to have started?

A. Ciclosporin
B. Etanercept
C. Infliximab
D. Leflunomide
E. Sulfasalazine

A. Ciclosporin

Ciclosporin may cause nephrotoxicity

Of the options above, **ciclosporin** is best known to cause nephrotoxicity. It is sometimes used as a disease-modifying agent for rheumatoid arthritis. As well as being nephrotoxic, it is hepatotoxic, causes fluid retention, hyperkalaemia, hypertrichosis, gingival hyperplasia and other side effects.

Etanercept is a newer, biologic drug that interferes with tumour necrosis factor-alpha. It is not

widely known to be nephrotoxic. There are some case reports but overall ciclosporin is a much more likely cause.

Infliximab is another biologic used in the management of rheumatoid arthritis and also interferes with tumour necrosis factor-alpha. Like etanercept, it is not particularly known for nephrotoxicity, unlike cyclosporin.

Leflunomide has a similar side effect profile to methotrexate, affecting a wide number of systems, but is not strongly associated with nephrotoxicity.

Sulfasalazine is an aminosalicylate, sometimes used in the management of rheumatoid arthritis. It is not strongly linked to nephrotoxicity.

Question 90 of 138

A 19-year-old male is found collapsed in a dark alley. He is of no known abode. He is very drowsy but oriented to person, place and time with a Glasgow coma scale of 14/15 (E3, V5, M6). He smells of alcohol but denies having consumed any. His clinical examination is significant for impairment in visual acuity bilaterally. He has a tremor of his outstretched hands but the rest of his examination is normal. His blood pressure is 145/76mmHg with a pulse of 101/min regular, respiratory rate of 22/min and an oxygen saturation of 95% on room air.

Investigations:

Hb	11.3 g/dl
MCV	102 fl
Platelets	110 * 10 /l9
WBC	12 * 10 /l9
Creatinine	117 umol/L
Urea	9 umol/L
Na+	146 mmol/L
K+	5.4 mmol/L
CL-	109 mmol/L

Arterial blood gas:

pH	7.21
PaO2	10.9 kPa
PaCO2	4.2 kPa
HCO3	16 mEq/L

Considering the ingested toxin, what is the next best step in your management?

A. Fomepizole
B. N-acetyl cysteine
C. Activated charcoal
D. Gastric lavage
E. Sodium bicarbonate

A…Fomepizole

Answer: Fomepizole or 4-methylpyrazole.

This patient has ingested methanol. Clue to this is the fact that he smells of alcohol but denies having consumed any, though definitive diagnosis is based on a raised serum methanol level. Initial symptoms are similar to those felt in alcohol intoxication including ataxia, disinhibition, headaches, nausea and vomiting. These are followed by drowsiness which may progress to coma. Metabolic acidosis with raised anion gap is common.

He has visual impairment indicating severe methanol toxicity. Visual signs present in methanol toxicity include, photophobia, blurred vision, poor visual acuity and blindness. Fundoscopy could reveal optic disc swelling or pseudoglaucomatous changes.

This patient needs urgent treatment with i.v fomepizole. If this is not available then i.v ethanol is an adequate alternative though it will produce symptoms similar to alcohol intoxication.

Fomepizole acts by inhibiting the primary step in the conversion of methanol to formic acid, a highly toxic metabolite. Specifically it competitively inhibits alcohol dehydrogenase, the enzyme that converts methanol to formaldehyde which is then further oxidised to formic acid by formaldehyde dehydrogenase.

The signs of methanol toxicity are caused my formic acid so inhibition of its synthesis is a very important step in its management.

Dialysis may be needed to help rapid elimination of the toxin from the system. The following are the indications for haemodialysis in methanol intoxication:

- worsening acidosis despite sodium bicarbonate treatment
- visual involvement
- quantity of consumed methanol exceeding 30ml
- serum methanol level greater than 20mg/dl

Other conditions that may be present in methanol toxicity include:

- Seizures
- cardiac arrhythmias and heart failure
- haemorrhagic pancreatitis
- parkinsonism secondary to haemorrhagic and non haemorrhagic damage to the basal ganglia

He is acidotic and whilst sodium bicarbonate could help with acidosis it is unlikely to lead to overall improvement.

N-acetyl cysteine is used in paracetamol overdose.

Question 91 of 138

A 49-year-old woman comes to the Emergency department suffering from nausea and lethargy which has increased over the past few days. She has undergone a renal transplant for end stage renal failure due to chronic reflux nephropathy some 3 months ago. You understand her GP prescribed an antibiotic for a respiratory tract infection without checking for potential interactions with her ciclosporin based immunosuppressive regime. Creatinine has increased significantly, and ciclosporin is above the upper limit of the recommended range.

Investigations:

Na +	142 mmol/l
K +	5.1 mmol/l
Urea	8.2 mmol/l
Creatinine (3 months ago)	161 µmol/l
Creatinine (today)	225 µmol/l

Which of the following antibiotics is she most likely to have been prescribed?

A. Amoxicillin
B. Cephalexin
C. Clarithromycin
D. Doxycycline
E. Levofloxacin

C. Clarithromycin

The key here is to recognise that ciclosporin is metabolised by CYP3A4, and clarithromycin and erythromycin are both potent CYP3A4 inhibitors, leading to a potential elevation in ciclosporin levels, and subsequent nephrotoxicity. Because of the danger of either CYP3A4 inhibition or activation in patients taking ciclosporin, patients are advised to consult their transplant team before starting any new medication.

Amoxicillin is predominantly excreted unchanged in the urine, as is cephalexin. Levofloxacin undergoes very limited biotransformation, with 85% excreted in the urine. Doxycycline is

concentrated in bile, not metabolised via the P450 system. After 3 days around 40% is excreted in the urine and approximately 30% in faeces.

Question 92 of 138

A 48-year-old woman is brought in by ambulance to the emergency department, having been found at home by her neighbour with a decreased level of consciousness. She has a past medical history of open-angle glaucoma and is on regular acetazolamide.

On examination, she is obtunded. Her observations are heart rate of 111 beats per minute, blood pressure 93/65mmHg, respiratory rate of 22/min, temperature 36.7ºC, oxygen saturations of 94% on room air. Cardiovascular, respiratory and abdominal examinations are otherwise unremarkable. Her Glasgow coma scale is 10/15 (E2, V3, M5).

IV fluids are administered and arterial blood gas and blood tests are obtained. Arterial blood gas results:

pH	7.24	(7.35-7.45)
paO2	10.2 kPa	(10-14)
paCO2	5.5 kPa	(4.5 - 6.0
Base excess	-4.2 mmol/L	(-2 - +2)
Chloride	95 mmol/L	(95-105)
Bicarbonate	14 mmol/L	(22-26)
Glucose	5.0 mmol/L	(4-11)
Lactate	2.2 mmol/L	(0.5-2.0)
SaO2	95 %	(94-98)

Blood test results:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.4 * 10 /L 9	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	5.0 mmol/L	(3.5 - 5.0)
Urea	8.0 mmol/L	(2.0 - 7.0)

Creatinine	111 µmol/L	(55 - 120)
CRP	8 mg/L	(< 5)
Measured osmolality	320 mOsm/Kg	(280-290)

What is the most likely diagnosis?

A. Acetazolamide administration
B. Addisonian crisis
C. Ethylene glycol administration
D. IV sodium chloride 0.9% administration
E. Type 1 renal tubular acidosis

C. Ethylene glycol administration

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

Ethylene glycol administration is the correct answer. This is a case of a raised anion gap metabolic acidosis with a raised osmolar gap. The anion gap is calculated as (sodium + potassium) - (chloride + bicarbonate). In this case, it is 36 mmol/L, which is raised (normal range 8-16 mmol/L). The osmolar gap is calculated as osmolality (measured) - osmolarity (calculated). Osmolarity (calculated) is [2*sodium + glucose + urea]. In this case, it is (320) - (293) = 27mOsm (normal range < 10), indicating a raised osmolar gap. A high osmolar gap means the presence of an unmeasured solute in high amounts e.g. ethylene glycol in this case.

Acetazolamide administration is incorrect. This causes a normal anion gap metabolic acidosis.

Addisonian crisis is incorrect. This is a cause of a normal anion gap metabolic acidosis. The anion gap is raised in this case.

IV sodium chloride 0.9% administration is incorrect. This will cause a hyperchloremic acidosis with a normal anion gap.

Type 1 renal tubular acidosis is incorrect. This is a cause of a normal anion gap metabolic acidosis.

Question 93 of 138

A 62-year-old gentleman presents to the emergency department with central chest pain. He describes his pain as a heavy pressure in the middle of his chest which radiates to his left arm. It has improved with the use of his GTN spray, but he did not want to use more than two puffs as he is concerned about getting a headache with its us. He has a past medical history of angina, previous myocardial infarction three years ago and he is a current smoker with a 25 pack-year history.

His ECG demonstrates ST depression in V3 to V5 of 2mm, pathological Q waves and T wave inversion. His troponin is raised at 350ng/L. He is given aspirin, clopidogrel and morphine. His pain settles and he starts to feel comfortable. He has a high GRACE (Global Registry of Acute Coronary Events) score at 122, meaning that he has a 7.9% chance of death within 6 months. Following discussion with the cardiology registrar will be scheduled for an angiogram within 12 hours.

How should his acute coronary syndrome be further managed?

A. Fondaparinux
B. No further anticoagulants
C. Unfractionated heparin
D. Heparin sodium
E. Warfarin

C. Unfractionated heparin

The correct answer is unfractionated heparin. This is a patient who has presented with chest pain and diagnosed with an NSTEMI and deemed to be at sufficiently at high risk to warrant an urgent angiography. NICE recommends that patients should be treated with aspirin and clopidogrel immediately and this should be combined with fondaparinux unless at high risk of bleeding or angiography is planned within 24 hours. If angiography is planned, then unfractionated heparin should be used. This is because angiography has a risk of haematoma formation and this risk is increased when fondaparinux is used compared to unfractionated heparin as the latter has a much shorter half-life.

Question 94 of 138

A 43-year-old man attends the emergency department complaining of visual blurring, headache and nausea. He has a past medical history of alcohol dependency. He is not on any regular medications. He smokes 20 cigarettes daily and drinks at least one bottle of vodka daily. He is homeless and occasionally sources alcohol from other members of the homeless community.

His observations are as follows: heart rate 111 beats per minute, respiratory rate 28/minute, oxygen saturations 97% on room air, blood pressure 123/77 mmHg and temperature 37.1ºC.

He appears intoxicated. The cardio-respiratory examination is normal. His abdomen is mildly tender but soft and bowel sounds are present. Neurological examination is difficult but there are appears to be some blurring of his vision. His pupils are dilated. There is no epithelial defect upon staining of the eye.

Venous blood gas:

pH	7.31	(7.35-7.45)
HCO3	15 mmol/L	(22-26)
lactate	2.8 mmol/L	(0-2)
Potassium	4 mmol/L	(3.5-5.5)
Sodium	138 mmol/L	(135-145)
Cl-	96 mEq/L	(98-106

Based on the likely diagnosis, what is the most appropriate medication regimen?

A. Folinic acid
B. IV acetazolamide
C. Prednisolone
D. Thrombolysis
E. Topical antibiotics

A. Folinic acid

Folinic acid can be used in methanol poisoning to reduce ophthalmological complications

Folinic acid is the correct answer. This patient is likely to have methanol poisoning, based on the history of nausea, tachypnoea, visual disturbance, elicit alcohol use and raised anion gap (31) metabolic acidosis. Folinic acid can be used as adjunctive treatment in methanol poisoning to reduce the risk of ophthalmological complications. Anchor treatments for methanol poisoning include ethanol/fomepizole, sodium bicarbonate +/- haemodialysis if necessary.

Prednisolone is incorrect. This can reduce the risk of visual complications in giant cell arteritis but this man is too young to have a diagnosis of giant cell arteritis, despite his headache.

IV acetazolamide is incorrect. This can be used to reduce the risk of visual complications in acute angle-closure glaucoma. However, it typically causes a unilateral red eye, which is not mentioned here.

Topical antibiotics is the wrong answer. The absence of an epithelial defect in the eye makes a corneal ulcer and infection unlikely.

Thrombolysis is incorrect. The clinical history suggests methanol poisoning rather than a stroke as a cause of visual loss.

Question 95 of 138

A 48-year-old female presented with general fatigue, and nausea. She denies having pyrexia, vomiting diarrhoea or any pains. She appeared dehydrated but otherwise, observations and physical examination were within normal limits.

Blood results are as follows:

Na +	130 mmol/l
K +	4.8 mmol/l
Urea	18 mmol/l
Creatinine	162 µmol/l
Lithium	1.6 mmol/l (0.4-1.0 mmol/l)

Looking back at past results from 3 weeks ago, her renal function was in the normal range.

She has a history of bipolar disorder, diet-controlled diabetes and hypertension. She has been compliant with her lithium tablets and undergoing regular checks for the levels.

The patient revealed that her General Practitioner had recently started her on a new tablet 2 weeks ago.

Which of the following would most likely be the precipitant for her symptoms?

A. Indapamide
B. Amlodipine
C. Dihydrocodeine
D. Spironolactone
E. Propranolol

A. Indapamide

Lithium toxicity can be precipitated by thiazides

Acute renal impairment and lithium toxicity can be precipitated by any medicines that can impair renal function or induce hyponatraemia:

- Angiotensin-converting enzyme (ACE) inhibitors
- Diuretics (particularly thiazides including bendroflumethiazide and indapamide)
- Non-steroidal anti-inflammatory drugs (NSAIDs)

Target concentrations of lithium:

- acute episode (mania, hypomania, depression) 0.6-1.0 mmol/L (elderly 0.4-0.8 mmol/L).
- prophylaxis of bipolar affective disorder 0.4-0.8 mmol/L.
- toxic range usually >1.5 mmol/L; however, may begin at >1.0 mmol/L (levels >2 mmol/L need urgent treatment).

Question 96 of 138

An elderly lady brings her 32-year-old lodger into the emergency department after she witnesses him having two generalised seizures, lasting for around 4 minutes before spontaneously terminating, followed by a loss of consciousness lasting for around 10 minutes before slowly becoming rousable again. He is not known to have a history of epilepsy and does not take any regular medications. He denies any history of illicit drugs, smoking or excessive alcohol intake, corroborated by his landlady, who reports not to have seen him ever drinking in the 4 years he has been living in her loft space. Apart from a mild headache, he claims to have been well recently, continuing to work on his start-up computer software in the loft. She states that he has always 'kept himself to himself' in a cluttered dark loft space without a window, with a simple mattress and a small wardrobe. He didn't even ask for an additional heater during the cold winter as he thought 'the loft gas boiler provides enough warmth'. On examination, he is slightly sleepy but rousable. His Glasgow Coma Score is E4 V5 M6. Apart from erythematous lips, you note no other remarkable features. Neurological examination of his cranial nerves, upper and lower limbs are unremarkable. There is no ophthalmoscope available. His observations are heart rate 90/min and regular, BP 132/88 mmHg, sats 98% on air.

His blood tests demonstrate:

Hb	159 g/l
Platelets	282 * 10 /l9
WBC	7.9 * 10 /l9

Na +	143 mmol/l
K +	4.2 mmol/l
Urea	6.1 mmol/l
Creatinine	88 µmol/l
CRP	3 mg/l

His arterial blood gas demonstrate:

pH 7.25	
PaO2	15.8 kPa
PaCO2	2.9 kPa
Lactate	4.5 mmol/l

HbCO	24%

A CT head demonstrates a small area of acute ischaemic change in the right globus pallidus.

Which is the most appropriate next management?

A. High flow oxygen
B. Aspirin 300mg
C. Clopidogrel 300mg
D. PO chlordiazepoxide 40mg QDS
E. Start levetiracetam 250mg BD

A. High flow oxygen

The young patient presents with new seizures of on a background of a mild headache, red lips and a significantly raised COHb. This is a history suggestive of carbon monoxide poisoning. The ischaemic change on CT head, particularly in the globus pallidus with haemorrhagic transformation, a classic neurological consequence of carbon monoxide poisoning. It should be noted that pulse oximetry and PaO2 are commonly normal in CO poisoning. Carbon monoxide reduces haemoglobin binding capacity and not the amount of O2 dissolved in blood. A metabolic acidosis is present in the blood gas secondary to lactic acidosis from systemic ischaemia. If fundoscopy could have been performed, a cherry-red spot in the macula is the classic finding.

The initial management of CO poisoning is high flow oxygen, which reduces the half-life of CO binding to haemoglobin from 300 to 90 minutes. It is recommended that patients with severe acidosis (pH<7.1), COHb >25%, continued loss of consciousness and severe end organ failure be transferred to a unit for hyperbaric oxygen therapy.

Question 97 of 138

A 65-year-old man presents to the emergency department with dysuria and abdominal pain. He has a past medical history of chronic kidney disease stage IV. His medications include atorvastatin, amlodipine and ramipril.

On examination, there is mild suprapubic tenderness. Urinalysis:

Nitrites	positive
Leucocytes	+++
Blood	+
Protein	+
Glucose	negative

Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	22.1 mmol/L	(2.0 - 7.0)
Creatinine	278 µmol/L	(55 - 120)
EGFR	23 mL/min/1.73m2	(90-120)
CRP	48 mg/L	(< 5)

Given the likely diagnosis, which antibiotic would be unsuitable?

A. Amoxicillin
B. Cephalexin
C. Ciprofloxacin
D. Co-amoxiclav
E. Nitrofurantoin

E. Nitrofurantoin

Nitrofurantoin is best avoided in patients with CKD stage 3 or higher due to the significant risk of treatment failure and occurrence of side effects due to drug accumulation

Nitrofurantoin is correct. The patient has a urinary tract infection. Nitrofurantoin is a reasonable choice in some circumstances. However, this antibiotic should be avoided in patients with CKD stage 3 or higher due to the significant risk of treatment failure and occurrence of side effects due to drug accumulation.

Amoxicillin is incorrect. This may be a suitable choice for a urinary tract infection in some circumstances. Again, a dose reduction could be considered in severe renal impairment but it is not contraindicated.

Cephalexin is not the right answer. This is a potential antibiotic choice for a urinary tract infection. The BNF states the dose adjustment for renal impairment is a max dose of 1.5 g daily if eGFR 10- 40 mL/minute/1.73 m2.

Ciprofloxacin is not the right answer. This would be a suitable choice for a urinary tract infection in some circumstances. The BNF states the dose adjustment in renal impairment is to give 250-500 mg every 12 hours if eGFR 30-60 mL/minute/1.73 m2 or every 24 hours if eGFR is less than 30 mL/minute/1.73 m2.

Co-amoxiclav is not the right answer. This is a possible antibiotic choice for a urinary tract infection. The BNF states the dose adjustment in renal failure if eGFR 10-30 mL/minute/1.73 m2 is one 250/125 strength tablet every 12 hours or one 500/125 strength tablet every 12 hours.

Question 98 of 138

A 29-year-old male from Eastern Europe presents to the Emergency Department with 48 hours of severe 'burning and sharp' electrical pains in his arms and legs. He is well known to the department, having been treated for alcohol withdrawal a number of times in the past and is a known intravenous drug user. He reports no weakness, dysarthria or hallucinations. He reports drinking about 7 pints of beer in the past 24 hours, which he says is normal for him, and has used intravenous heroin daily for the past 2 weeks.

On examination, both upper and lower limbs are rigid and mildly bradykinetic. A bilateral resting tremor is noted in both hands. Reflexes and sensation are normal. Examination of cranial nerves and eye movements are unremarkable.

His initial blood tests return and are as follows:

Hb	163 g/l
Platelets	276 * 10 /l9
WBC	5.5 * 10 /l9
Vitamin B12	202 ng/l
Folate	471 (>317 nmol/l)

Na +	142 mmol/l
K +	4.3 mmol/l
Urea	6.4 mmol/l
Creatinine	85 µmol/l
CRP	7mg/l
HIV	negative

Which investigation is most likely to yield the underlying diagnosis?

A. DAT scan
B. Anti-GM1b antibodies
C. Borrelia burgdorferi serology
D. Urine porphybilinogen
E. Serum heavy metals

E. Serum heavy metals

The patient has presented with extrapyramidal signs in the context of a HIV-negative intravenous drug user with alcohol excess. The differential causes for Parkinsonism should be considered: idiopathic, genetic, trauma, vascular etc.

Urinary porphobilinogen is a diagnostic test for acute intermittent porphyria (AIP), typically presenting with significant abdominal pain, urinary symptoms and a peripheral neuropathy. AntiGM1b are antibodies typically present in multifocal motor neuropathy with conduction block, an immune disorder affecting motor peripheral nerves alone. Heavy metal poisoning must be considered in a young patient with Parkinsonism, in addition to the MPTP toxins found in classic cases of intravenous drug users in 1980s California. This patient is vulnerable to metals such as manganese, which is often found in 'dirty' preparation of intravenous heroin from Eastern Europe and produces extrapyramidal symptoms similar to idiopathic Parkinson's disease. Similar symptoms should be suspected in heavy industry workers.

Question 99 of 138

A 24-year-old woman presents to the emergency department following a paracetamol overdose. She advises you that she took 20 x 500mg tablets 26 hours ago. Her body weight is 62kg. On examination there is no evidence of decompensated liver failure, she is not confused, and her abdomen is soft and non-tender.

Blood results are as follows:

Hb	122 g/L	Male: (135-180)Female: (115 - 160)
Platelets	164 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.6 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	72 µmol/L	(55 - 120)

Bilirubin	14 µmol/L	(3 - 17)
ALP	66 u/L	(30 - 100)
ALT	28 u/L	(3 - 40)
Î³GT	52 u/L	(8 - 60)
Albumin	46 g/L	(35 - 50)

INR	6.2	(0.9-1.1)
Prothrombin time	82 secs	(12-16 secs)
Activated partial thromboplastin time (APTT)	28 secs	(25-35 secs)
Fibrinogen	4.5 g/L	(2 - 4)

Paracetamol level at 26 hours	Awaited

How will you manage this patient?

A. Activated charcoal
B. Await paracetamol level results
C. Discuss with the liver transplant unit
D. Gastric lavage
E. Start N-acetylcysteine

E. Start N-acetylcysteine

Paracetamol overdose: if presentation > 24 hours after an overdose start acetylcysteine if the patient is jaundiced, has hepatic tenderness or an elevated ALT

Start N-acetylcysteine is correct. Acetylcysteine should be started immediately in all patients if it is thought that 150 mg/kg or more paracetamol (or an unknown amount) has been ingested as an acute overdose (i.e. all doses taken within one hour) or if they are symptomatic with jaundice or hepatic tenderness. The patient in this case has ingested 10,000 mg / 62 kg = 161 mg/kg. She should therefore start N-acetylcysteine immediately. If the patient is asymptomatic and has ingested less than 150 mg/kg, then TOXBASE recommends waiting for blood results before considering treatment with N-acetylcysteine.

Start or continue treatment with acetylcysteine if:

- ALT is above the upper limit of normal, or
- INR is greater than 1.3 (in the absence of another cause, e.g. warfarin), or
- Paracetamol concentration is detectable

Activated charcoal is incorrect. Activated charcoal can be considered if the paracetamol has been ingested within one hour of presentation.

Await paracetamol level results is incorrect. Since the patient has ingested > 150 mg/kg of paracetamol she should be started on acetylcysteine immediately. Blood tests including paracetamol level are then monitored serially to determine the ongoing need for N-acetylcysteine treatment.

Discuss with the liver transplant unit is incorrect. There are no indications for liver transplant as per the King's college hospital criteria which includes:

- Arterial pH < 7.3 (24 hours after ingestion)
- All of the following: prothrombin time > 100 seconds, creatinine > 300 µmol/l, and grade III or IV encephalopathy

Gastric lavage is incorrect. Gastric lavage is not recommended due to concerns over perforation.

This was a previously widely favoured method that has now been all but abandoned due to a lack of evidence of efficacy and the risk of complications.

Question 100 of 138

A 44-year-old man presents to the emergency department complaining of breathlessness. He reports that he was leaving a restaurant because he was starting to feel lightheaded, developed a headache and was breathless.

An ABG done on admission demonstrated carbon monoxide at 26%.

Three hours later he feels tired and weak, but his headache and lightheadedness have improved since admission. He has a past medical history of asthma which he reports to be well controlled, rarely needing his blue inhaler. He smokes 15-ciagarettes per day and has a 23 pack-year history. He works as a teacher in central London. On examination, he is receiving 15L of oxygen via a nonrebreather mask. His chest is clear on auscultation. Neurological examination is normal. An ECG demonstrates no ischaemic changes.

Observations:

Saturations	100%
Respiratory rate	16/min
Blood pressure	126/87mmHg
Heart rate	84/min
Temperature	36.8°C

What is the most appropriate management plan?

A. Wean off oxygen guided by standard pulse oximetry saturation levels

B. Prescribe IV mannitol

C. Maintain high-flow oxygen until asymptomatic or carbon monoxide levels are <10%

D. Refer urgently for hyperbaric oxygen treatment

E. Arrange urgently for non-invasive ventilation

C. Maintain high-flow oxygen until asymptomatic or carbon monoxide levels are <10%

The answer is to maintain high-flow oxygen until asymptomatic or carbon monoxide levels are <10%. Weaning off oxygen is not appropriate to be guided by pulse oximetry as standard pulse oximetry will detect carbon monoxide bound haemoglobin as well and are therefore falsely reassuring. IV mannitol is indicated if cerebral oedema is anticipated, such as in severe cases, or established. Hyperbaric oxygen again also reserved for severe cases or pregnancy, and noninvasive ventilation has no role in carbon monoxide poisoning.

Question 101 of 138

A 23-year-old woman is admitted to the emergency department with agitation and she refuses to answer any questions. Her partner is with her and reports she has become increasingly agitated throughout the day. He states she has no past medical history but is on some tablets for her mood which her GP has recently changed. You find that she is taking sertraline and mirtazapine, but the patient and her partner are unable to tell you dosages.

The patient allows you to examine her briefly. No abnormality is found on cardio-respiratory and abdominal examination. You note her pupils are dilated, her reflexes are brisk and myoclonus is present. Her observations are shown below:

Temperature	38.8ºC
Heart rate	110/min
Blood pressure	178/102mmHg
Respiratory rate	25/min
Oxygen saturation	98% on air

Blood tests are in progress. You prescribe some intravenous fluids and lorazepam to calm the patient.

Given the diagnosis, what other treatment should the patient receive?

A. Dantrolene

B. Cyproheptadine

C. Bromocriptine

D. Co-amoxiclav

E. Procyclidine

B. Cyproheptadine

Treatment of severe serotonin syndrome- cyproheptadine (5-HT2 receptor antagonist)

The patient is presenting with serotonin syndrome. The clues in the history that lead to the diagnosis are the fact that she is on 2 serotonergic agents, she has autonomic excitability (tachycardia, hypertension etc), and neurological features such as hyperreflexia. The differential diagnosis could be neuroleptic malignant syndrome which also presents with autonomic excitability, however, the patient is not taking a neuroleptic and the neurological features would be different (hyporeflexia is expected).

Treatment of serotonin syndrome is usually supportive but in severe cases, cyproheptadine can be used and so option 2 is correct.

Dantrolene is a muscle relaxant that acts via inhibiting calcium release in muscle tissue and is used for the treatment of neuroleptic malignant syndrome.

Bromocriptine is a dopamine agonist, also used in the treatment of neuroleptic malignant syndrome.

Co-amoxiclav is an antibiotic that can be used for numerous infections. Although the patient is febrile, there is no other information from the history or examination to suggest an infection, therefore is not the correct answer.

Procyclidine is an anticholinergic used for acute dystonia.

Question 102 of 138

A 66-year-old gentleman was admitted for an elective aortic valve replacement. His past medical history included a non-ST elevation myocardial infarction three years prior, as well as hypertension and hypercholesterolaemia. He also suffered a deep vein thrombosis 16 years ago after open reduction and internal fixation of a tibial fracture requiring treatment with warfarin postoperatively. There was no family history of note. He was currently taking aspirin 75mg OD, clopidogrel 75mg OD, ramipril 5mg OD, bisoprolol 2.5mg OD, atorvastatin 20mg ON and lansoprazole 15mg OD.

Two days prior to the operation the patient was commenced on an intravenous heparin infusion which was continued perioperatively. The operation was deemed successful and the infusion was discontinued. He was commenced on enoxaparin 40mg OD sc as prophylaxis for venous thromboembolism postoperatively. He was otherwise making a good post operative recovery and was already mobilising readily. He complained of no chest pain or shortness of breath with no syncopal episodes. He resumed a full and normal diet and his bowel habits were normal. There was no evidence of bleed or any other adverse symptoms.

Routine post operative bloods at day 5 were as follows:

Hb	110 g/l
MCV	81 fl
Haematocrit	0.36
Platelets	28* 10 /l9
WBC	9.0 * 10 /l9
PT	36 seconds
APTT	86 seconds
D-dimer	136 ng/mL
Fibrinogen	236 g/L

Na +	142 mmol/l
K +	4.5 mmol/l
Urea	6.3mmol/l

Creatinine	77 µmol/l
Bilirubin	17 µmol/l
ALP	101 u/l
ALT	16 u/l
Albumin	39 g/l

Blood tests at day 2 were as follows:

Hb	116 g/l
Platelets	161 * 10 /l9
WBC	10.0 * 10 /l9

What is the single most appropriate management step?

A. Stop heparin and commence treatment with vitamin K
B. Continue with enoxaparin
C. Stop all anticoagulation until platelet count is >100 x 10^9/l
D. Stop enoxaparin and commence danaparoid
E. Stop enoxaparin and commence warfarin

D. Stop enoxaparin and commence danaparoid

The diagnosis is strongly suggestive of heparin induced thrombocytopaenia type 2, given the treatment with intravenous heparin, the platelet count in the absence of other haematological abnormalities, the absence of clinical signs of haemorrhage and the onset of low platelet count at day 5 post operatively. This patient is at very high risk of an arterial or venous thrombotic event and needs urgent anticoagulation. Warfarin should not be used alone and there is a 10% crossreactivity with LMWH, and so of the options available anticoagulation with danaparoid is the most suitable option.

Question 103 of 138

A 45-year-old man presents to the emergency department complaining of palpitations. He states that these started suddenly 2 hours ago. He has no past medical history and takes no regular medication. An ECG (electrocardiogram) is done and shows atrial flutter with 2:1 block

His observations are the following Sats 97% on air

Heart rate 150 bpm Respiratory rate 22/min Blood pressure 105/78 mmHg Temperature 36.8ºC

Which of the following treatments should be avoided?

A. Electrical cardioversion
B. Atenolol
C. Diltiazem
D. Digoxin
E. Flecainide

E. Flecainide

You risk causing 1:1 conduction if you give flecainide in atrial flutter

Flecainide slows the rate of atrial flutter which can 1:1 conduction and cardiovascular compromise. It can also cause 'organisation' of atrial fibrillation turning it into atrial flutter with 1:1 conduction.

Class IA and class IC antiarrhythmic drugs should not be given to treat atrial flutter unless patients are first pre-treated with a drug that blocks AV (atrioventricular) node conduction such as a beta blocker or calcium channel blocker.

All of the other options can be used to treat atrial flutter

- Cardioversion should be used first line
- In patients who are not suitable for cardioversion beta blockers and calcium channel blockers can be used to slow AV node conduction
- Digoxin used to be first line treatment for ventricular rate control in flutter. Now it is used mostly in patients with heart failure alongside a beta blocker. It is also used in patients whose rate has not been adequately controlled by a calcium channel blocker, a beta blocker or both.

Management of Atrial flutter

- Is similar to that of atrial fibrillation although medication may be less effective
- Atrial flutter is more sensitive to cardioversion however so lower energy levels may be used
- Radiofrequency ablation of the tricuspid valve isthmus is curative for most patients

Question 104 of 138

A 31-year-old man is brought to the Emergency Department from a nightclub. He is accompanied by a friend who tells you he has taken the street drug NRG-1. The patient is agitated and difficult to assess as he will not stay on the trolley. He is sweating profusely. Formal assessment is impossible but he is obviously confused and appears to be hallucinating. Examination shows a heart rate of 139bpm with a blood pressure of 158/105mmHg. Heart sounds are rapid but with no murmurs. The chest is clear to auscultation and oxygen saturations are 99% on air but his respiratory rate is 36/min. He is globally hypertonic with marked clonus in the lower limbs. Tympanic temperature is 40.6°C.

Blood results show:

Haemoglobin	129g/L	Sodium	119mmol/L	Creatine Kinase 1895ng/mL
Haematocrit	0.29	Potassium	5.5mmol/L	CRP 8.9mg/L
White cells	15.6x10^9/L	Chloride	90mmol/L	
Neutrophils	11.7x10^9/L	Urea	7.2mmol/L	
Platelets	303x10^9/L	Creatinine	100µmol/L	

Urine is dilute but contains blood, protein and ketones on dipstick analysis

Which one of the following interventions is the most appropriate in the first instance?

A. Rapid intravenous infusion of 0.9% sodium chloride with 1g IV paracetamol
B. Rapid intravenous infusion of 3% sodium chloride with 1g IV paracetamol
C. Slow intravenous infusion of 3% sodium chloride with 10mg IV midazolam
D. Slow intravenous infusion of 3% sodium chloride with 1g IV paracetamol and oralcyproheptadine 12mg
E. Intravenous methylene blue (methylthioninium chloride) 1mg/kg over 5 minutes

C. Slow intravenous infusion of 3% sodium chloride with 10mg IV midazolam

NRG-1, a synthetic cathinone, can cause agitation, hyponatraemia and serotonin syndrome. Treatment is with benzodiazepines, cooling and hypertonic saline if hyponatraemic. Patients may require intubation and paralysis to control hyperpyrexia

Hyperpyrexia is a consequence of muscle activity, not hypothalamic dysregulation so paracetamol is not useful. Indeed, if multiorgan failure develops, paracetamol is not conjugated and excreted safely, thus paracetamol toxicity may worsen the picture. Intravenous benzodiazepines are the mainstay in reducing agitation and helping to control muscle activity and this should be commenced in the short term. Given the concurrent hyponatraemia and elevated CK slow fluids with hypertonic saline is advised.

External cooling manoeuvres such as ice baths may be tried but when hyperpyrexia rises above 40°C it is safer to anaesthetise and paralyse patients and this patient is likely to warrant this.

Cyproheptadine is a specific 5HT-2A receptor antagonist and may be used in moderate serotonin syndrome. In this case, it is unlikely the patient will be cooperative enough to take it and its effects will be too slow. This option also includes paracetamol making this an incorrect answer.

Methylene blue is an antidote for methaemoglobinaemia; it would be unusual for NRG-1 to cause this although users of the drug often display a blue tinge to their skin for unknown reasons. The methaemoglobin level is not given here so use of methylene blue is not advisable.

Question 105 of 138

A 26 year old male is admitted to hospital with difficulty in breathing, wheeze and a cough productive of green sputum. He is assessed and determined to have a community acquired lower respiratory tract infection with biochemical and radiological evidence lending weight to this diagnosis. His medical history is significant for capricious asthma and he has been admitted to intensive care previously and ventilated. Currently he is taking salbutamol and formoterol/budesonide inhalers at their maximum doses, montelukast, aminophylline and omalizumab (Xolair) monthly subcutaneous injections.

Which of the following antibiotics is best avoided in this patients treatment?

A. Amoxicillin
B. Azithromycin
C. Ciprofloxacin
D. Doxycycline
E. Gentamicin

C. Ciprofloxacin

Co-administration of aminophylline and ciprofloxacin can cause significant toxicity and should be avoided

This question is about drugs which interact via their effect on hepatic cytochrome metabolising enzymes. Pharmacokinetically speaking, any drug has the potential to affect how another is processed, metabolised or excreted but only some have a relevant clinical effect.

In the above vignette we are concerned about a newly commenced antibiotic affecting one of the patients regular medications and causing a deleterious effect. Salbutamol and formoterol are beta agonist drugs which have their own side effects of adrenergic updrive but they rarely have any clinically relevant interactions. Similarly, the inhaled steroid budesonide is seldom affected by other co-administered drugs to a vast degree. Omalizumab is a monoclonal antibody to unbound human IgE and is used as an adjunct treatment in atopic asthma in steroid resistant patients who display extreme histamine sensitivity and elevated IgE levels. It has few clinical interactions. Aminophylline derivatives are moderately active bronchodilators which work two-fold; by inhibiting phosphodiesterases and hence ultimately dampening inflammatory cytokines, and also by acting as an antagonist at adenosine receptors in the heart, brain and lung. It is metabolised extensively by the liver, predominantly by the enzyme 1A2 and has a narrow therapeutic window with elimination pathways becoming saturated even at therapeutic doses. Any drug which inhibits cytochrome enzyme 1A2 can rapidly lead to aminophylline toxicity.

Ciprofloxacin in particular, is a strong inhibitor of enzyme 1A2 causing a decrease in function of at least 80% and an average rise in serum concentrations of metabolising substrate of five-fold. Coadministration of ciprofloxacin with aminophylline is extremely likely to cause toxicity.

The use of macrolide antibiotics with aminophylline is contentious. Most macrolides actually induce activity of 1A2 leading to a reduction in aminophylline levels (similar to the effect of long term smoking). Both aminophylline and macrolide antibiotics however tend to predispose to prolongation of myocardial repolarisation time and there is a risk of ventricular arrhythmia. Azithromycin only poses a theoretical risk rather than an observed one and dose reduction and drug monitoring of aminophylline levels is appropriate if the two drugs must be used together. Erythromycin is best avoided.

Doxycycline use with aminophylline can cause theoretical fluctuations in serum aminophylline levels but regular monitoring of drug levels is sufficient to avoid toxicity.

Neither amoxicillin nor gentamicin have clinically relevant drug interactions with aminophylline.

Question 106 of 138

A 27-year-old patient has been asked to attend the emergency department 2 weeks post colectomy and stoma formation due to the following blood results:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	412 * 10 /L 9	(150 - 400)
WBC	10 * 10 /L 9	(4.0 - 11.0)
Na^+	147 mmol/L	(135 - 145)
K^+	4.9 mmol/L	(3.5 - 5.0)
Urea	16.9 mmol/L	(2.0 - 7.0)
Creatinine	244 µmol/L	(55 - 120)
CRP	65 mg/L	(< 5)

She has been struggling to manage her stoma due to high output of between 1-2litres of liquid stool per day. She has been using rehydration salts and loperamide at home.

Abdominal x-ray: unremarkable appearances Stool culture: negative

What further treatment would be most appropriate to reduce her high-output diarrhoea?

A. Bismuth subsalicylate
B. IV fluids
C. Morphine sulphate
D. Octreotide
E. Vancomycin

D. Octreotide

Octreotide may reduce high output diarrhoea following ileostomy or colectomy. It can be given by continuous subcutaneous infusion

Octreotide is correct. This can be given via a continuous subcutaneous infusion in the management of high-output stoma diarrhoea.

Bismuth subsalicylate is incorrect. It is usually used for symptoms of dyspepsia and is occasionally used in the management of travellers' diarrhoea. There is no evidence to support its use in the reduction of diarrhoea as a result of a high-output stoma.

Morphine sulphate is incorrect. Although morphine and other opiate-class medications can cause constipation as a side effect, they are not used routinely in the management of high-output stomas.

IV fluids is incorrect. Using IV fluids to manage acute kidney injury would be entirely appropriate, however, it would not have any effect on the ongoing diarrhoea itself.

Vancomycin is incorrect, this would be the treatment for *C. difficile* diarrhoea, however, in this case, stool samples were unremarkable.

Question 107 of 138

A 28-year-old woman attends the emergency department with reduced consciousness. She has a past medical history of depression which is treated with sertraline. She also has chronic pain (for which she takes tramadol, gabapentin, ibuprofen, and a lidocaine patch) and epilepsy (which is managed with phenytoin).

On examination, her Glasgow Coma Score is 11 (M4, V4, E3). You also note mydriasis, hyperreflexia, and clonus.

What drug is most likely implicated?

A. Gabapentin
B. Ibuprofen
C. Lidocaine
D. Phenytoin
E. Tramadol

E. Tramadol

Tramadol co-prescribed with SSRIs is a common cause of serotonin syndrome

The patient has clinical features of serotonin syndrome.

Tramadol is correct. Tramadol co-prescribed with SSRIs is a common cause of serotonin syndrome.

Gabapentin is incorrect. The use of SSRIs with gabapentin can increase the risk of hyponatraemia. **Lidocaine** is incorrect. There are no interactions with SSRIs and lidocaine.

Phenytoin is incorrect. The use of sertraline with phenytoin increases the risk of phenytoin toxicity. Phenytoin toxicity manifests predominantly as nausea, and central nervous system dysfunction (particularly confusion, nystagmus, and ataxia), with depressed conscious state, coma, and seizures occurring in more severe cases. Cardiac complications such as arrhythmias and hypotension can also occur. The clinical features, in this case, are more in keeping with serotonin syndrome.

Ibuprofen is incorrect. The use of these two agents increases bleeding risk. It is important to remember that SSRIs have an anti-platelet effect since serotonin is an important transmitter involved in platelet function.

Question 108 of 138

A 27-year-old man is brought to the Emergency Department following a suspected deliberate overdose. On arrival, he is drowsy with a GCS of 13/15 (E3V4M6) and confused. His airway is currently patent. The respiratory rate is 30 breaths per minute although oxygen saturations are 98% on 2L/min oxygen. The chest is clear to auscultation. Heart rate is 108bpm and blood pressure is 96/48mmHg. The ECG shows sinus tachycardia only. He complains of severe abdominal pain and is groaning on examination. There is significant tenderness in the right upper quadrant. Bowel sounds are hyperactive. Neurological examination is difficult but discloses downgoing plantars and reactive, mid-size pupils.

Blood tests show:

Haemoglobin	112g/L	Sodium	131mmol/L	Glucose	17.8mmol
MCV	96fL	Potassium	Haemolysed	Lactate	5.3mmol/L
White cells	15.7x109/L	Urea	15.6mmol/L	pH	7.14
Neutrophils	13.7x109/L	Creatinine	207mol/L	pCO2	2.9kPa
Platelets	278x109/L	ALP	234U/L	pO2	19.2kPa
INR	1.2	ALT	2453U/L	Bicarbonate	9.4mmol/L
PT	14secs	AST	3109U/L	Base excess	-15.4mEq/L
APTT	49.2secs	Bilirubin	36mol/L	Anion gap	30.8

The laboratory comments there is significant haemolysis of the samples. He has a massive vomit whilst being assessed, of black liquid and fresh blood.

Which of the following drugs is this patient most likely to have overdosed upon?

A. Aspirin
B. Ferrous sulphate
C. Ibuprofen
D. Paracetamol
E. Venlafaxine

B. Ferrous sulphate

Severe iron toxicity presents with liver failure, gastrointestinal caustic damage and coagulopathy with raised APTT. Early hyperglycaemia and extensively haemolysed samples may also indicate significant iron burden

Iron is a surprisingly toxic drug. When taken in overdose symptoms may be expected to be seen at ingestions of 20mg/kg. 200mg/kg can be expected to be fatal. Symptoms of direct corrosion on the gastrointestinal tract may be seen within six hours of ingestion with abdominal pain, vomiting, diarrhoea and GI bleeding. Stool and vomitus may be black or grey unless frank bleeding predominates. During this interval, a hallmark of iron toxicity is a raised blood glucose; only a few drugs may cause this in overdose. Hypoglycaemia occurs later in presentation due to liver failure. Other early features may include a neutrophil leucocytosis and significant haemolysis of samples due to the high plasma iron burden. Arterial blood gases will show a significant metabolic acidosis with a high anion gap. Lactate may be elevated but not sufficiently to explain the anion gap. Coagulopathy develops rapidly but the APTT tends to be prolonged in iron toxicity compared to the prolongation of prothrombin time in a paracetamol poisoning. In the ensuing hours, iron deposition within the myocardium, brain and liver can be expected to cause rapid cardiac failure, encephalopathy and hepatocellular necrosis with liver failure respectively. Renal failure develops due to hypovolaemia and acute tubular necrosis.

Unless treated, death may result from haemorrhagic volume loss or from hepatic failure, although in significant overdose, early death results from respiratory failure due to coma. Treatment for iron overdose is with decontamination of the bowel, including whole bowel irrigation if needed and chelation therapy with desferrioxamine.

Although paracetamol toxicity can be expected to cause fulminant hepatic failure with renal failure and coagulopathy, the INR would be expected to be significantly deranged if this was the culpable drug given the extent of other organ damage. Also hypoglycaemia would be expected due to liver failure.

Aspirin, when taken in significant overdose, causes a characteristic constellation of symptoms including metabolic acidosis (although alkalosis may be seen at lower dose intoxications), convulsions, tinnitus, hyperpyrexia and pulmonary oedema. Often ventricular arrhythmia occurs due to metabolic acidosis and intracellular anaerobic respiration. Rarely coagulopathy develops but usually in association with disseminated intravascular coagulation which is not the case here. Aspirin overdoses may present with hyperglycaemia however and along with iron and aminophylline, these agents should be considered when unexplained hyperglycaemia is seen.

Ibuprofen and other non-steroidals are of low toxicity unless taken in massive overdose. Gastrointestinal upset and occasional GI haemorrhaging may be seen but liver failure and coagulopathy is rare. In massive overdose, central nervous depression with cerebellar signs and global electrolyte imbalances may be seen with blood dyscrasias. Multi-organ failure may develop but individual organ dysfunction is less likely.

Venlafaxine, a noradrenaline and serotonin modulator, may cause serotonin syndrome and sympathomimetic symptoms, including arrhythmia, hyperpyrexia and respiratory failure. Hepatitis is rare.

Question 109 of 138

A 21-year-old woman presents to the emergency department after her flatmate found her drowsy in her bedroom. She had been incontinent of urine.

On examination the patient is obtunded with a Glasgow Coma Score of 7 (E1V2M4). The pupils are 7mm bilaterally and sluggishly reactive to light. The heart rate is 133bpm and the blood pressure is 99/65mmHg.

A 12-lead ECG reveals sinus tachycardia with a QT interval of 510ms. The QRS duration is 115ms.

What is the most likely cause for this patient's presentation?

A. Amyl nitrate toxicity
B. Gamma hydroxybutyric acid toxicity
C. Toluene solvent toxicity
D. Tricyclic antidepressant toxicity
E. Heroin toxicity

D. Tricyclic antidepressant toxicity

Dilated pupils in combination with ECG changes including prolonged QT interval and QRS duration (borderline prolonged in this case) should suggest tricyclic antidepressant toxicity.

Features of toluene toxicity include irritation to the eyes, nose and respiratory tract from inhalation, along with confusion, ataxia, headache, slurred speech and euphoria. Prolongation of the QT interval is not usually associated.

Features of amyl nitrate toxicity include blurred vision, xanthopsia and haemoptysis. It does not typically affect the corrected QT interval.

Features of gamma hydroxybutyric acid (GHB) toxicity include CNS and respiratory depression, hypersalivation, bradycardia and hypotension. It does not typically affect the corrected QT interval.

Heroin toxicity typically results in depression of the respiratory and central nervous systems and pin-point pupils (rather than mydriasis in this case). It does not typically affect the corrected QT interval.

Question 110 of 138

A 48-year-old farmer is found in a state of distress having collapsed whilst mixing insecticides in his barn. On arrival in the Emergency department, he is confused, salivating excessively, and has been incontinent of urine and faeces. You note noisy breathing, his blood pressure is 90/60 mmHg, with a pulse of 48 beats per minute.

Which of the following is the most appropriate intervention?

A. Atropine
B. Hyoscine
C. Glucagon
D. NG activated charcoal
E. Noradrenaline

A,. Atropine

Organophosphate insecticide – atropine

The clue here is insecticide exposure, coupled with evidence of muscarinic effects of organophosphate poisoning including excessive secretions, incontinence, hypotension and bradycardia. Time is of the essence, and administration of atropine in this situation may be lifesaving.

Pralidoxime is also used once atropine has been administered, although it's additive benefit is debated.

Hyoscine is less potent versus atropine and is mainly used in palliative care to manage pain from the gastrointestinal tract and excessive respiratory secretions. Glucagon is used as a treatment for beta-blocker overdose. Activated charcoal may be of value but is subsidiary to use of anticholinergics. Anticholinergics are also preferred to sympathetic agonists such as noradrenaline.

Question 111 of 138

A 33 year female of Arabic descent with bullous pemphigus is admitted electively for intravenous immunoglobulins. She has no other past medical history, no recent travel history and has lived in rural Norfolk her whole life. On day 4 of a 5 day planned course of treatment, she develops pyrexia, nausea and vomiting. On examination, you note mild neck stiffness and photophobia. She also complains of a posterior headache. Her serum markers are as below:

WBC	14.0 * 10 /l9
Neuts	11.0 * 10 /l9

Na +	133 mmol/l
K +	3.8 mmol/l
Urea	4.7 mmol/l
Creatinine	80 µmol/l
CRP	4 mg/l

A CT head is unremarkable. The immunoglobulin is stopped. You perform a lumbar puncture: WCC 10/mm3, protein 0.4g/L, no organisms, opening pressure 17.8 cm H2O. Blood cultures taken during a temperature spike grow no organisms after 48 hours.

What is the diagnosis?

A. Aseptic meningitis
B. Bullous pemphigus flare
C. TB reactivation, resulting in TB meningitis
D. Viral meningitis
E. Bacterial meningitis

A. Aseptic meningitis

Aseptic meningitis is a classic complication of IVIg treatment. This patients inflammatory markers are unremarkable, as is the rest of her septic screen. There is little to suggest worsening of underlying bullous pemphigus. Aseptic meninigits occurs in 1% of patients with intravenous immunoglobulin. The key is to rule out any infective causes and to stop the immunoglobulin treatment until this is been done. Modern preparations can be stored in a fridge for months: there

Question 112 of 138

A 17-year-old girl presents to the emergency department with her mother. She is drowsy, ataxic, vomiting, her heart rate is 130 beats per minute and her blood pressure 130/84 mmHg. Her only past medical history is epilepsy which has recently been well controlled. After arguing with her boyfriend 40 minutes ago she took an unknown quantity of sodium valproate.

Following initial fluid resuscitation which of the following would you implement?

A. Activated charcoal
B. Observe for 3 hours and discharge
C. Fomepizole
D. Loperamide
E. Transfer to psychiatric bed

A. Activated charcoal

As the question states that she has taken the overdose less than an hour previously she would be suitable for activated charcoal.

Of the other options, discharging her while severely symptomatic, or transfer to a psychiatric ward while there are acute medical issues would be inappropriate.

Fomepizole is used in methanol or ethylene glycol poisoning.

The question does not give any indication for loperamide at present.

Question 113 of 138

You are called to review a 48-year-old woman in the Surgical Ward. She was admitted directly to the ward five hours ago post-operation for an elective open right hemicolectomy for adenocarcinoma of the caecum. The operation was completed without any concern. For postoperative pain relief, the patient has a local anaesthetic infusion to rectus sheath catheters and an oxycodone PCA. No significant previous medical history. No known drug allergies.

The patient had been reviewed by the nursing team half an hour before for postoperative antibiotics and replacement intravenous fluids. Her observations were all within normal parameters, however, the patient complained of new tinnitus.

She has just had a self-terminating seizure and remains post-ictal with a GCS of 10. Her observations are:

- Heart rate 45 bpm
- Blood pressure 78/35 mmHg
- Respiratory rate 25/min
- Temperature 36.5ºC
- Blood glucose 4.4mmol/l

What treatment should be started immediately?

A. Intravenous levetiracetam loading dose
B. Intravenous fluid and vasopressor
C. Intravenous lipid emulsion
D. Major haemorrhage transfusion
E. Intravenous glucose

C. Intravenous lipid emulsion

Local anaesthetic toxicity can present with CNS (e.g. reduced GCS, seizures) and cardiovascular (e.g. tachyarrhythmias, hypotension, bradyarrhythmias) features. Treatment of severe toxicity is with IV lipid emulsion.

Local anaesthetic toxicity is correct. The patient has a local anaesthetic infusion in place. This may be delivering local anaesthetic directly into the bloodstream or the local anaesthetic infusion may have inadvertently been connected to the intravenous access port. This is severe toxicity with seizures, bradycardia, hypotension and low GCS. Tinnitus, perioral numbness, metallic taste and auditory changes can be earlier symptoms. In this case of severe toxicity, lipid emulsion should be administered. This acts as a binding agent for the circulating local anaesthetic molecules.

Intravenous levetiracetam loading dose is incorrect. The patient's seizure is secondary to local anaesthetic toxicity and not epilepsy. Although further seizure control may be required the underlying cause should be treated immediately to prevent further seizures, cardiovascular collapse and death.

Intravenous fluid and vasopressor are incorrect because the patient's deteriorating clinical condition does not fit with sepsis. They have had an operation without complication, are already on prophylactic antibiotics and their clinical signs do not make sepsis the most likely diagnosis. IV fluids and vasopressors may be required in the course of their treatment for local anaesthetic toxicity but they do not treat the underlying cause of the deterioration.

Major haemorrhage transfusion is incorrect. Although postoperative haemorrhage should always be considered there is a more likely diagnosis in this case. Although the operation progressed well there is a risk of postoperative bleeding. If the patient is displaying symptoms of haemorrhage and cardiovascular shock then the surgical team and anaesthetic team must be notified immediately to facilitate an urgent return to theatre. Activation of the major haemorrhage protocol may be appropriate depending on the clinical picture.

Intravenous glucose is incorrect because the clinical scenario points towards local anaesthetic toxicity. Although it is important to ensure that glucose is correct to be within normal range, it is more important to start the lipid emulsion immediately. This will prevent further seizures, cardiovascular collapse and death.

Question 114 of 138

A 57-year-old man is bought to ED by ambulance after being found on the street unwell.

On examination, he is maintaining his own airway but is tachypnoeic with a respiratory rate of 28 breaths/minute. He complains of a headache and blurred vision and has poor coordination on examination.

After a short period in the department, he deteriorates further and is drowsy with a GCS of 11. An arterial blood gas (ABG) shows:

pH	7.2	(7.35-7.45)
pO2	16.4 kPa	(10.0-13.0 kPa)
pCO2	2.3 kPa	(4.50-6.00 kPa)
HCO3-	14 mmol/L	(22.0-28.0 mmol/L)
BM	6.4 mmol/L	(3.9-8.0 mmol/L)
Na+	143 mmol/L	(135-145 mmol/L)
Cl-	98 mmol/L	(98-107 mmol/L)

What is the most appropriate next step in management for this patient?

A. Activated charcoal
B. Ethanol
C. Fomepizole
D. Haemodialysis
E. Naloxone

C. Fomepizole

Methanol poisoning is preferentially treated with IV fomepizole; this should be commenced immediately the suspicion is raised

This patient presents with symptoms of methanol poisoning (tachypnoea, headache, blurred vision, impaired coordination and reduced consciousness). The significant metabolic acidosis with raised anion gap should increase your suspicion. The immediate management of methanol poisoning is with the antidote **fomepizole**.

Activated charcoal has no effect to bind methanol and therefore plays no role in the use of methanol poisoning.

Ethanol can be used in methanol poisoning as it competitively binds to alcohol dehydrogenase and blocks methanol binding. However, it is no longer used first-line in the UK since the introduction of fomepizole.

Haemodialysis may be considered for this patient but fomepizole would be the next step in management while this was arranged.

Naloxone is used in opioid overdose but has no role in methanol poisoning.

Question 115 of 138

A 65-year-old female presents to respiratory outpatients with an 8-week history of gradually worsening shortness of breath. Her exercise tolerance has reduced to 50 yards from several miles; she reports chronic lower back pain but no other symptoms. Her past medical history includes type 2 diabetes mellitus, psoriasis, recurrent urinary tract infections and ischaemic heart disease. She currently takes metformin 500 mg BD, bisoprolol 2.5 mg OD, aspirin 75 mg OD, atorvastatin 40 mg ON, ramipril 2.5 mg and nitrofurantoin 50 mg ON with no change in the last 6 months. She has never smoked, has no pets and works as a secretary. On examination, the patient is breathless on minimal exertion. Observations are normal, there is no clubbing and she has fine endinspiratory crepitations at both bases. A CT chest shows ground glass changes with minimal honey combing at both bases.

What is the most likely cause of her underlying respiratory condition?

A. Asbestosis
B. Psoriasis
C. Metformin
D. Ankylosing spondylitis
E. Nitrofurantoin

E. Nitrofurantoin

This patient has a history and examination consistent with pulmonary fibrosis. Her CT chest supports this demonstrating ground glass and honey combing at both bases. Pulmonary function tests will demonstrate a restrictive pattern and arterial blood gas analysis will show a type 1 respiratory failure. Long-term use of nitrofurantoin is known to cause a basal pattern of pulmonary fibrosis and is the most likely culprit in this case. There is no suggestion of asbestos exposure in the history and both psoriasis and ankylosing spondylitis classically cause an apical pattern of fibrosis. Lower back pain is a common medical complaint in this age group and ankylosing spondylitis tends to present in younger males.

Question 116 of 138

A 64-year-old woman comes to the Emergency department complaining of palpitations at rest, and worsening angina over the past month. She has been treated with amiodarone for the past 3 years for recurrent ventricular tachycardia. She has a blood pressure of 110/70 mmHg, pulse of 95 beats per minute, and a fine tremor. There is no goitre. TSH is suppressed at less than 0.05 U/ml.

You suspect she has amiodarone induced thyrotoxicosis.

How best can you determine the underlying pathophysiology?

A. IL6 level
B. Thyroglobulin level
C. TSH level
D. Duration of amiodarone therapy
E. Colour flow doppler ultrasonography

E. Colour flow doppler ultrasonography

Type 1 amiodarone induced thyrotoxicosis is caused by increased production of thyroid hormone, most likely as a result of the excess iodine load administered to the patient as a result of amiodarone treatment. Type 2 amiodarone induced thyrotoxicosis is caused by a destructive thyroiditis. Colour flow doppler ultrasonography needs to be performed by an experienced operator, but is thought to distinguish between the two causes of amiodarone induced thyrotoxicosis around 80% of the time. In patients where the diagnosis is uncertain, radioiodine uptake, (which is low in type 2 disease) my further help differentiating between the two.

Type 2 disease is generally seen later in the time course of amiodarone therapy, although this isn't an invariable differentiating factor, and data on the usefulness of IL6 and thyroglobulin is conflicting.

Question 117 of 138

An 82-year-old man presents with pain following a fall. He was brought in by ambulance after he slipped and hurt himself on the pavement. He ended up tripping whilst returning from the local shops. He remembers his fall and noted immediate pain in his right leg, and was unable to get up. A passerby called an ambulance and he was brought into the hospital. He has a past medical history of ischaemic heart disease, mild dementia, hypertension and high cholesterol.

Pelvic X-rays demonstrated an intertrochanteric right hip fracture. He is due to be operated on within the five hours and is put nil by mouth and started on IV fluids.

How should his risk of venous thromboembolism (VTE) be managed?

A. Low molecular weight heparin before surgery
B. Unfractionated heparin before surgery
C. Delay VTE prophylaxis until following surgery
D. Mechanical VTE prophylaxis before surgery
E. IV heparin infusion until surgery

D. Mechanical VTE prophylaxis before surgery

The correct answer is mechanical VTE prophylaxis before surgery. This is a patient with a hip fracture due to be operated on within 12 hours. He should have careful mechanical VTE prophylaxis with stockings or pneumatic compression despite having a fracture. If surgery was to occur in over 12 hours then low molecular weight heparin should be started, with the last dose given 12 hours before surgery. If he also had renal failure, then unfractionated heparin should be used and also stopped 12 hours before surgery.

Question 118 of 138

A 56-year-old man is brought into hospital with palpitations, restlessness and agitation. His wife tells you he has lost 2 kilograms of weight over the past month. She attributes this to persistent diarrhoea over the same period.

He has a past medical history of persistent atrial fibrillation and takes amiodarone.

On examination, he has a heart rate of 144 beats per minute and his ECG confirms atrial fibrillation with no ischaemic changes. You are unable to palpate any abnormality of the thyroid cartilage.

Investigations are as follows:

TSH	0.1 mU/L
Tc scan 99	reduced uptake

Which of the following is the most important step in this patient's immediate management?

A. Carbimazole
B. Corticosteroids
C. Propylthiouracil
D. Thyroidectomy
E. Increase dose of amiodarone

B. Corticosteroids

In this case, amiodarone is likely the underlying cause of this man's fast AF. Indeed he has a number of symptoms suggestive of hyperthyroidism.

The mainstay of treatment, in this case, would be to give steroids. The absence of a goitre points towards type 2 AIT. The reduced uptake on radioisotope imaging reflects the destructive changes to the thyroid seen in this type of AIT.

Increasing the dose of amiodarone may help with cardioversion but will not treat the underlying cause. Treating with anti-thyroid drugs, such as carbimazole or PTU, may help with thyrotoxicosis but again will not reverse the destructive changes to the thyroid gland. At this stage surgical removal of the thyroid is not indicated.

Question 119 of 138

You are asked to review a 23-year-old patient with a history of ulcerative colitis who was admitted one week ago with a flare unresponsive to steroids. However, over the last three days, he has noticed a visible tremor, and the nurses have noted higher blood sugars on the ward.

On examination, his BP is 154/104mmHg, and his fasting blood glucose is 6.0. His abdomen is soft, with generalised lower abdominal discomfort but no guarding. His chest is clear.

He reports feeling more stressed recently at work and tells you he often uses cannabis in his downtime. The nurses have noticed him leaving the ward often during their shift.

Which medication was he most likely started on?

A. Azathioprine
B. Ciclosporin
C. Infliximab
D. Mesalazine
E. Prednisolone

B. Ciclosporin

Cannabidiol may increase the concentration of ciclosporin

Ciclosporin is the correct answer. In this case, a patient with a severe flare of UC refractory to steroids might be started on ciclosporin. This question assesses knowledge of ciclosporin's side effects and its interaction with cannabis. Ciclosporin may interact with cannabidiol, and adverse effects include tremor, impaired glucose tolerance and susceptibility to infection. Cannabis use can increase ciclosporin levels due to inhibition of cytochrome P450 enzymes by cannabinoids such as CBD.

The other medications listed are used in the treatment of ulcerative colitis but do not exhibit this combination of side effects or interactions with cannabis (as seen on the BNF interaction checker).

Azathioprine commonly interacts with cannabidiol. The levels of azathioprine are increased as cannabidiol decreases its metabolism. Side effects of azathioprine include bone marrow suppression, thrombocytopenia and increased susceptibility to infections. However, the mentioned side effects in the case don't align with azathioprine side effects.

Infliximab is not known to interact with cannabidiol. Side effects include diarrhoea, infusionrelated reactions and increased susceptibility to infections.

Mesalazine is not known to interact with cannabidiol. Side effects include arthralgia, pancreatitis (rarely), skin reactions and diarrhoea.

Prednisolone is not known to interact with cannabidiol. It is unlikely that this patient would be on this medication if the current episode is unresponsive to steroids. Side effects include fluid retention, increased risk of infection, peptic ulcer and hypertension.

Question 120 of 138

A 45 year-old Russian woman complains of a 2 week history of joint pain affecting her wrists, shoulders and knees bilaterally. She also reports calf pain bilaterally. She has been started on first line treatment for pulmonary tuberculosis 2 months previously. Symptoms resolved after the addition of aspirin.

Which drug is most likely causing her symptoms?

A. Rifampicin
B. Isoniazid

C. Pyrazinamide
D. Ethambutol
E. Streptomycin

C. Pyrazinamide

By far the most common cause of arthralgia from the above is pyrazinamide.

Question 121 of 138

A 32-year-old male illicit drug user is caught attempting to sell cocaine on the street by the police. On seeing the officers approach him, he swallows a plastic bag containing around 1.5g of cocaine in an attempt to destroy the evidence. The police officers bring the gentleman into the emergency department. He is asymptomatic and complains of no chest pain. His ECG is unremarkable and his admission blood tests demonstrate no abnormalities, including a negative troponin.

What should you do next?

A. Treat presumptively as acute coronary syndrome
B. Discharge the patient to police custody
C. Await 12 hour troponin and if negative, discharge to police custody
D. Repeat ECG and if no dynamic changes, discharge to police custody
E. Monitor the patient until the ingested cocaine is excreted

A. Monitor the patient until the ingested cocaine is excreted

Cocaine produces significant cardiovascular sequelae, classically coronary vasospasm resulting in cardiac ischaemia, presenting as chest pain and similar ECG changes to acute coronary syndrome. Similar vasospasm can lead to transient cerebral ischaemia, resulting in ischaemic infarcts. In addition, cardiac dysrhythmias are also common, including sinus tachycardia, sinus bradycardia, supraventricular tachyarrhythmias, bundle branch block, ventricular fibrillation and torsades de pointes. In this scenario, it is clear that the ingested cocaine has not penetrated to coverings and released systemically. However, the danger remains until the ingested cocaine has been excreted. Patients like this should be monitored for cardiovascular and cerebral sequelae until the ingested amounts are collected.

Question 122 of 138

You are asked to review a 44-year-old lady in the emergency department. She is well known to the mental health liaison team because of her multiple suicide attempts. She is agitated and slightly confused and unable to give a precise history. She is able to tell you that she can't see clearly and has a dry mouth.

Her sister explains that the patient has been prescribed medicines for chronic neuropathic back pain and has taken them all after splitting up with her boyfriend.

On examination she has symmetrically dilated pupils but no focal motor deficit. Her heart sounds are normal and her lung fields are clear on auscultation. An ECG shows sinus tachycardia with a QRS of 170.

Bloods results are as follows:

Hb	125 g/l
Platelets	440 * 10 /l9
WBC	9.9 * 10 /l9
Na +	135 mmol/l
K +	4.2 mmol/l
Urea	5.1 mmol/l
Creatinine	88 µmol/l
Plasma Paracetamol	<5mmol/l

You request an arterial blood gas which shows the following readings:

pH	7.29
pCO$_2$	3.4 kPa
pO$_2$	14.5 kPa

What is the most appropriate next step in this patient's management?

A. IV sodium bicarbonate
B. Haemodialysis
C. IV lignocaine
D. IV amiodarone
E. Naloxone

A. IV sodium bicarbonate

The culprit here is a tricyclic antidepressant, such as dosulepin or amitriptyline. The first step in treating this patient is to reverse the metabolic acidosis with IV bicarbonate. Dialysis is of no benefit in this scenario.

The dilated pupils and absence of respiratory depression point away from opioid overdose, making naloxone the wrong answer.

Question 123 of 138

A 56 year old gardener is brought to the Emergency Department by his wife. He was bitten on the right hand by a snake while clearing bushes in his back garden. It is identified as a common European adder. There is an obvious, red puncture site on the dorsum of the right hand with significant swelling of the entire hand to the level of the wrist. He is in significant discomfort. Examination reveals a normal cardiovascular examination with a heart rate of 112bpm, blood pressure of 137/90mmHg and normal respiratory rate and oxygen saturations. Capillary glucose is 5.6mmol. ECG shows normal sinus rhythm with normal PR, QRS and QT intervals. Routine blood tests including liver function, electrolytes, creatine kinase, full blood count and arterial blood gases are normal.

Which of the following interventions is the most appropriate at this stage?

A. Application of a tourniquet above the site of envenomation to prevent systemic toxicity
B. Bathe the site of envenomation in hot, sterile water to inactivate the venom
C. Intravenous access and rapidly infuse 0.9% sodium chloride with 1g intravenousparacetamol
D. Intravenous access and administer 200mg IV hydrocortisone, 10mg IV chlorphenamineand 0.5mg IM adrenaline 1:1000
E. Intravenous access and administer 10ml adder antivenin in 500ml 0.9% sodium chlorideover 30 minutes

B. Bathe the site of envenomation in hot, sterile water to inactivate the venom

Adder bites are rare, but when they occur may be extremely painful; the mainstay of treatment is analgesia and supportive therapy. Discuss the use of antivenin with NPIS and do not apply a tourniquet

Application of a tourniquet is absolutely contraindicated since it increases the likelihood of localised necrosis of the affected limb as well as the risk of venous thrombosis which in turn increases the likelihood of central venous thrombosis on release of the tourniquet, as well as cardiac arrhythmia due to the systemic flooding of released potassium and other necrosis factors from tissue damage and haemolysis in a ligatured extremity when the tourniquet is removed.

Unlike venom of the United Kingdom's only other native poisonous animal, the weeverfish (Trachinidae family), viper venom is not heat labile. Application of cold water to a bite may help to assuage pain, but hot water will not deactivate the venom. Weeverfish stings may be treated by bathing the affected limb (usually a foot) in hot water to denature the active proteins.

Adder antivenin is readily available for use in severe bites and can be obtained by contacting local zoos or the National Poisons Information Service. However, severe anaphylactic reactions to the antivenin are common and may be seen in up to 20% of recipients, particularly in atopic or asthmatic individuals. For this reason, antivenin is reserved only for severe systemic envenomations in patients with resistant hypotension, new ECG changes, significant rise in white cell count, raised CK, metabolic acidosis or swelling involving more than half the affected limb or crossing a joint boundary, e.g. beyond the wrist if bitten on the hand. The patient in the above scenario has none of these symptoms. Similarly, in the absence of any symptoms suggestive of an acute anaphylactoid reaction, treatment with adrenaline and hydrocortisone is unnecessary, although antihistamines may help symptomatically. Often, symptomatic treatment is all that is required with analgesia taking priority. Intravenous analgesia is often faster acting and fluids may be required if swelling is significant or vomiting is profuse.

Question 124 of 138

A 25-year-old man attends the emergency department with his partner. He reports having taken an overdose of paracetamol approximately 30 hours ago. Initially, he vomited several times but has not done so for the last 10 hours. He complains of mild vague abdominal discomfort.

On examination, he has some right upper quadrant tenderness on palpation. There is no guarding and there is no obvious jaundice present.

What is the most appropriate management?

A. Send paracetamol levels and await the result to decide on N-acetylcysteine

B. Start N-acetylcysteine after taking paracetamol levels

C. Start N-acetylcysteine and then take paracetamol levels

D. Start N-acetylcysteine, paracetamol levels not required

E. Supportive management

B. Start N-acetylcysteine after taking paracetamol levels

Paracetamol overdose: if presentation > 24 hours after an overdose start acetylcysteine if the patient is jaundiced, has hepatic tenderness or an elevated ALT

For patients who have taken an overdose of paracetamol with presentation later than 24 hours, start treatment before blood tests are available if the patient has visible jaundice or hepatic tenderness or has taken 150mg/kg or more of paracetamol as per Toxbase guidance, and start treatment after blood results if there is a raised ALT or INR, or detectable paracetamol level.

Given the clinical picture, this patient's right upper quadrant tenderness is highly likely to represent hepatic tenderness so he should be commenced on treatment. The best practice is to take the paracetamol levels before starting the infusion. Hence the option to **start Nacetylcysteine after taking paracetamol levels** is correct. This is because if paracetamol levels are taken during N-acetylcysteine infusion, some analysers may significantly underestimate paracetamol levels.

As this patient has hepatic tenderness, it would not be correct to wait for the levels before starting treatment. Hence, the option to **send paracetamol levels and await the result to decide on N-**acetylcysteine is incorrect.

Due to this potential interference with the analyser, the option to **start N-acetylcysteine and then take paracetamol levels** is incorrect.

Taking paracetamol levels is helpful in management and is recommended by Toxbase. Therefore, the option to **start N-acetylcysteine, paracetamol levels not required** is incorrect.

This patient warrants N-acetylcysteine treatment, therefore **supportive management** is incorrect.

Question 125 of 138

A 45-year-old man presents to the emergency department with haematemesis. He states that he drank 'some liquid' in order to end his life. His observations are as follows: heart rate 105 beats per minute, blood pressure 125/75 mmHg, respiratory rate 24 breaths per minute, temperature 37.2ºC, and SpO2 96% on air. On examination, you note nystagmus, ataxia, and ophthalmoplegia.

Blood results are as follows:

Hb	145 g/L	Male: (135-180)Female: (115 - 160)
Platelets	85 * 10 /L 9	(150 - 400)
WBC	20.8 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	3.5 mmol/L	(3.5 - 5.0)
Urea	8.4 mmol/L	(2.0 - 7.0)
Creatinine	110 µmol/L	(55 - 120)
CRP	22 mg/L	(< 5)
Glucose	5.1 mmol/L	(3.9 - 5.6)
Serum osmolarity	310 mOsm/kg	(275 - 295)

What is the treatment of choice?

A. Activated charcoal

B. Ethanol

C. Folinic acid

D. Fomepizole

E. Haemodialysis

D. Fomepizole

Ethylene glycol toxicity management - fomepizole. Also ethanol / haemodialysis

The patient has clinical and biochemical features of ethylene glycol toxicity.

The osmolar gap = osmolality (measured) - osmolarity (calculated). A normal osmolar gap should be < 10.

The calculated osmolarity in this case = (2 x [Na+]) + [glucose] + [urea]) = 289.5 mOsm/kg. Therefore the osmolar gap = 310 - 289.5 = 20.5 mOsm/kg.

The patient thus has a high osmolar gap which indicates the presence of an abnormal solute present in significant amounts.

Causes of a high osmolar gap include:

- Mannitol
- Methanol
- Ethylene glycol

Fomepizole is correct. For patients with ethylene glycol toxicity, early administration of fomepizole or ethanol will minimise the further metabolism of ethylene glycol and the development of clinical and metabolic complications. Fomepizole is the agent of choice if available.

Activated charcoal is incorrect. Activated charcoal is of no use since it does not adsorb significant quantities of ethylene glycol.

Ethanol is incorrect. Fomepizole is the preferred antidote since, unlike ethanol, it does not require regular monitoring of blood concentrations or cause inebriation. Ethanol is an effective antidote but is associated with more complications. If there is any delay in obtaining fomepizole, administer ethanol urgently initially, followed by fomepizole when available.

Folinic acid is incorrect. Folinic acid is used to reduce ophthalmological complications in methanol poisoning.

Haemodialysis is incorrect. The patient is symptomatic and requires urgent treatment. Haemodialysis has a role in severe or refractory cases.

Question 126 of 138

A 20-year-old university student attends the emergency department with his friends who were concerned after they found him urinating on the living room sofa. On examination, he appeared agitated, sweaty, and had occasional muscle twitching.

Observations: heart rate 110 beats per minute, blood pressure 165/105 mmHg, temperature 37.9ºC.

On review of his medical record, you can see he takes citalopram for depression and has also recently been started on another medication.

What other medication is most likely to account for his presentation?

A. Cyclizine
B. Cyproheptadine
C. Methylene blue
D. Phenoxymethylpenicillin
E. Tramadol

E. Tramadol

Tramadol co-prescribed with SSRIs is a common cause of serotonin syndrome

The patient in the stem is likely presenting with serotonin syndrome, as indicated by disorientation, agitation, muscle twitching, hypertension, tachycardia, and pyrexia.

Tramadol is the correct answer. When this is co-prescribed with SSRIs such as citalopram it can precipitate serotonin syndrome. This is because tramadol acts as a central serotonin reuptake inhibitor and so further increases serotonin levels.

Cyclizine is incorrect. There is no evidence to suggest that cyclizine is implicated in the development of serotonin syndrome.

Cyproheptadine is incorrect. Cyproheptadine can be used as a treatment for serotonin syndrome. Other treatments can include intravenous fluids and benzodiazepines.

Methylene blue is incorrect. It is a thiazine dye used to treat methemoglobinemia and is not implicated in the development of serotonin syndrome.

Phenoxymethylpenicillin is incorrect. Other antibiotics such as ciprofloxacin, isoniazid, and linezolid can potentiate serotonin syndrome, however, there is no evidence to suggest that phenoxymethylpenicillin is a cause.

Question 127 of 138

A 30-year-old man attends the emergency department with chest pain. He describes the pain as a squeezing sensation in the centre of his chest. There is no radiation of his pain but he feels mildly breathless. He works as a city lawyer which he admits can be particularly stressful. He is an occasional smoker and binge-drinks alcohol on the weekends. He has no other past medical history.

On examination, he is tremulous and sweating profusely. He has a temperature of 37.9ºC. His heart rate is 140bpm and regular with a blood pressure of 143/87mmHg. His chest is clear with normal heart sounds. Saturations are 96% on air. He has increased rigidity in his upper and lower limbs. His pupils are dilated and reactive to light.

Investigations:

Hb	151 g/L	Male: (135-180)Female: (115 - 160)
Platelets	288 * 10 /L $_9$	(150 - 400)
WBC	9.1 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	149 mmol/L	(135 - 145)
K $_+$	5.4 mmol/L	(3.5 - 5.0)
Urea	10.3 mmol/L	(2.0 - 7.0)
Creatinine	134 µmol/L	(55 - 120)
D-Dimer	398 ng/L	(<400)
Troponin	67 ng/L	(0-14)

ECG - ST depression in I, aVL, V5 and V6.

He is diagnosed with an NSTEMI and dual antiplatelet therapy, fondaparinux and sublingual glyceryl trinitrate (GTN) is initiated for acute coronary syndrome (ACS). His pain begins to settle after GTN.

What is the most appropriate medication to give in addition to the ACS protocol?

A. Atenolol
B. Sodium nitroprusside
C. Diazepam
D. Intravenous fluids
E. Glyceryl trinitrate infusion

C. Diazepam

Cocaine toxicity - avoid beta-blockers

This man is likely to have taken a cocaine overdose. Symptoms include an increased sympathetic drive causing hyperthermia, sweating, tachycardia and dilated pupils. Chest pain is secondary to vasospasm of the coronary arteries causing ECG changes and raised cardiac enzymes. Benzodiazepines are indicated in cocaine toxicity and in this scenario, ACS treatment should be initiated with the addition of benzodiazepines such as diazepam.

Sodium nitroprusside is an indicated additive in the instance of cocaine toxicity and hypertension.

Glyceryl trinitrate infusions are indicated in ACS with ongoing chest pain. This patient has shown good response to sublingual GTN, making a GTN infusion less appropriate at this stage.

Intravenous fluids are likely to also be prescribed to treat his co-existing acute kidney injury. However, in the instance of cocaine toxicity and chest pain, diazepam is the more appropriate initial choice.

Atenolol and other beta blockers should be avoided or used with caution in cocaine toxicity due to the risk of unopposed alpha-agonism. Benzodiazepines should be given instead, making diazepam the correct answer.

Question 128 of 138

A 35-year-old farmer who is in financial difficulties presents to the Emergency department some 40 minutes after taking an unknown amount of paraquat-based weed killer. On arrival in the Emergency department, he has a Glasgow coma scale score of 15 and tells you he regrets what he has done. He feels sick and says there is a burning sensation in his mouth. On examination his blood pressure is 135/80 mmHg, his pulse is 85 beats per minute and regular. There are no abnormal physical signs.

Which of the following is the most important intervention?

A. Administration of emetic
B. Gastric lavage
C. IV normal saline
D. IV sodium bicarbonate
E. Oral fuller's earth

E. Oral fuller's earth

Both activated charcoal and fuller's earth are recognised to adsorb paraquat in vitro. They are thought to be most effective when given in the first two hours after overdose, although benefit may still be present up to 12hrs after ingestion. Neither has significant toxicity issues.

Gastric lavage is not recommended. Administration of emetic risks spreading caustic material further, potentially driving greater absorption of paraquat. IV normal saline and IV sodium bicarbonate do not affect prognosis in paraquat overdose. No anti-inflammatory, immunosuppressive, or anti-oxidant interventions have demonstrated a benefit either.

Question 129 of 138

A 63-year-old woman is brought in by ambulance to the emergency department, having been found at home by her neighbour with a decreased level of consciousness. She has a past medical history of osteoarthritis and hypertension. She takes ramipril and uses ibuprofen regularly for pain relief.

Her observations are heart rate of 118 beats per minute, blood pressure 95/66mmHg, respiratory rate of 20/min, temperature 36.7ºC and oxygen saturations of 94% on room air.

Cardiovascular, respiratory and abdominal examinations are otherwise unremarkable. Her Glasgow coma scale is 11/15 (E3, V3, M5).

IV fluids are administered and an arterial blood gas and blood tests are obtained.

Arterial blood gas results:

pH	7.24	(7.35-7.45)
paO2	10.2 kPa	(10-14)
paCO2	5.7 kPa	(4.5 - 6.0
Base excess	-4.2 mmol/L	(-2 - +2)
Chloride	95 mmol/L	(95-105)
Bicarbonate	14 mmol/L	(22-26)
Glucose	5.0 mmol/L	(4-11)
Lactate	2.5 mmol/L	(0.5-2.0)
SaO2	94 %	(94-98)

Blood test results:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	4.4 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	141 mmol/L	(135 - 145)
K $_+$	5.0 mmol/L	(3.5 - 5.0)
Urea	8.0 mmol/L	(2.0 - 7.0)
Creatinine	111 µmol/L	(55 - 120)
CRP	8 mg/L	(< 5)
Measured osmolality	324 mOsm/Kg	(280-290)

What is the most likely diagnosis?

A. Aspirin overdose
B. Ethylene glycol administration
C. IV sodium chloride 0.9% administration
D. NSAID treatment
E. Ramipril overdose

B. Ethylene glycol administration

Metabolic acidosis with a high anion gap and high osmolar gap is seen in ethylene glycol poisoning

Ethylene glycol administration is the correct answer. This is a case of a raised anion gap metabolic acidosis with a raised osmolar gap. The anion gap is calculated as (sodium + potassium) - (chloride + bicarbonate). In this case, it is 37 mmol/L, which is raised (normal range 8-16 mmol/L). The osmolar gap is calculated as osmolality (measured) - osmolarity (calculated). Osmolarity (calculated) is [2*sodium + glucose + urea]. In this case, it is (324) - (295) = 29mOsm (normal range < 10), indicating a raised osmolar gap. A high osmolar gap means the presence of an unmeasured solute in high amounts e.g. ethylene glycol in this case.

Aspirin overdose is incorrect. This can cause a high anion gap metabolic acidosis with a high osmolar gap. However, If the aspirin overdose was sufficiently large to cause the patient to be obtunded with a low GCS, we would expect a respiratory alkalosis and possibly convulsions. Aspirin has direct effects on the respiratory centre and causes tachypnoea and respiratory alkalosis. In this case, the oxygen saturations are 94%, the pO2 is low normal, the pCO2 is on the upper end of normal and the respiratory rate is merely 20, making this a less likely cause clinically than ethylene glycol.

IV sodium chloride 0.9% administration is incorrect. This causes a normal anion gap metabolic acidosis with high chloride. Additionally, the fluids were administered after she had become unwell, excluding this as a cause of her presentation.

NSAID treatment is incorrect. This can cause a type 1 renal tubular acidosis, which will have a normal anion gap.

Ramipril overdose is incorrect. This is associated with a type 4 renal tubular acidosis, which will have a normal anion gap. Furthermore, if the patient took a significant ramipril overdose, we might expect the blood pressure to be lower.

Question 130 of 138

You are looking after a 76-year-old man on an orthogeriatric ward. He is day 7 post dynamic hip screw for neck of femur fracture. He appears to be doing relatively well, but the nurse has noticed that he has a dark black necrotic looking skin over his left iliac fossa, and has asked you to come and look at it.

His past medical history includes hypertension, mild chronic kidney disease and atrial fibrillation.

He is currently on Ramipril 2.5mg once daily, Bisoprolol 5mg once daily, and treatment dose Clexane (patient was on Warfarin pre-operatively).

Pre-admission operative bloods:

Hb	142 g/l
Platelets	212 * 10 /l9
WBC	14.1 * 10 /l9
Na +	138 mmol/l
K +	4.6 mmol/l
Urea	8.2 mmol/l
Creatinine	167 µmol/l

Bloods yesterday:

Hb	112 g/l
Platelets	27 * 10 /l9
WBC	10.1 * 10 /l9
Na +	136 mmol/l
K +	4.0 mmol/l
Urea	9.1 mmol/l
Creatinine	182 µmol/l

What should you do with regards to his Clexane?

A. Stop Clexane and give Warfarin (target INR 2-3)
B. Stop Clexane and give treatment dose Argatroban
C. Switch treatment dose Clexane to Unfractionated Heparin infusion
D. Give 1 pool of platelets
E. Switch treatment dose Clexane to prophylactic Clexane

B. Stop Clexane and give treatment dose Argatroban

This is a case of heparin induced thrombocytopaenia

Criteria	2	1	0
Thrombocytopaenia	>50% fall, and nadir >20*10 /l9	30-50% fall, or nadir 10-19*10 /l9	fall < 30%, or nadir < 10*10 /l9
Timing of platelet fall	Between 5-10 days, or <1 day if exposure to heparin within last 20 days	consistent with immunisation, unclear due to missing samples	fall <4 days after exposure (with no recent exposure history
Sequelae	Thrombosis, skin necrosis or systemic reaction post-bolus	Progressive or recurrent thrombosis, suspected but unproven thrombosis, erythematous skin reaction	
Alternative cause	None	Possible	Definite

- 0-3 - Low
- 4-5 - Intermediate
- 6-8 - High

This patient fits all the criteria for heparin induced thrombocytopenia

The recommendations for treatment are as follows:

- Therapeutic danaparoid should be used
- The anticoagulant effect of danaparoids can be measured with anti-Xa assay
- Therapeutic dose fondaparinux is an acceptable alternative anticoagulant (although it is unlicensed)
- Therapeutic anticoagulation should be continued for 3 months (in those with thrombosis) and 4 weeks (in those without thrombosis)
- When transitioning from argatroban to warfarin, the INR should be >4 for 2 days prior to discontinuing argatroban
- Warfarin should not be used till platelet count is back in normal range

Question 131 of 138

A 61-year-old man with a history of bipolar affective disorder presents to the Emergency Department with a 2-week history of feeling unwell. This started off as a coarse tremor in the limbs and has now progressed to slurred speech and disorientation. On examination, you find an ataxic gait and myoclonus. His lithium level 2.6. You diagnose lithium toxicity. In addition to bipolar affective disorder, he has a history of rheumatoid arthritis, atrial fibrillation and GORD.

Which of the following recent events is most likely to explain the cause of his toxicity?

A. Recent addition of carbamazepine to augment lithium
B. Recent prescription of naproxen for knee pain
C. Recent increase in caffeine intake
D. Recent addition of amiodarone for atrial fibrillation
E. Recent use of sodium bicarbonate tablets for symptoms of dyspepsia

B. Recent prescription of naproxen for knee pain

The answer is B. NSAIDs reduce excretion of lithium in the kidneys and can, therefore, increase serum lithium levels and give rise to lithium toxicity as seen above. ACE inhibitors, ARBs and thiazide diuretics also reduce the kidney's ability to excrete lithium.

Caffeine and sodium bicarbonate both increase the excretion of lithium from the body and therefore will reduce serum lithium levels

When carbamazepine is added to lithium therapy, it is known to increase the risk of neurotoxicity, but it does this without increasing serum lithium levels. Similarly, use of amiodarone with lithium is known to increase the risk of VT, but it does this without increasing lithium levels

Question 132 of 138

A 25-year-old female was admitted to the emergency department following an overdose of unknown tablets 4 hours ago. Her past medical history includes depression, previous overdoses and gastric ulcer disease. On examination, she was drowsy but easily rousable with a Glasgow Coma Score of 14. She has a heart rate of 112 beats per minute, blood pressure of 106/60mmHg, respiratory rate of 22 and saturations of 96% on air.

Electrocardiogram shows a sinus tachycardia with QRS complexes measuring 160 ms. An arterial blood gas on air revealed the following results:

pH	7.29
pCO2	6.2 kPa
pO2	10.5 kPa
HCO3-	18 mmol/l
BE	-6.6 mmol/l

Which of the following management is the most appropriate?

A. Intravenous magnesium
B. Activated charcoal
C. Gastric lavage
D. Sodium bicarbonate
E. 5% dextrose infusion

D. Sodium bicarbonate

Tricyclic Antidepressant (TCA) overdose is most likely in this case, based on the presentation, mixed acidosis seen on ABG and ECG changes. TCA overdose can present in various ways. Cardiovascular effects include tachycardia, prolong QRS complexes and induce cardiac arrhythmias. Central nervous system effects include altered mental status, coma and seizures.

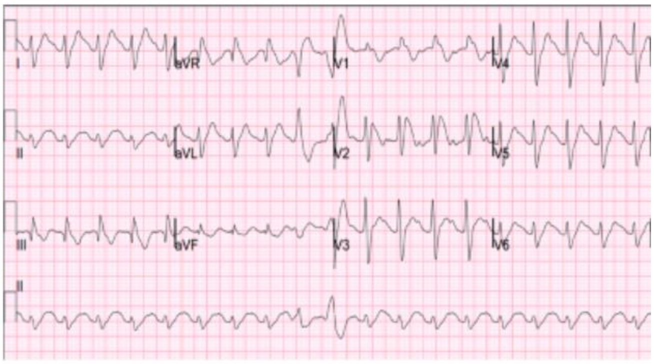
- Intravenous magnesium: no indications in this case of TCA overdose
- Activated charcoal: only appropriate if GCS is not reduced and if patients present within 2 hours of ingestion
- Gastric lavage: may be considered for potentially life-threatening TCA overdoses only when it can be delivered within 1h of ingestion and the airway is protected
- Sodium bicarbonate: is the main treatment for dysrhythmias or hypotension associated with TCA overdoses
- 5% dextrose infusion: has no role in treatment of TCA poisoning or fluid resuscitation

Question 133 of 138

A 40-year-old woman is brought into the emergency department after being found unresponsive by her partner. Her partner reports that she has been well up until today. She has a past medical history of fibromyalgia, migraines and depression for which she has tried several pharmacological agents.

On examination, she has a heart rate of 120 beats/min with a blood pressure of 131/76mmHg. Her chest sounds are clear with a respiratory rate of 28 breaths/min and oxygen saturations of 94% on air. She is drowsy but responsive to voice and her pupils are dilated. She smells strongly of alcohol.

An ECG is taken:



© Image used on license from Dr Smith, University of Minnesota

Given the likely diagnosis, what is the recommended management for this patient?

A. DC cardioversion
B. Fomepizole
C. Haemofiltration
D. Magnesium sulphate
E. Sodium bicarbonate

E. Sodium bicarbonate

Sodium bicarbonate is correct. This patient has a likely diagnosis of a tricyclic antidepressant (TCA) overdose given the tachycardia and dilated pupils in combination with this patient's ECG. This patient's ECG shows tachycardia with widened QRS complexes which is a characteristic feature of a TCA overdose. The past medical history of depression is another suggestion that this patient may be prescribed tricyclic antidepressants. The medical management includes intravenous sodium bicarbonate, particularly if there are any arrhythmias or QRS widening on the ECG. Of note, a QRS interval > 160ms is associated with an increased risk of arrhythmias (e.g. ventricular fibrillation).

DC cardioversion is incorrect. This is used in the cardioversion of tachyarrhythmias with adverse features (e.g. ischaemia, shock, syncope and heart failure). In patients with a TCA overdose, DC cardioversion is unlikely to be successful even in the presence of a ventricular arrhythmia. In this circumstance, intravenous sodium bicarbonate is still recommended along with supporting any additional features (e.g. intubation for low GCS or IVF/phenylephedrine for hypotension).

Fomepizole is incorrect. This is used in the management of ethylene glycol and methanol poisoning. Although this patient smells strongly of alcohol which is suggestive of ethylene glycol or methanol use, the past medical history of depression and the patient's ECG findings are more likely to be secondary to a TCA overdose.

Haemofiltration is incorrect. Although haemofiltration can remove some substances from the circulation (e.g. barbituates, lithium, alcohol, salicylates and theophylline), it has no role in the management of a TCA overdose.

Magnesium sulphate is incorrect. This is used in the management of torsades de pointes, a polymorphic ventricular tachycardia associated with a widened QTc interval. This arrhythmia is more likely to be present if the patient had taken an overdose of a serotonin-selective reuptake inhibitor (SSRI) which is also used to treat depression. However, this arrhythmia is not what is seen here making magnesium sulphate incorrect.

Question 134 of 138

A 58-year-old gentleman is admitted to the acute medical unit with abnormal movements and confusion. He has a past medical history of bipolar disorder and epilepsy. His drug history includes lithium and sodium valproate. On examination you note choreathetoid movements of all four limbs. His Glasgow coma score is 11 (M5, E3, V3).

Blood results are as follows:

Hb	145 g/l	Na^+	138 mmol/l
Platelets	524 * 10^9/l	K^+	3.9 mmol/l
WBC	11.6 * 10^9/l	Urea	10.5 mmol/l
Neuts	9.8 * 10^9/l	Creatinine	125 µmol/l

Lithium level	2.6 mmol/L (therapeutic range 0.4 to 1.0 mmol/L)

What definitive treatment does this patient require?

A. Sodium bicarbonate
B. Gastric lavage
C. Haemodialysis
D. Whole bowel irrigation
E. Reassurance

C. Haemodialysis

Acute on chronic overdose of lithium can lead to serious toxicity even after a modest overdose, as the the extracellular tissues are already saturated with lithium

Acute on chronic overdose of lithium can lead to serious toxicity even after a modest overdose, as the extracellular tissues are already saturated with lithium.

Dialysis should be considered in symptomatic lithium toxicity and:

- A lithium concentration greater than 5.0 mmol/L in patients with acute lithium overdose and who are not prescribed lithium
- A lithium concentration greater than 2.5 mmol/L in patients with chronic poisoning

Haemodialysis should be continued until:

- All new neurological features have resolved, and
- Lithium concentration remains stable at less than 1mmol/L

Gastric lavage, even if possible within one hour of overdose, is likely to be of limited value as slowrelease tablets do not disintegrate in the stomach and most are too large to pass up to a lavage tube.

Whole bowel irrigation can be used, however, there are no clinical trials to confirm its efficacy.

Some studies have shown that urinary alkalisation with sodium bicarbonate may be of use, however the evidence is weak.

Ultimately, this patient has severe neurological features, and a lithium level > 2.5 mmol/L in the context of chronic poisoning, and therefore the definitive management required is haemodialysis. The patient should be fluid resuscitated with crystalloid while discussing the case with a renal physician to arrange dialysis.

Question 135 of 138

A 42-year-old man presents to his GP, wanting to discuss his alcohol intake. For several years, he has been drinking 15-20 units per day. He is now keen to cut down to recommended limits but is enquiring about potential pharmacological options that can be used to aid him.

What can be used to promote abstinence by causing unpleasant symptoms?

A. Acamprosate
B. Diazepam
C. Disulfiram
D. Naltrexone
E. Thiamine

C. Disulfiram

Disulfram is an acetaldehyde dehydrogenase inhibitor. When combined with alcohol, it results in high levels of acetaldehyde which can cause flushing of the skin, nausea, vomiting, arrhythmias, and even death

The correct answer is **disulfiram**. This is an acetaldehyde dehydrogenase inhibitor. By inhibiting this enzyme, consumption of alcohol leads to a build-up of acetaldehyde, which can cause unpleasant symptoms such as flushing of the skin, nausea, vomiting, and arrhythmias. However, a problem with the use of disulfiram is poor compliance, as it does not reduce cravings for alcohol.

Acamprosate is another drug used to promote abstinence. Rather than causing unpleasant symptoms, it reduces the craving for alcohol. It is a weak antagonist of NMDA receptors.

Diazepam is incorrect. Whilst this benzodiazepine is often used in the management of acute withdrawal, it does not cause symptoms like disulfiram.

Naltrexone is incorrect. This is used to treat both opioid and alcohol dependence. Rather than causing unpleasant symptoms, however, it instead reduces cravings and feelings of euphoria associated with substance use disorder.

Thiamine is also incorrect. This is recommended to be given orally to alcoholic patients if their diet may be deficient. It does not cause unpleasant symptoms.

Question 136 of 138

A 27-year-old lady presents to her GP with symptoms of polyuria and dysuria. She is currently 7 weeks into her second pregnancy. Her urine dipstick shows 2+ protein, 2+ blood, 3+ leucocytes and is positive for nitrates. Her records indicate a past reaction to penicillin.

Which of the following would be the most appropriate in her treatment?

A. Nitrofurantoin
B. Trimethoprim
C. Co-amoxiclav
D. Cefalexin
E. Ciclosporin

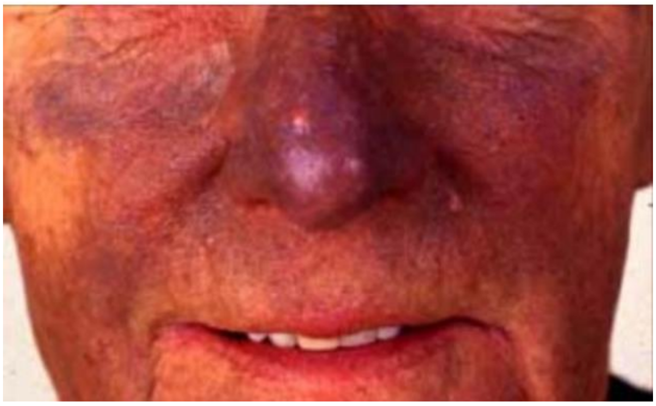
A. Nitrofurantoin

Trimethoprim should be avoided in the first 3 months of pregnancy

Nitrofurantoin has been used extensively in the treatment of UTIs in pregnant ladies in first trimester since the 1950s and has a good safety profile. The anti-folate action of trimethoprim could yield trimethoprim as a second-line agent provided that enough folate cover is offered. NICE guidelines state that 5 mg of folate must be co-administered in case that trimethoprim is prescribed. The antibiotic regime unlike simple UTI lasts for 7 days.

Question 137 of 138

The patient below has noticed a gradual change to his facial skin since starting a new medication a few months ago:



© Image used on license from DermNet NZ

Which drug has he been taking?

- A. Amiodarone
- B. Phenytoin
- C. Ciclosporin
- D. Digoxin
- E. Sildenafil

A. Amiodarone

The correct answer is **Amiodarone**. This drug, which is used to manage arrhythmias, can cause a bluish-grey discolouration of the skin due to the deposition of lipofuscin pigments. This effect is particularly noticeable on sun-exposed areas such as the face and hands. The condition is usually reversible upon discontinuation of the drug, although it may take several months for the skin colour to return to normal.

The other options are incorrect for the following reasons:

Phenytoin can cause a variety of skin changes including hirsutism, acneiform eruptions, and gingival hyperplasia but it does not typically cause skin discolouration.

Ciclosporin, an immunosuppressant agent used in transplant patients and certain autoimmune conditions, can cause hypertrichosis (excessive hair growth) and gingival hyperplasia. It may also increase susceptibility to infections and malignancies due to its immunosuppressive effects. However, it does not lead to skin discolouration.

Digoxin, a cardiac glycoside used in heart failure and atrial fibrillation, has many potential side effects but they do not include skin discolouration. Instead, digoxin toxicity can manifest with visual disturbances (xanthopsia or yellow vision), gastrointestinal symptoms (nausea, vomiting), neurological symptoms (confusion, delirium), and cardiac arrhythmias.

Finally, **Sildenafil**, commonly known as Viagra and used for erectile dysfunction and pulmonary arterial hypertension, does not typically cause any significant changes in skin colour either. Its most common side effects include headache, flushing, dyspepsia, visual disturbances (blurred vision or cyanopsia - seeing blue-tinted vision), nasal congestion or rhinitis.

Question 138 of 138

A 47-year-old man is admitted to the Medical Assessment Unit with a pneumonia. He has had a cough for the last week which has not settled with amoxicillin from his GP.

His past medical history includes alcoholic liver disease with a hepatic transplant 6 months previously, hypertension and diet-controlled type II diabetes. He has remained abstinent from alcohol for the last 18 months and is a lifelong non-smoker. His medications are ramipril, simvastatin and tacrolimus.

On admission he has a temperature of 38.1 ºC and oxygen saturations of 94% on air. His heart rate is 110 beats per minute and blood pressure is 105/65 mmHg. On auscultation he has left basal crepitations and chest x-ray confirms a left lower lobe pneumonia.

He is started on intravenous fluids, 2 litres oxygen via nasal cannulae, co-amoxiclav and clarithromycin. His statin is withheld.

2 days later, the ward team are asked to review the patient as he has developed limb twitching. During the assessment he has a generalised tonic-clonic seizure which requires lorazepam to terminate it.

Which investigation is most likely to reveal the cause for his seizures?

- A. Blood cultures
- B. CT head
- C. Electrolytes
- D. Lumbar puncture
- E. Tacrolimus level

E. Tacrolimus level

The first issue to consider in this question is whether this gentleman's seizure is most likely to be related to infection or metabolic disturbance.

Given that it is two days following his admission with infection, it is unlikely that he has an undetected meningitis, as he would likely have exhibited other symptoms and become much more unwell in this time.

A CT head would be done prior to a lumbar puncture but would not confirm a diagnosis of meningitis, and this gentleman is unlikely to have a new intracranial pathology given the history. Although febrile seizures are a possibility, they are unusual in adults, and again would be uncommon after 2 days of appropriate antibiotics.

Although blood cultures would of course have been taken, they would not prove that a seizure was the result of infection.

This leaves metabolic causes, including hypoglycaemia, hypomagnesaemia, hyper- and hyponatraemia and an altered tacrolimus level.

Tacrolimus is metabolised by the cytochrome P450 system of enzymes. This gentleman has been started on clarithromycin as an antibiotic, which inhibits this system and is therefore likely to cause an increased blood concentration of tacrolimus. Side effects of high tacrolimus level include hyperkalaemia, hypomagnesaemia, hyperglycaemia, hypertension, twitching and seizures. Although checking electrolytes may give clues as to the cause of this gentleman's seizure, and should definitely be done, a tacrolimus level is necessary to prove the diagnosis.

It is also worth keeping in mind that in this type of patient, the suspicion of withdrawal seizures may be high. However, one would expect to see other signs and symptoms earlier on in the admission.

GERIATRICS
PASSMEDICINE
PART 2
2024

Question 1 of 16

An 85-year-old man with hypertension has been admitted to the hospital following a fall with a subsequent fractured neck femur. Before his admission, he lived with his wife and was independent with all activities of daily living. Four days after his admission, the nursing staff mentioned that he is confused at night and calls for his deceased parents. His vital signs are normal. Upon your assessment, he has bilateral crackles on the auscultation of his chest.

His blood tests show:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	200 * 10 /L 9	(150 - 400)
WBC	7.1 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.0 mmol/L	(3.5 - 5.0)
Urea	5.0 mmol/L	(2.0 - 7.0)
Creatinine	100 µmol/L	(55 - 120)

What is the single most likely cause of his symptoms?

A. Alcohol withdrawal
B. Anaemia
C. Constipation
D. Hospital-acquired pneumonia
E. Undiagnosed Alzheimer's

C. Constipation

Constipation can cause delirium in the elderly

The patient presents with acute and fluctuating symptoms of confusion, which are indicative of delirium. This condition can arise from many causes, including infections. **Constipation** should be considered as a potential cause of delirium, particularly after hospitalisation for a fracture due to a fall. Such patients may not be as mobile, have a different diet from their normal, and may be on medications which cause constipation, such as opioids.

It is crucial to exclude **alcohol withdrawal** as a differential diagnosis. Symptoms include confusion, hallucinations and agitation. Symptoms that may help to differentiate alcohol withdrawal from delirium include tremors, sweating, nausea and, if severe, autonomic instability. The most severe symptoms often occur 48-96 hours after a person's last drink. The lack of such features makes alcohol withdrawal unlikely.

This patient is slightly **anaemic**, and this requires a review of his pre-surgery blood tests to determine if it could be due to his recent surgery or other causes. However, this degree of anaemia is less likely to cause delirium.

While **hospital-acquired pneumonia** is frequently implicated in delirium, the current case lacks specific symptoms (including fever and productive cough) or diagnostic blood test results (including deranged white cell count) to substantiate this cause. His chest findings are more likely to be due to atelectasis post-surgery rather than bilateral pneumonia.

Delirium is characterised by acute onset and fluctuating cognitive symptoms. There is no description of cognitive impairment before admission. He is, therefore, more likely to have delirium than **undiagnosed Alzheimer's**. If the patient's confusion is not resolved with treatment, obtaining a comprehensive history and considering further investigations would be necessary.

Question 2 of 16

A 73-year-old man is being treated in hospital for a urinary tract infection. He was initially confused, however, this has since improved. His daughter, however, reports that over the past six months his short-term memory has declined and he is having visual hallucinations.

On physical assessment, his respiratory rate is 16/min, oxygen saturation 95% on air, and the chest is clear. His heart rate is 69/min, blood pressure is 121/80mmHg, and is warm and well perfused. The abdomen is soft and non-tender. His Glasgow coma score is 14 due to confusion for voice and he is afebrile at 36.6ºC. Some mild rigidity is noted on neurological examination but otherwise is normal.

Which medication is most likely to treat his ongoing symptoms?

A. Aspirin
B. Levodopa
C. Memantine
D. Prophylactic antibiotics
E. Rivastigmine

E. Rivastigmine

Acetylcholinesterase inhibitors (e.g. donepezil, rivastigmine) can help alleviate the features of Lewy body dementia

This man has presented with Lewy body dementia. This is evidenced by memory impairment, visual hallucinations, and signs of parkinsonism. Donepezil and rivastigmine are very effective in the treatment of Lewy body dementia therefore rivastigmine is the correct answer.

Aspirin is a treatment that may be used in vascular dementia, however, this is not the diagnosis here. Vascular dementia presents with step-wise determination in memory and is not associated with visual hallucinations or parkinsonism.

Levodopa is a treatment for Parkinson's disease. Although this man is exhibiting some mild parkinsonism on neurological examination, this is likely due to Lewy body dementia given his memory impairment and visual hallucinations. Acetylcholinesterase inhibitors are the most effective treatment in Lewy body dementia and can treat both cognitive and motor symptoms. Therefore, levodopa would not be indicated first-line in this case.

Memantine is used in advanced Alzheimer's dementia with behavioural and psychological symptoms. Alzheimer's is not the diagnosis here as it is not associated with visual hallucinations in a mild or moderate stage and does not cause motor symptoms. Memantine is therefore incorrect as it is not indicated in Lewy body dementia.

As this man has had a continuous six-month history of memory impairment, visual hallucinations, and parkinsonism, recurrent UTIs are unlikely to be the culprit. Therefore, prophylactic antibiotics are not indicated.

Question 3 of 16

A 74-year-old female has been diagnosed with moderate to severe Alzheimer's disease, on a background of a two-year progressive gradual cognitive decline. Her family had tried to cope on their own without seeking medical help, putting it down to old age but now, most likely requires nursing home care. MMSE 7/30. She has a past medical history of previous myocardial infarctions. She has not complained of chest pain recently and her ECG demonstrates no ischaemic changes, a PR interval of 290ms.

What is the most appropriate treatment strategy?

A. Donepezil
B. Memantine
C. Galantamine
D. Rivastigmine
E. Aspirin

B. Memantine

There are two key facts to this patient: firstly, the patients MMSE is suggestive of severe dementia. Secondly, the diagnosis of 1st degree heart block and hence atrioventricular nodal block is a contraindication for cholinesterase inhibitors, which could precipitate complete heart block. In accordance with the latest set of NICE guidelines, donepezil, galantamine and rivastigmine are all appropriate for mild to moderate dementia, defined as MMSE between 10 and 26/30. However, only memantine, an NMDA antagonist, has demonstrated efficacy and is licensed for severe Alzheimer's disease.

Question 4 of 16

A 78-year-old woman with a background of hypertension, depression, and dementia is admitted due to social concerns as her husband is struggling to provide care for her activities of daily living at home. She has her observations taken which include oxygen saturations of 96% on room air, a respiratory rate of 16/min, a heart rate of 47/min, a blood pressure of 101/64mmHg, and a temperature of 36.3ºC.

An ECG is performed which shows normal sinus rhythm with no other abnormalities. A medication review is conducted.

What medication should be stopped?

A. Amlodipine
B. Donepezil
C. Memantine
D. Mirtazapine
E. Sertraline

B. Donepezil

Donepezil is generally avoided (relative contraindication) in patients with bradycardia and is used with caution in other cardiac abnormalities

Donepezil is a cholinesterase inhibitor used to treat Alzheimer's dementia. Due to the procholinergic effects it has, it is strongly associated with bradycardia which is an indication to stop the medication. With a heart rate of 47/min, donepezil should be stopped in this case.

Amlodipine is a dihydropyridine calcium channel blocker that is non-cardio-selective. It is therefore not the medication most likely to be resulting in this woman's bradycardia. As her blood pressure is normal, there is no indication to stop this medication.

Memantine is a N-Methyl-D-Aspartate antagonist used for advanced dementia. Although bradycardia is a reported side effect of memantine, this is relatively rare. As memantine is much less likely to be the cause than donepezil, it would be prudent to hold the donepezil initially.

Mirtazapine can cause prolonged QT interval however the ECG here shows sinus bradycardia and is otherwise normal so it is unlikely to be causing this woman's bradycardia.

Sertraline is another medication that can cause QT prolongation but again as the only positive finding from the ECG is sinus bradycardia, it is not likely to be the cause.

Question 5 of 16

A 82-year-old man is reviewed in memory clinic. He denies any problems himself, but his wife has noticed changes in his memory and therefore asked his GP to see if he has dementia. She has noticed that he at times forgets where he is, forgets that he has asked things in the middle of a conversation, seems to respond to things that are not there and has reported that he 'sees things'. However, at other times he is able to have completely normal conversations. He has a past medical history of prostate cancer which has been managed with hormone therapy, of which she knows he had 'blood tests' to monitor which have been normal. Other than this he has COPD which is well controlled, hypertension and osteoarthritis. He has had no recent changes in medication. He used to smoke, but quit 20 years ago. He used to drink heavily but has completely stopped five years ago.

On examination the patient is alert and orientated. He has a slight tremor in his left hand, and increased tone in muscles.

What is the most likely diagnosis?

A. Lewy-body dementia
B. Alzheimer's disease
C. Brain metastases
D. Vascular dementia
E. Subdural haematoma

A. Lewy-body dementia

A history of progressive decline in cognitive function with fluctuations, visual hallucinations and Parkinsonisms is most likely Lewy-body dementia. The main differential diagnosis is Alzheimer's disease, which has a greater element of progressive cognitive decline, and is not usually associated with hallucinations and fluctuations. Brain metastases are important to exclude but the normal blood tests for prostate cancer - likely PSA - are a good indicator that this is unlikely. Vascular dementia can occur with progressive changes of dementia, especially with a history of high blood pressure and smoking, but this is not what has been described. A subdural haematoma is a strong differential when there is fluctuating consciousness in the context of head trauma and anticoagulant medications.

use at what stages. Please see the link for more details

neuroleptics should be avoided in Lewy body dementia as patients are extremely sensitive and may develop irreversible parkinsonism. Questions may give a history of a patient who has deteriorated following the introduction of an antipsychotic agent

Question 6 of 16

A 72-year-old man presents to the emergency department with confusion. He has a past medical history of hypertension, Parkinson's disease and hypercholesterolemia. His medications include cocareldopa, amlodipine and atorvastatin. He normally lives alone and is independent.

Observations:

- Heart rate 101 beats per minute
- Blood pressure 120/77 mmHg
- Respiratory rate 20/minute
- Oxygen saturations 97% on room air
- Temperature 37.8ºC

On examination, there is suprapubic tenderness. His Glasgow coma scale is 14/15.

He is treated with appropriate antibiotics for a presumed urinary tract infection. Despite clinically and biochemically improving, he remains confused 3-4 days into the admission. Alternative causes of delirium are excluded. He subsequently becomes increasingly agitated and presents a danger to himself and other patients, despite conservative measures designed to re-orient him.

Given the clinical history, what is the most appropriate choice of medication?

A. Clozapine
B. Haloperidol
C. Olanzapine
D. Quetiapine
E. Zopiclone

D. Quetiapine

Quetiapine may be useful in the management of patients with Parkinson's disease who are in an acute confusional state

Quetiapine is correct. This patient presents with delirium secondary to a urinary tract infection on a background of PD. He has a progressively worsening confusional state and conservative measures have failed. He is a danger to himself and others and therefore pharmacological sedation is warranted. The most appropriate choice given his diagnosis of PD is quetiapine, which is less likely to cause worsening of his Parkinsonism than other antipsychotics, which have greater antidopaminergic effects.

Haloperidol is incorrect. This typical antipsychotic is used in the management of delirium. However, it has significant D2 antagonism effects and may therefore worsen the patient's PD.

Olanzapine is incorrect. This antipsychotic can be used in the management of delirium. However, it may worsen PD and therefore should be avoided.

Zopiclone is incorrect. The Z-drug class of medications is not a typical first-line choice for the management of delirium, in Parkinson's disease or otherwise.

Clozapine is incorrect. This atypical antipsychotic can be used in the management of delirium associated with PD. However, quetiapine would be the preferred initial choice due to the potential toxicity of clozapine treatment.

Question 7 of 16

An 85-year-old woman is admitted to the acute medical unit with abdominal pain, swelling and confusion. She has a past medical history of Parkinson's disease, recurrent urinary tract infections and hypertension. She is on amlodipine, co-careldopa and doxazosin. She lives in a care home. Her behaviour is out of character. She is usually pleasant and talkative and there is no history of memory problems.

Her observations are heart rate 88 beats per minute, respiratory rate 18/minute, oxygen saturations 97% on room air, blood pressure 145/88mmHg and temperature 37.1ºC.

Examination reveals impacted faeces in the rectum and some mild suprapubic tenderness. She is inattentive and confused and her cognition fluctuates. She does not tolerate a full neurological exam but you note a unilateral resting tremor and mild bradykinesia.

Urinalysis:

Leucocytes	+++
Nitrites	+
Blood	Negative
Protein	Negative

An ECG is unremarkable. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	111 µmol/L	(55 - 120)
CRP	34 mg/L	(< 5)
Calcium	2.24 mmol/L	(2.20 - 2.6)
TSH	1.2 mIU/L	(0.2 - 5.5)

She is treated with antibiotics for a presumed urinary tract infection and laxatives and suppositories for constipation. Within a few days, her inflammatory markers have normalized, she has no clinical features of a urinary tract infection and her bowels are opening twice a day normally.

However, despite environmental modifications, 1:1 nursing and the support of her close family, she remains confused, agitated and inattentive. She is a danger both to herself and to other patients on the ward.

Given the likely diagnosis, what is the most appropriate pharmacological management?

A. Haloperidol
B. Olanzapine
C. Pramipexole
D. Quetiapine
E. Ropinirole

D. Quetiapine

Quetiapine may be useful in the management of patients with Parkinson's disease who are in an acute confusional state

Quetiapine is the correct answer. This patient has delirium that has not responded to conservative measures. Given that she is a danger to herself and others, pharmacological management of her condition is indicated. It is good practice to attempt administration of oral medications in the first instance, where possible. Quetiapine is a suitable choice to aid in the management of delirium in patients with Parkinson's disease as it does not cause worsening of the motor features of Parkinson's disease and can have beneficial effects cognition and psychotic features, if present.

Haloperidol is incorrect. While this is a possible choice for the pharmacological management of delirium, it is a dopamine-antagonist and therefore will worsen the motor features of Parkinson's disease.

Olanzapine is incorrect. This has been shown to cause excessive sedation and worse the motor features of Parkinson's disease.

Ropinirole is incorrect. This is a dopamine agonist used in the management of Parkinson's disease itself. Delirium is a side effect.

Pramipexole is incorrect. This is a dopamine agonist used in the management of Parkinson's disease itself. Delirium is a side effect.

Question 8 of 16

A 75-year-old lady with memory problems attended a specialist memory clinic with her daughter. Her daughter was very concerned and mentioned that her mother had been much more forgetful over the past year. She had left the gas cooker on and occasionally got lost when she walked to the shops. On one occasion she had been found by a neighbour wandering the streets in her dressing gown.

This lady had a family history of Alzheimers disease with both her mother and sister being diagnosed with the condition in their seventies.

On examination she had a Mini Mental State Examination Score of 19/30. Otherwise a full physical examination was unremarkable.

Magnetic resonance of imaging of the brain showed marked atrophy of the medial temporal lobes bilaterally with no evidence of a reversible cause of dementia.

You suspect that this lady has Alzheimers disease and wish to start her on donepezil.

Before starting her on this medication which of the following should you arrange?

A. Electrocardiogram (ECG)
B. Chest X-ray
C. Echocardiogram
D. Lung function tests
E. Ophthalmology review

A. Electrocardiogram (ECG)

Donepezil is generally avoided (relative contraindication) in patients with bradycardia and is used with caution in other cardiac abnormalities

Cholinesterase inhibitors such as donepezil, galantamine and rivastigimine are licensed for use in patients with mild to moderate Alzheimers disease. The National Institute for Health and Care Excellence (NICE) currently recommends treatment for all patients with moderate Alzheimers disease with a Mini Mental State Examination (MMSE) score of 10 20.

The British National Formulary lists sick sinus syndrome and supraventricular conduction problems (such as atrial flutter and atrial fibrillation) as relative contraindications in the prescribing of cholinesterase inhibitors. Although it is not specifically stated in NICE guidance there is a large evidence base to support the practice of performing a routine ECG prior to initiating treatment. There is insufficient evidence to support the use of routine echocardiograms prior to the initiation of cholinesterase inhibitor

Question 9 of 16

A 64 year old man presents with a 6 month history of abnormal behaviours which have been noticed by his wife. He has described seeing vivid visual hallucinations of clowns in his living room which sometimes talk to him and appear very real. He believes that he is the head of a circus and is about to go on a world tour although this is not true.

At times he is lucid and is fully independent but at other times he is disorientated in time and place and is unable to perform simple tasks such as preparing food and going to the shops. His wife thinks that his mood is also lower since the onset of symptoms. He presented in A+E today because of having a second fall in two weeks.

There is no history of infective symptoms. He went to see his GP two days ago who thought that he may have a UTI and prescribed trimethoprim.

He has a history of stroke 10 years ago and hypertension and takes warfarin, amlodipine and enalapril.

Physical examination is unremarkable except for slightly increased tone on the left side compared to the right.

Bloods:

Hb	14.9 g/dl
Platelets	387 * 10 /l9
WBC	12.8 * 10 /l9
Na +	142 mmol/l
K +	4.6 mmol/l
Urea	6.4 mmol/l
Creatinine	84 µmol/l
Bilirubin	6 µmol/l
ALP	64 u/l
ALT	15 u/l
Calcium	2.35 mmol/l

Albumin	41 g/l

MSU (from GP from 2 days ago): Heavy growth of E.coli Sensitive to trimethoprim, nitrofurantoin, amoxicillin and co-amoxiclav

CT Brain: some generalised atrophy and periventricular white matter changes normal for age. Changes in keeping with an old left sided lacunar infarct Mini Mental State Examination 17/30

Which medications would most appropriately treat the underlying diagnosis?

A. Olanzapine
B. Rivastigmine
C. Co-amoxiclav
D. Sinemet
E. Aspirin 300mg

B. Rivastigmine

The answer is Rivastigmine. The diagnosis here is Lewy Body dementia. Lewy body dementias core clinical features are fluctuating g cognition, visual hallucinations (present in 2/3rds of cases) and parkinsonism. Two out of three are needed for diagnosis. The visual hallucinations are often very vivid. This patient definitely has two out of the three. He also may have parkinsonism as he has bilaterally increased tone that is not in keeping with his old lacunar infarct.

He also has a few supportive features of Lewy Body Dementia hallucinations in other modalities, delusions, depression and repeated falls.

Currently, evidence best supports cholinesterase inhibitors in the treating of Lewy Body Dementia. It must be remembered that these patients have high sensitivity to neuroleptics so Olanzapine should not be used here. Schizophrenia is a less likely diagnosis as visual hallucinations are rare in late onset schizophrenia and late onset schizophrenia itself is rare. Also, fluctuating mental state is not usually seen in schizophrenia.

Whilst this patient has a UTI, it is sensitive to trimethoprim and therefore is already being appropriately treated and therefore further antibiotics are not required. As the symptoms have been present for 6 months, UTI is unlikely to be the underlying diagnosis.

Whilst the patient does have risk factors for stroke and focal neurology and a TIA is possible, it does not explain his other symptoms and therefore aspirin would not therefore represent treatment for the underlying diagnosis.

The patient does show features of parkinsonism but a diagnosis of Lewy Body is more suggested by the cognitive and psychiatric symptoms and therefore Sinemet would be not be considered before a cholinesterase inhibitor.

Question 10 of 16

A 67-year-old man is admitted to the hospital with community-acquired pneumonia. In the acute medical unit, he is becoming progressively more confused and has started having visual hallucinations of children running around the ward. These symptoms are worse at night. Otherwise, there is no evidence of any other neurological or psychiatric symptoms. There is no known past medical history of dementia.

What test would be most appropriate in to confirm the cause of this man's confusion?

A. Cambridge cognition examination
B. Confusion assessment method
C. Mental state examination
D. Mini-mental state examination
E. Six-item cognitive impairment test

B. Confusion assessment method

The Confusion Assessment Method (CAM) is the best way to differentiate between delirium and dementia

Current NICE guidance advises the use of the **Confusion Assessment Method** as the first-line diagnostic test for delirium rather than any of the other cognitive tests. This patient has symptoms consistent with delirium; acute onset, fluctuating course, and visual hallucinations with a preceding insult. It is therefore the most appropriate test in this acute setting. The diagnostic criteria for this test include an acute onset with a fluctuating course with inattention plus either disorganised thinking or an altered level of consciousness.

The **Cambridge cognition examination** is designed to diagnose and assess the severity of dementia. It is not specific for delirium which is the most likely diagnosis here and therefore is not the most appropriate test.

A **mental state examination** is a comprehensive way to assess mental disorders. Although this does include cognitive testing, it is not as useful or concise as the confusion assessment method to quickly differentiate between delirium and dementia. Therefore, as the psychiatric symptoms are limited to cognition, it would be more appropriate in this acute setting to use the confusion assessment method.

Although the **mini-mental state examination** can be used to assess cognition, it is not designed to distinguish between dementia and delirium. Although repeat tests may be useful in demonstrating deterioration or fluctuation in cognition, the confusion assessment method would be more appropriate in this instance of acute confusion to differentiate between delirium and dementia.

The **six-item cognitive impairment test** is again a test used to quantify the extent of dementia, rather than delirium. Therefore it would not be the most appropriate test here to distinguish between the two.

Question 11 of 16

A 65-year-old man is reviewed in the memory clinic. He has been diagnosed with Lewy-body dementia as well as Parkinson's disease. Whilst the Parkinson's disease is being managed with levodopa, he and his wife have found the dementia to be worsening. On objective testing, he is found to have mild dementia.

Which one of the following medications should be offered to alleviate his cognitive impairment?

A. Donepezil
B. Clopidogrel + atorvastatin
C. Haloperidol
D. Increase levodopa dose
E. No medical treatment is available

A. Donepezil

Acetylcholinesterase inhibitors (e.g. donepezil, rivastigmine) can help alleviate the features of Lewy body dementia

The correct answer is **Donepezil**. Donepezil is a cholinesterase inhibitor which works by increasing the levels of acetylcholine in the brain, improving cognitive function. According to the UK guidelines (NICE), donepezil can be prescribed for patients with mild to moderate dementia due to Alzheimer's disease or Lewy body dementia. In this case, as the patient has mild Lewy body dementia, donepezil would be an appropriate choice to alleviate his cognitive impairment.

Clopidogrel + atorvastatin are not indicated for treating cognitive impairment in dementia. Clopidogrel is an antiplatelet agent used for preventing thrombotic events, while atorvastatin is a statin used for lowering cholesterol levels and reducing cardiovascular risk. Although there have been studies suggesting that statins may have a protective effect against dementia, they are not recommended as a treatment for cognitive decline in current guidelines.

Haloperidol is an antipsychotic medication that might be used in managing behavioural and psychological symptoms of dementia (BPSD) such as agitation or hallucinations. However, it does not improve cognitive function and should be used with caution in patients with Lewy body dementia or Parkinson's disease due to the risk of worsening extrapyramidal symptoms.

Increase levodopa dose would not be an appropriate choice since levodopa mainly targets motor symptoms of Parkinson's disease rather than cognitive impairment associated with Lewy body dementia. Additionally, increasing the dose may lead to side effects such as dyskinesia or hallucinations without providing significant benefits for cognition.

No medical treatment is available is incorrect because there are medications like donepezil that can help alleviate cognitive impairment in patients with mild to moderate Lewy body dementia. Although there is no cure for dementia, medications like donepezil can help improve the quality of life for patients and their caregivers by managing symptoms.

Question 12 of 16

You are in General Practice when a 75-year-old lady is brought in by her concerned daughter. She reports that she has been acting strangely recently and calling her up in the middle of the night thinking that strangers are in the house. She also seems disorientated with time and frequently gets ready for bed in the middle of the day. Her daughter reports that some days she can seem 'back to her old self' and appears completely lucid.

On direct questioning the patient is orientated to time and space but is rambling and tangential, often speaking off topic. She admits to visual hallucinations including a cat that has been following her round very several months. She is otherwise well but says that she has become 'slowed down' in general over the last year.

Current medication includes rivaroxaban for atrial fibrillation and amitriptyline for fibromyalgia.

On review of the patient's medical records, you note she has been brought in several times over the past six months with similar complaints and each time has been given a course of antibiotics for a suspected UTI.

What is the most underlying cause of the patient's presentation?

A. Psychotic episode
B. Recurrent urinary tract infections
C. Lewy body dementia
D. Medication induced
E. Subdural haemorrhage

C. Lewy body dementia

Lewy body dementia typically presents with fluctuating cognition in contrast to other forms of dementia

The three cardinal features of Lewy body dementia are visual hallucinations, fluctuating confusion, and features of Parkinsonism. Presentations can be mistaken for delirium and are often treated for UTIs. A detailed history to uncover the longstanding and progressive nature of the disease is essential. Patients often report the sensation that others are present in their homes. Other features that could suggest Lewy body include a history of REM sleep behaviour disorder or 'confusional arousals' on waking from a nap. Careful examination should be taken to look for bradykinesia, rigidity, or rest tremor - this was suggested by the general 'slowing down' in this patient.

Medications such as amitriptyline have a high anticholinergic burden index and can contribute to cognitive impairment but wouldn't typically cause visual hallucinations. Equally subdural haemorrhage can cause a fluctuating confusion but would be more likely to have focal neurology rather than hallucinations. Nevertheless, brain imaging in this patient is essential.

Question 13 of 16

An 80-year-old man was brought to hospital after a collapse. A carer at his nursing home reports he became pale and slumped unresponsive in a chair but regained consciousness after a few minutes. His past medical history includes hypertension, hypothyroidism, mild dementia and a previous seizure 15 years ago.

Paramedics at the scene reported a heart rate of 34/min which has now resolved. Examination reveals normal heart sounds, capillary refill of 3 seconds and a regular pulse of 60/min.

Which of his medications may be responsible for the collapse?

A. Bendroflumethiazide
B. Triamterene
C. Levothyroxine
D. Sodium valproate
E. Donepezil

E. Donepezil

Donepezil is a cholinesterase inhibitor used in the treatment of mild to moderate dementia. Its vagotonic effect can lead to bradycardia and heart block. This can occur particularly when coadministered with other anticholinergics and drugs that inhibit the CYP450 enzyme 3A4 and 2D6 as plasma levels of donepezil will be increased.

Question 14 of 16

An 83-year-old woman attends the memory clinic along with her son with a 7-month history of memory loss. She reports feeling well today, but her son explains the previous week she was confused and disoriented. Her son also tells you that he fears his mother has been hallucinating since she has told him that she sees her husband sitting at the dinner table with her. However, he died 5 years ago. She has a background of osteoarthritis and borderline diabetes but has otherwise been well with no recent illnesses.

On examination, her heart rate is 86bpm and regular. Her sitting and standing blood pressures are 152/95mmHg and 138/86mmHg respectively. On auscultation, she has a clear chest with normal heart sounds. Her abdomen is soft with no palpable masses. There is a slight tremor in her left hand with increased rigidity. She walks well with a walking stick but there is a shuffling gait. Her MMSE is 20/30.

Assuming the likely diagnosis, what is the most appropriate treatment to initiate?

A. Haloperidol
B. Levodopa
C. Memantine
D. Rivastigmine
E. Ropinirole

D. Rivastigmine

Acetylcholinesterase inhibitors (e.g. donepezil, rivastigmine) can help alleviate the features of Lewy body dementia

This patient has Lewy body dementia (LBD). An MMSE of 20 suggests a diagnosis of mild dementia. Symptoms of LBD can vary from person to person and typically include fluctuating confusion, disturbances in sleep, mood changes and hallucinations. There is an overlap with Parkinson's disease, and motor symptoms may manifest as the disease progresses. This scenario describes a woman with increased rigidity, tremor and a shuffling gait which suggests the onset of Parkinsonian features. Unlike Parkinson's disease dementia, LBD is the development of cognitive impairment prior to the onset of motor symptoms. Whereas, the definition of Parkinson's disease dementia requires the duration of motor symptoms to be present for at least 1 year before the onset of cognitive impairment. NICE guidelines recommend the use of acetylcholinesterase inhibitors in the management of Alzheimer's disease and LBD, making rivastigmine the correct choice.

Haloperidol is an antipsychotic medication that works through the inhibition of dopaminergic receptors. It is sometimes given to treat acute agitation. However, it can worsen co-existing parkinsonian symptoms and should not be given in patients with Parkinson's disease or LBD.

Levodopa is the first-line treatment for Parkinson's disease. Whilst this patient does have symptoms of Parkinson's disease, she also has fluctuating confusion and cognitive impairment. From the clinical history, it seems that the onset of memory loss preceded motor symptoms, making LBD more likely.

Memantine is an NMDA receptor antagonist, blocking glutamate transmission in the brain. Memantine monotherapy is recommended as an option for managing severe LBD and Alzheimer's disease or moderate disease in patients who cannot tolerate AChE inhibition. An MMSE score of 12 or less suggests severe dementia. This patient has a much higher MMSE score and no contraindications to AChE therapy are given in the scenario, making rivastigmine the preferred initial treatment option.

Ropinirole is another treatment option for Parkinson's disease. It is not used in the treatment of cognitive impairment in LBD.

Question 15 of 16

A 58-year-old male is brought into your outpatient clinic by his wife. The patient does not understand why he needs to see a doctor and just wants to get back to work. However, she reports a rather vague history of increasing withdrawal from social interactions and odd repetition of 'catch phrases' over the past 9 months. In addition, she feels his behaviour has changed and is very inappropriate when meeting up with friends, once urinating at the table while having dinner. Last week, he gave her a grave headstone for her birthday, saying 'it is nice to be well-prepared!' While she was understandably upset, he was mystified as to why his well thought out gift might have caused distress. On examination, he continues to repeat the phrase 'Whats up doc?!' at a regular interval, disturbing your history taking. You finally complete a mini-mental test examination, scoring 27/30.

What is the most likely diagnosis?

A. No medical diagnosis
B. Borderline personality disorder
C. Bipolar disorder
D. Schizophrenia
E. Frontotemporal dementia

E. Frontotemporal dementia

The history described of behavioural change, lack of insight, mental rigidity and stereotyped behaviours. The prominent behavioural features with a lack of amnestic features are typical for the behavioural variant of frontotemporal dementia. These patients do not typically retain insight and cognitive functions may be normal in early disease. The main differential diagnoses consist of psychiatric disorders. The patient presents with first symptoms at late-fifties and while not impossible, it is rare for psychiatric disorders to be diagnosed so late in life. It is important to rule out other organic causes of behavioural changes with MRI neuroimaging, such as frontal lobe space occupying lesions.

Question 16 of 16

A 72-year-old man attends the memory clinic with his wife. He was referred by his GP after his wife noticed his short term memory had deteriorated, he was getting lost around the village he had lived in for the last 40 years and his mood had changed.

His past medical history includes hypothyroidism, hypertension and arthritis. He has recently been discharged from cardiology outpatients where they decided a pacemaker was not indicated as he is asymptomatic of the abnormalities found on his ECG. He takes levothyroxine, ramipril, amlodipine and paracetamol.

There was no abnormality found on physical examination. The patient scored 20/30 on MMSE (mild impairment 21-30, moderate impairment 11-10 and severe impairment 0-10). The results of his blood tests are listed below:

Hb	137 g/L	(135-180)

Platelets	279 * 10 /L 9	(150 - 400)
WBC	7.5 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	130 µmol/L	(55 - 120)
Calcium	2.4 mmol/L	(2.1-2.6)
Thyroid-stimulating hormone (TSH)	4.9 mU/L	(0.5-5.5)
Free thyroxine (T4)	13.5 pmol/L	(9.0 - 18)
Haematinics	normal	
HIV serology	negative	
Syphilis serology	negative	

His ECG showed sinus rhythm at 41bpm with a PR interval of 140ms.

An MRI head showed global cerebral atrophy, particularly in the temporal lobe (disproportionate hippocampal atrophy).

The patient and his wife are keen to discuss what treatments and support are available to them.

What would be the most suitable treatment for this patient?

A. Donepezil
B. Atorvastatin
C. Memantine
D. Galantamine
E. Sertraline

C. Memantine

Donepezil is generally avoided (relative contraindication) in patients with bradycardia and is used with caution in other cardiac abnormalities

Alzheimer's disease is the most common form of dementia. The short term memory loss and MRI findings in this patient are in keeping with this diagnosis.

Donepezil is advocated as the first-line treatment for Alzheimer's disease by NICE. However, this is contraindicated in this patient given his bradycardia on ECG and so is incorrect.

Atorvastatin can be used in vascular dementia as cardiovascular risk factor modification.

Galantamine is another acetylcholine esterase inhibitor like donepezil. Like donepezil, it can cause bradycardia but also atrioventricular block, and so is contraindicated in this patient who has resting bradycardia and 1st-degree heart block.

Sertraline is an antidepressant and is not recommended by NICE for the management of mood symptoms in Alzheimer's disease.

Memantine is the correct answer. This is used as second-line treatment (where 1st line treatment has failed or is contraindicated) or add on therapy. Given first-line treatment is contraindicated in this patient, memantine is the most suitable management option.
